Woodbury jig (Fig. 10) is a fixed-sieve quick-return plunger jig, with a plunger having a smaller area than the sieve compartment. Two plunger rods with separate eccentrics are used on each plunger. The jig is made in units that are erected end-to-end at different levels (PYRAMID SETTING), the feed enters over an apron above the plunger compartment. The jig is best known by reason of a slime-separating device that is used on the first unit of a series treating ungraded feed. This consists of a shield (*a*), that projects above the water-level and dips sufficiently into the sand layer on the screen to prevent slime from entering at the bottom. Slime is thus diverted around the shield and overflows a dam at the discharge side of the compartment. This same dam serves to hold back sand tailing, which rises within shield (*a*) and overflows lip (*b*). A concentrate cup (*c*), within shield (*a*), projects above the sand level and down into the concentrate layer on the screen, allowing, therefore, concentrate only to enter and overflow into pipe (*d*). This pipe is connected with pressure water to allow fine sand to be excluded from the cup concentrate by classification. De-slimed sand tailing (middling) passes to a second unit fitted with the usual gate-and-dam concentrate dis-

charge placed, however, at the tailing-discharge end of the compartment. When further units are used a dewatering trough is placed ahead of each subsequent unit and a similar device on the tailing-discharge box of the final unit.

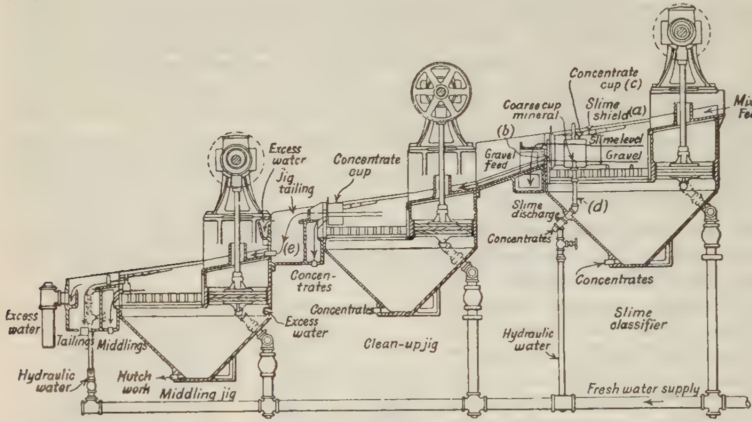

FIG. 10.—Three-unit Woodbury jig.

Performance. The Woodbury jig has had its largest use in treating native-copper ores. At CALUMET AND HECLA two 5-compartment jigs handle 300 to 375 tons per 24 hr. of $-\frac{3}{16}$-in. conglomerate rock from one steam stamp. Sieves are 30 × 48 in.; plungers, 15 × 48 in. Sieves on the first compartment are 10-mesh brass-wire, 12-mesh on the others (average life, 22 months). 180 strokes per min., 1- $\frac{7}{8}$-, $\frac{3}{4}$-, $\frac{1}{2}$- and $\frac{1}{2}$-in. length on compartments 1 to 5 respectively. 2.75-in. bed. One man attends 30 sieves and other work in addition. Lost time about 1 per cent., principally due to cleaning sieves. About 45 per cent. of the feed is separated as slime on the first compartments. The first two units discharge high-grade concentrate and the other three middling. Assays, per cent. Cu: Feed, 1.75; tailing, 0.6; concentrate, 80. On amygdaloid, three 5-compartment units handle 600 tons, of which 40 per cent. is separated as slime. At ANACONDA the Woodbury system was thoroughly tried but finally rejected. Feed was − 8-mm., ungraded. The classifier compartment when treating 2.7-per cent. Cu feed at the rate of 242 tons per 24 hr. rejected 39.3 tons of slime and fine sand (− 0.4-mm.) assaying 3.34 per cent., made 3.1 tons of cup concentrate assaying 14.4 per cent., 11.59 tons hutch concentrate at 9.11 per cent., 138.8 tons cup middling at 1.43 per cent. and 48.8 tons hutch middling at 3.88 per cent.; compartment 2, treating hutch middling assaying 3.09 per cent. Cu from the classifier jig, at the rate of 49.6 tons per 24 hr., made 2.2 tons of cup concentrate assaying 12.26 per cent. Cu, 6.4 tons hutch concentrate assaying 7.68 per cent., 14.6 tons hydraulic middling assaying 1.74 per cent., 8.8 tons hutch middling assaying 4.57 per cent. and a tailing assaying 0.62 per cent. Water consumption on the classifier jig was 859 gal. per ton of feed and on the regular jig 3431 gal. per ton. When treating de-slimed undersize of a 4-mesh screen, a classifier jig and three re-treatment jigs in series produced, from 127 tons per 24 hr. of feed containing 0.82 per cent. Cu, 15.5 tons of middling (concentrate) at 2.43 per cent., 6.8 tons hydraulic middling assaying 1.14 per cent., slime assaying 3.4 per cent. and tailing assaying 0.45 per cent. A 5-compartment system was tried on − 2.5-mm. material but failed to better the work of the Evans jig. At RAY CONSOLIDATED COPPER CO. the Woodbury system was tried on − 2.2-mm. ungraded material. Hutch concentrate only was made and this was cleaned on Wilfley tables. Slime was re-treated on vanners. On a feed containing 2.3 per cent. copper this flow-sheet made 25-per cent. concentrate and 0.83-per cent. tailing representing 64.9 per cent. recovery and 16.8 ratio of concentration. Competitive work on Garfield tables with the Garfield middling cleaned on Wilfley tables and slimes re-treated on vanners yielded 26.9 per cent. concentrate and 0.66 per cent. tailing, representing 73.1 per cent. recovery and 15.9 ratio of concentration. The failure of the Woodbury system was attributable to the fact that it cut out only 56 per cent. of the original feed, containing 35 per cent. of the copper as middling while the Garfield system put 80 per cent. of the original feed containing 50 per cent. of the total copper in the middling division. The

Woodbury system rejected 71 per cent. of the original feed containing 57 per cent. of the total copper as slime against 33 per cent. by weight and 24 per cent. of the copper content in Garfield slime. There was always much free mineral in the Woodbury-jig tailing. At Old Dominion three 3-compartment jigs were used, treating 350 tons each. Feed: 10 per cent. on 4-mesh, 59 per cent. moisture. No.1 jig compartments were 24 × 36 in. and Nos. 2 and 3, 30 × 50 in. Screens were woven brass wire, 0.187-in. aperture, on the first compartment of No. 1 and 0.120-in. on the second and third compartments; 0.120-in. on all compartments of the other jigs (life, about 6 months). Stroke on all compartments, 1.5-in. 4- to 5-in. beds. One man attended 5 jigs and the preceding screens. Change of water rate and feed distribution were left to the operator. Water consumption, 760 gal. per min. per jig. Assays, per cent. Cu: Feed, 4.10; tailing, 2.50; concentrate, 9.00. At the Ohio Brass Co. (*65 A 652*) a 2-compartment jig, first compartment 12 × 21 in. with 10-mesh screen and 1⅜-in. stroke, the second 18 × 24 in. with 6-mesh screen and ¾-in. stroke, 200 r.p.m., treated brass-foundry ashes sized between 3- and 10-mesh on heavy wire stationary screens set at 45°. Cup concentrate was almost pure metal (70 to 80 per cent. Cu) and represented 60 to 70 per cent. of the total metal in the feed; hutch concentrate assayed 65 to 70 per cent. Cu and contained about 20 per cent. of the total copper fed.

Bull jigs are jigs of any type, but usually of the fixed-sieve variety, used for treating the coarsest feeds. Heavy ores up to 3-in. diameter have been treated. Bull jigs differ from others of the same type only in that they are built heavier to withstand the longer stroke and greater wear, and discharge ports must be larger to prevent clogging. In a Joplin bull jig with 36 × 60-in. sieve compartments, two eccentrics are used on each plunger.

Performance. At Bunker Hill and Sullivan (*61 A 225*) bull jigs treat material sized between 1.25- and 0.5-in. and make middling and tailing only. This method of operation saves the heavy wear on soft galena concentrate that results if it is attempted to make a high-grade concentrate. The best grade that can be made on these jigs is 55 per cent. lead and to make this results in wearing the concentrate into rounded marbles. But by taking a 25 per cent. rough concentrate, crushing it, and re-jigging, a 65 per cent. concen-

a Slime overflow, 10 in.

trate is made with but little wearing of the galena. These jigs will handle 150 tons per 24 hr. and reject 90 tons of tailing containing less than 0.4 per cent. lead. In the West mill five bull jigs treat 450 tons per 24 hr. at a cost per jig (1918) of $2. At other Coeur d'Alene mills the upper size of bull-jig feeds is as follows: HERCULES, 1.4-in.; MAMMOTH, 0.6-in.; MORNING, 0.9-in. At SLOCAN, B. C., bull jigs make a lead concentrate as coarse as 0.75-in. containing 100 to 175 oz. Ag. (*114 J 677.*) At OLD DOMINION two one-compartment Woodbury bull jigs, 30 × 50-in., treat 500 tons each per 24 hr.; feed, 51 per cent. on 3-mesh, 54 per cent. water. Brass-wire screen with 0.130-in. aperture lasts 8 months. Bed, 6 in. thick. Stroke, 2.25 in. Water, 240 gal. per min. Assays, per cent. Cu: Feed, 3.60; tailing, 2.70; concentrate, 11.00. One operator attends 11 sieves and the preceding screens and controls jig water and feed distribution. Table 24 gives data on a competitive test between a Woodbury bull or DE-WOODING JIG and the Harz bull-jig system at ANACONDA C. M. Co.

6. Fixed-sieve jigs used principally for coal

The jigs most widely used for anthracite are the Reading, Lehigh, Elmore, Wilmot (Simplex) and Delaware (Tench) which are all of the piston variety. Their use is explained by the fact that the feed in anthracite washeries is invariably sized and the piston jig is best suited for treating such feeds. For bituminous coal both pan (movable-sieve) and piston jigs are used, the former to a greater extent. The most widely used piston jigs are the Luhrig, Elmore, Foust, and Forrester.

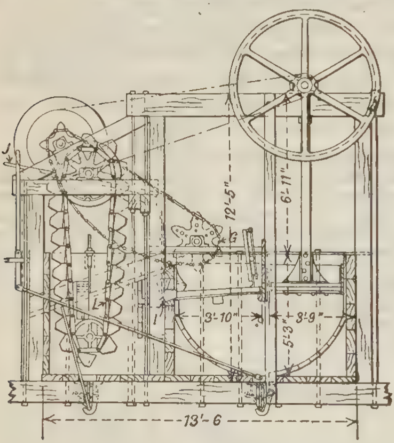

FIG. 11.—Reading jig.

Reading jig (Fig. 11) is of the typical piston type with coal discharge aided by the chain drag *G* and with intermittent slate discharge manually controlled by gate *I* and lever *J*. Discharged slate is removed by the bucket elevator *L*. The usual operating conditions are 140 @ 2-in. strokes per min. for pea and buckwheat sizes and 100 @ 4-in. strokes for larger sizes.

Lehigh jig (Fig. 12) is of the piston type with grate inclined about 1 in. to the foot toward the discharge side. Working adjustments are given in

Table 25. Operating adjustments of Lehigh jig working on anthracite

Size of feed	Strokes per minute	Length of stroke, inches	Height of feed gate, inches	Height of slate gate, inches	Size of openings (*a*)

a Round or oblong holes, the latter set with long axis parallel to the run of the material.

Table 25. The hutch (slush) gate is opened intermittently for discharge only; normally the jig is run to give minimum suction. Slate discharge is regulated by the slate conveyor, which is run only when necessary to prevent slate from going with coal or when the bed becomes packed. PERFORMANCE is given in Table 26.

Elmore jig (Fig. 13) is a double-compartment machine of the piston type with overflow coal discharge and automatic slate discharge. According to Ashmead (*66 A 422*) it requires 700 gal. per min. of circulating water; 12 hp. to operate the jig mechanism and 18 hp. for the circulating pump. Capacity of the double unit is as high as 50 tons per hr. on the coarse sizes of anthracite. Two- and 3-

a Jig overflow. *b* Combined for shipment. *c* Valve operated almost continuously in both tests. *d* Valve operated intermittently, open about one-fifth of total time in second test. *e* In the first test the percentages of good coal in these products were 9.5, 15.1 and 36.3 respectively; in the second, 5.9, 9.1 and 19.7.

At Indianola mine of Inland Collieries Co. (*Bul. 16 CIT*) a 3-compartment unit was subjected to careful test. Each compartment was 6 ft. wide by 6¼ ft. long; the grates had ⅛-in. round holes; beds were 12½, 15 and 11½ in. deep in compartments 1, 2 and 3 respectively. Feed was bituminous coal crushed to about 1-in. and fed without sizing. Performances are shown in Table 27. The long, slow strokes of the second test improved the grade of shipped coal by improving the ash reduction in the coarse sizes. There was, however, a reduction in yield and capacity. The longer stroke gave a more fluid bed, permitting better stratification, as evidenced by the higher grade of coal in the coarse sizes and the larger quantity and lower grade of slate drawn. On the other hand, more fine coal was drawn down into the first two hutches and lost, on account of the increased suction. Fig. 14 shows the results of a sizing-specific-gravity analysis on the feed and products of the jig, reduced, in plotting, to efficiencies of removal of material of different specific gravities at different sizes. This shows that ease of removal decreases, of course, with decreasing specific gravity, that material of +1.80 sp. gr. is readily removed at all sizes down to 1⁄64-in., that −1.80 +1.70 material is also readily removed in the same size range, that the −1 +½-in. material is the most difficult of the +1⁄64-in. material to remove, due, no doubt, to the fact that the interstices in the coal bed are too small for its ready passage downward; that for the lighter materials maximum removal takes place in the size range from 1⁄64- to ⅛-in., which is accounted for by the fact that this material can pass down readily through the interstices of the bed and discharge either through the coarse-slate draw valve or into the hutch; finally that distinct ash reduction is effected even at 1⁄64-in. to 200-mesh size on a jig handling 1-in. lumps. Hancock (*6 CI 56*) found, on the other hand, that the ordinary single-compartment jig sends most of the −¼-in. impurities into the washed coal and that substantially no improvement in grade is effected at 20-mesh or finer sizes. Hancock's results are not entirely at variance with Yancey's, in that Yancey worked with a long, slow stroke and much suction, thereby making rather high-coal hutch products, but effecting noticeable reduction of fine ash, while Hancock refers to ordinary jig operation with suction minimized.

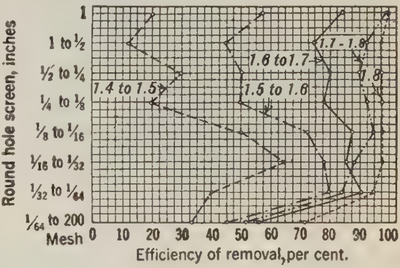

Fig. 14.—Relation between particle size, specific gravity and efficiency of removal in an Elmore coal jig (*after Yancey*).

Wilmot (Simplex) valve-plunger jig is of the pulsion-type with gate-and-dam discharge. The plunger is similar in position and arrangement to that of the Dee jig (Fig. 6) and is fitted with a plurality of small valves that open on the downstroke and thus, with free water inflow under the plunger, prevent any downward flow through the jig bed.

With a speed of 140 r.p.m. on buckwheat-size anthracite (−½ +¼-in. round hole) the capacity was 25 tons per hr. At this rate, with a feed containing 30 per cent. slate, the coal discharge contained 8 per cent. slate and the slate discharge 1 per cent. coal (*25 CA 674*). Performance at Drifton breaker (p. 48) is shown in Table 28.

Table 28. Capacities of Simplex jigs at Drifton breaker

Size	Tons per hour		Coal content of refuse, Oct., 1916
	Oct., 1916	Maximum	
Egg	5.5	7.4	1.00

Nut	6.8	11.7	1.50
Pea	5.4	11.0	2.90
Buckwheat	9.9	14.7	3.75

Delaware jig (Fig. 15) is of the piston type with grate inclined toward the discharge side. Feed enters through a chute under the piston compartment behind baffle A. Slate is discharged through and under adjustable baffle F, thence under another adjustable baffle and presses against the slate gate I which is connected by means of rods J and rope K to an adjustable counter-weight L, which, therefore, controls the rate of discharge into the boot of the bucket elevator. Coal discharges over a plate onto the lifting plunger O and is thereby discharged over chute R. The jig is usually built with two sieve compartments side-by-side, each about 4 ft. wide by 5 ft. 8 in. long. Depth of bed is about 21 in. at the discharge end. Performance is shown in Table 29 (*DHH*).

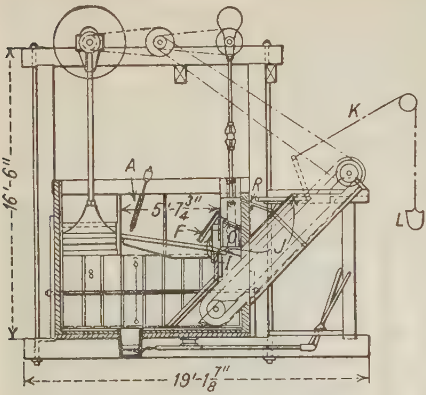

Fig. 15.—Delaware jig.

Breakage of stove sizes 3.7 per cent.

Luhrig jig is a piston jig that is largely used for treating sized bituminous-coal feeds. It is made in two different forms according to whether the feed is fine or coarse. The coarse-coal jig (Fig. 16) has the grate slanting toward the discharge end, and is fitted with manually controlled slate-discharge gate and slush-discharge valve. Coal discharge is by overflow. The fine-coal jig is similar except the grate slopes slightly toward the feed end; there is no slate-discharge valve, but the jig is bedded with coarse feldspar and slate is discharged through the bed into the hutch. Coal is discharged by simple overflow. Grate sizes range from 33 × 35 to 42 × 54 in.

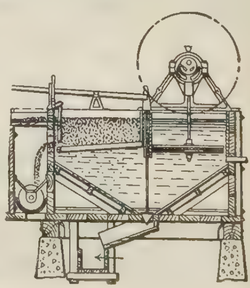

Fig. 16.—Luhrig coarse-coal jig.

Average speeds in Illinois practice (*Bul. 11 UI No. 9*) are 79 @ 3- to 7-in. strokes per min. for coarse-coal jigs, $-3\frac{1}{2}$ $+3$-in. to -1 $+\frac{3}{4}$-in. feeds, and 157 @ $\frac{3}{4}$- to 2-in. strokes per min. on fine ($-\frac{3}{4}$-in.) coal. Grates have $\frac{1}{4}$- to $\frac{3}{4}$-in. round holes in coarse jigs and $\frac{3}{4}$-in. or larger holes in fine jigs. Average capacity, all sizes, in twenty Illinois washeries was 0.6 ton per sq. ft. of grate surface per hour.

Foust jig (Fig. 17) is a multi-compartment piston jig for coal treatment, designed to jig refuse into the hutch through a bed made by the jig itself.

It has also had considerable success in treating lead-zinc ores in the Joplin district. It uses two plungers to each sieve, placed one on each side of the sieve, the combined area of the plungers being about 10 per cent. greater than that of the screen. The eccentric shafts are rigidly linked together to synchronize the plungers. More uniform water distribution is thus obtained than in the single-plunger construction, allowing a thinner and lighter bed with consequent reduction in water consumption. The construction is, however, necessarily more massive. A cup-type concentrate draw is used in metal concentration. This is designed to be self-regulating but is difficult to reach and liable to clog. The hutch draw must be placed under the center of the jig tank in a most inconvenient position. Partitions between screen and plunger compartments are extended 18 in. below the screen.

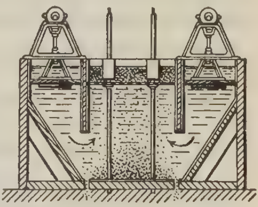

FIG. 17.—Foust jig.

A 2-compartment jig at ILLINOIS HOCKING WASHED COAL CO. (*Bul. 11 UI No. 9*) treated 45 tons per hr. of $-\frac{3}{4}$-in. bituminous coal, making a refuse containing 74 per cent. ash. This jig made 130 strokes per min., 1 in. long on the first compartment and $\frac{7}{8}$ in. on the second.

At PACIFIC COAL CO., Issaquah, Wash., (*28 UW 128*) a 2-compartment Foust jig treating -1-in. slack assaying 21 per cent. ash, at the rate of 13 tons per hr., made washed coal containing 13.3 per cent. ash and refuse assaying 46.1 per cent. ash. Recovery of combustible was 84 per cent.; yield, 77 per cent.; reduction of ash, 37 per cent.

Forrester jig (*Bul. 11 UI No. 9*) is of the plunger type; it is used in treating unsized coal. The plunger is carried by stirrups, actuated from a lever, which in turn is actuated by a crank wheel and connecting rod. Washed coal and refuse are discharged from the screen in the usual manner.

A 30 × 36-in. jig with $\frac{7}{16}$-in. screen perforations making 40 @ 6-in. strokes per min. treats 25 tons per hr. of -2.5-in. raw-coal screenings.

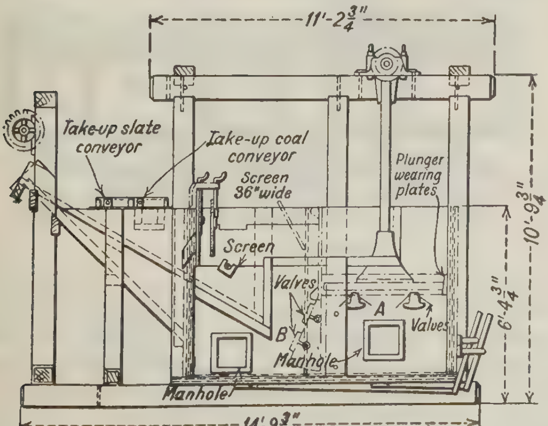

FIG. 18.—Ransom jig.

Ransom jig (Fig. 18) is a piston jig designed to eliminate suction and was particularly built for the treatment of fine sizes of anthracite. The characteristic element is the set of flap valves *B*, which open on

the pulsion (down) stroke of the plunger and close on the up stroke, thus causing a pulsating rising current with no downward currents. The valves *A* prevent the plunger from becoming airbound. Slate discharge is of the gate-and-dam type.

The following are the composite results of one 4-hr. and two 7-hr. tests on anthracite (*25 CA 674*): Feed, No. 1 buckwheat [20 to 30 per cent. ash]; slate in coal discharge, 3 per cent.; coal in slate discharge, 6 to 8 per cent, average 7⅓ per cent.

Baum jig is a fixed-sieve jig, built like the ordinary piston jig except that pulsation of the water is obtained by intermittent admission of air into and expulsion from a closed chamber which replaces the usual piston working zone.

A one-box machine (12 ft. long × 8 ft. wide) treats 20 tons per hr. of – ¼-in. bituminous coal at a British washery, making a clean coal containing 5.3 per cent. ash (*67 IME 497*).

New Century coal jig is similar to the Luhrig coarse-coal jig, except that the jig grate slopes toward the feed side and the piston mechanism gives a quick down stroke, controlled by means of a cam and spring.

Feeding coal jigs is a more difficult problem, even, than feeding jigs in metal-concentrating plants on account of the great variations from hour to hour, in normal operation, in the tonnage of different sizes coming from the screens. At the Pennsylvania breaker of the Susquehanna Collieries Co. (*19 CA 618*), a battery of jigs treating the same feed was arranged in steps and fed from the same feed chute. The latter was so designed that no material left the chute except by the lowermost outlet until the latter had filled with banked-up coal and the banking had extended back to the preceding opening, which then also drew. This banking repeated until all chute outlets, each feeding one jig, were filled, or until conditions stabilized at some lower feed rate. The individual chutes were so arranged that when coal backed up in them a belt shifter operated to start the jig, and when feed had all worked out of the chute the jig stopped. With this arrangement only the highest jig in the bank operated underloaded.

MOVABLE-SIEVE JIGS

7. Hancock jig

Description. The principal parts of the apparatus (Fig. 19) are a compartmented tank (*a*), movable sieve (*b*), and sieve-actauting mechanism (*c*, *h*,

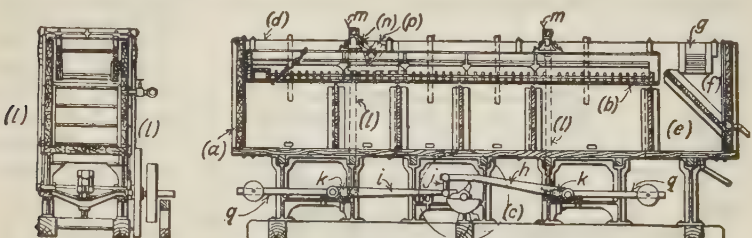

Fig. 19.—Hancock jig.

i, *j*, *k*, *l*, *m*, *n*, *p*). Feed is introduced onto the screen at (*d*), and caused to progress along the screen by a series of grasshopper-like jumps induced by the sieve-frame motion. Concentrate works down through the sieve into the head-end hutch compartments, middling is drawn down into the later compartments under the screen, coarse tailing falls into compartment (*e*), fine sand collects in (*f*), and slime and excess water overflow at (*g*). An extra, small compartment is often provided under a coarse screen between the last middling and the tailing compartments to catch any chance pieces

of concentrate or middling too coarse to pass the screen or any piece of the bedding material (RAGGING) that may carry over. Two standard sizes of jig are made: the larger with a 6-compartment tank 25 ft. long, 4 ft. 2 in. wide and 5 ft. 9 in. high; the smaller with a 5-compartment tank 18 ft. 6 in. × 4 ft. ft. 5 in. × 5 ft. The sieve of the larger jig is about 20 ft. × 2 ft. 8 in. in the clear, when made of wood; when made of steel the screening surface is 20 ft. 4 in. × 3 ft. The actuating mechanism, usually placed below the tank but occasionally above to escape splash and grit, is driven by a cam shaft with a 3-armed cam (*c*). The cam ears engage the end of lever (*i*). Lever (*i*) actuates lever (*h*) through the link (*j*) and the levers (*i*) and (*h*) actuate rocker-arms (*k*) carrying 4 upright rods (*l*) connected in pairs at the top by cross-bars (*m*) to which the sieve frame is attached. The head-end cross-bar is linked at both ends to the jig tank by inclined radius-links (*n*) adjustable as to their inclination with the horizontal by movement of the pivot pins in quadrants (*p*). A considerable part of the weight of sieve frame and load is counterbalanced by the lever arms (*q*). When lever (*i*) is raised by a cam ear, the sieve frame is raised by rods (*l*) and pulled forward by the radius links (*n*); when the cam releases the frame falls by gravity and at the same time is pushed backward by the radius links. The links work with an amount of lost motion controllable between 0 and ⅛ in. which produces a bump of greater or less intensity. The effect of the backward fall of the sieve-frame and the bump combined is to cause forward travel of the material over the sieve-frame, while the vertical motion produces the reciprocating water currents through the bed that cause stratification and separation of the minerals.

Construction. Complete jigs may be bought from various manufacturers, but usually only the iron-work is purchased and the jig tank and supports and sieve frame are built on the ground. Wooden tanks are invariably used. They are built of 4-in. tongue-and-groove clear plank strongly stayed both vertically and horizontally at the compartment partitions. Partitions may be placed at any desired position, the best places being determined by experimental work. They are usually so placed that the first concentrate and last middling compartment are considerably longer than the others. The sieve frame is made either of wood or steel. The wooden-frame has four sides made of 2½- or 3-in × 18-in. plank set on edge, and a grate (*e*) (Fig. 20) whose upper surface is about 6 in. above the bottom of the sides, for holding the screen. Top slats or battens (*d*) serve the double purpose of holding down the screen and of keeping the bed in place. One method of holding down the battens is shown in Fig. 20. Hardwood movable wedges (*a*) are driven between a fixed wedge (*b*) and a longitudinal bearing strip (*c*) placed against the side walls above the upper grid. The battens may be cambered about ⅛ in. at the center. Packing strips (*f*) on the outside of the sieve frame and in a corresponding position on the inside of the tank prevent excessive displacement of water on the down stroke with consequent loss of pulsion. Steel sieve frames are built up with light-weight plate girders for side bars and suitably cross-braced. A sectional grate of 1 × 3-in. oak cross slats, iron-shod, with 2 × 3-in. oak rails is bolted in position in the frame (*93 J 1178*). Steel is lighter than wood, hence consumes less power, and gives greater screen area, which increases capacity. Bearing boards and hard-pine wedges are used to hold down the upper slats and screen. Hutch discharges are of many types. Two forms are shown in Fig. 21. Gates should be capable of reasonably close regulation and of quick wide opening. Considerable water economy may be effected by discharging coarse tailing with the chain drag or a shovel wheel. The water level is maintained about 3 to 4 in. above the surface of the solids on the screen or about 12 in. above the screen itself. It is controlled by slats placed in guides in the overflow weir, provided that the water supply is sufficient to more than satisfy any hutch

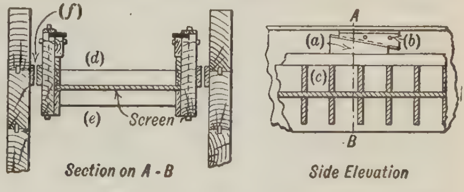

FIG. 20.—Wooden sieve frame for Hancock jig.

draws. To prevent fluctuation in water level at the Leadwood mill of the St. Joseph Lead Co. a float in the tailing compartment controlled a butterfly valve in the feed-water pipe. A solid foundation of concrete or masonry is usually provided but the Doe Run Lead Co. placed a 25-ft. jig on a steel trestle 18 ft. high with no serious vibration resulting.

Operation. The usual speed range is 180 to 195 strokes per min. corresponding to 60 to 65 revolutions of the drive shaft; a higher speed will increase tonnage but is very hard on the mechanism; at lower speeds the bed tends to pack. The length of the vertical stroke together with the amount of hutch water provided determines strength of pulsion and suction. The usual length is ⅜ to ¾ in. With a long stroke more hutch product is made and the operator varies this adjustment according to the tonnage and character of feed. Horizontal throw is usually about ¾-in. It should be as long as possible in order to cause quick travel across the bed and thus maintain a thinner bed for a given tonnage.

All of the concentrate and middling made on a Hancock jig is made through the screen. This necessitates the maintenance on the screen of a bed of grains of heavy material larger than the openings in the jig sieve. This may be coarser particles of the mineral that is being saved or artificial grains such as steel-plate punchings or iron or steel balls. The latter are used when the gangue is heavy. The bed is held in place by the grid on top of the screen and the maximum depth of bed is determined by the depth of the grid slats. The transverse slats in the grid correspond with the supporting slats and are spaced 3 to 6 in. in the clear. Frequently longitudinal slats are also used in order to permit close control of the thickness of the bed at different points. At Anaconda brass castings forming pockets 5 × 10 × 3 in. deep were used instead of wooden top slats. They were wedged down in the usual fashion. Before starting the machine each pocket is filled two-thirds to three-quarters full of ragging. If the bed is too loose, add more ragging and *vice versa*. The usual depth of the top grid is from 2 to 3 in. The screen aperture determines the size of particles held back and this, in turn, determines the size of interstitial passages, thus controlling the work of the jig. (See Art. 1.)

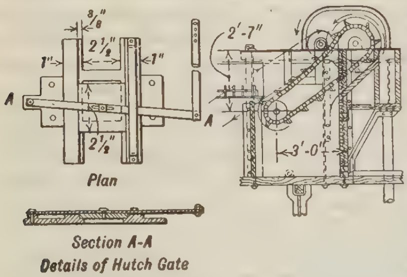

Fig. 21.—Discharge draws for Hancock jigs.

Screens are rarely of the same aperture for the full length of the sieve. The underlying principle controlling choice of screen aperture is that the bed should gradually decrease in specific gravity and increase in grain size from head to tail end. Openings are usually smallest over the first compartment in order to maintain a fairly tight bed and thus increase pulsion in comparison with suction and insure clean, fine-grained concentrate. The same opening may be maintained until near the end of the second compartment, when one to three rows of holes large enough to pass the largest particles of free mineral are introduced. These holes pass such particles while middling grains, both coarse and fine, are by this time stratified well above the large heavy grains of mineral and hence do not pass through with them. Smaller holes, although not usually so small as those over the first compartment, are placed above the third compartment and fine rich middling is drawn down. Openings generally increase in size toward the end of the screen, with or without intervening rows of larger holes. At the end of the screen large holes are again provided to pass the coarsest middling particles. It is, in general more difficult to make a clean separation of tailing from low-grade middling than to separate concentrate of suitable grade from high-grade middling, hence the latter operation is performed in as little space as possible and the balance of the jig is given over to the former work. In a particular operation on south-eastern-Missouri lead ores the concentrate was substantially clean galena assaying 82.3 per cent. Pb with a specific gravity of 7.00 and the rich middling assayed 60.4 per cent. Pb with a specific gravity of 5.20; difference in specific gravity, 1.80. The low-grade middling assayed 4.91 per cent. Pb, the tailing sought carried 0.14 per cent., the respective specific gravities were 2.95 and 2.82, difference 0.15. There being only a small amount of free galena in the feed, the first two hutches, used for making concentrate, were allowed only 80 in. out of a total length of 240 in.

The last hutch is usually run with very heavy suction in order to take out all possible value in the middling.

The screens are punched plate or woven wire. At Anaconda Ton-cap screen was most satisfactory; it outwore ordinary woven wire cloth and was easier to keep clean.

Satisfactory operation depends on a constant feed rate and metal content. Increase in the amount of valuable mineral from any cause produces heavy beds with consequent travel of concentrate and middling toward the tail end; decrease causes loss of bed with

consequent introduction of middling into the concentrate. The operator compensates for unavoidable fluctuation by shoveling off the bed when it becomes too heavy, shoveling on when the feed is light or plugging some of the screen holes or putting on finer screen. Fine gangue in concentrate may be due to leakage in the joints in the sieve tray. If the addition of ragging or increase in hutch water does not cure the condition, this possibility should be investigated.

Water consumption varies according to the size and character of feed, method of discharging tailing, tonnage treated and character of product desired. With chain-drag tailing discharge it may run as low as 150 gal. per min. when treating 350 to 400 tons per day of low-grade lead ore and about 850 gal. per min. with gate discharge of tailing and strong suction in the middling compartments induced by running with open gates.

Power consumption is from 4 to 6 hp. with normal load, stroke and speed. A test at ANACONDA showed 5.2 hp. for motor, countershaft and jig and 3.7 hp. for the jig alone.

Capacity depends on the character of work demanded but ranges from about 300 to 600 tons per day.

Applicability. The Hancock jig is particularly applicable to the treatment of low-grade ores, recovering a small amount of high-grade concentrate and rejecting tailing. It does this, however, at the expense of re-treatment, in circulation, of a large quantity of low-grade middling, much of which is true tailing. At many plants, also, it is necessary to re-treat the tailing of primary Hancock jigs in order to recover low-grade middling that has been carried along in the crowd for high tonnage. The jig is not suited to close separation of light middling grains from gangue and hence cannot be used where mineral is finely disseminated. It has had its principal use in this country in treatment of the mid-continent lead ores, but has also been used to treat copper ores at Anaconda and in the Lake Superior district. The best kind of feed is de-slimed but otherwise ungraded material ranging in size downward from about ⅜-in. Wiggin (*46 A 213*) determined that on ANACONDA ore the minimum economic size of free-mineral grain in the feed should be not less than 0.17-mm. On coarser grains the recovery was from 95 to 100 per cent., but at this size recovery dropped to 50 per cent. He found also, in treating de-slimed − 10-mm. material, that recoveries were improved by sizing the feed on a 4-mm. round-hole trommel and treating the sizes separately. Substitution of Hancock for Harz jigs in FEDERAL LEAD CO. NO. 3 MILL caused simplification of the flow-sheet by reduction in number of jigs and elimination of the screens and classifiers required for close grading of feed for Harz jigs; increase in capacity in the same mill space from 2600 to 4000 tons per day; and marked decrease in power and water consumption per ton milled. Experience at ANACONDA was similar, higher recoveries and saving in operating and repair labor were noted. DISADVANTAGES noted at DOE RUN NO. 3 MILL (*95 J 1283*) were the low recovery of mineral finer than 1.5-mm., no way to remove coarse galena concentrate from the screen until it wore down or went into middling, and inability to maintain even depth of bed with variable feed rate. Difficulty in separating low-grade middling from tailing has already been mentioned.

Performance. BONNE TERRE MILL, ST. JOSEPH LEAD CO. A most exhaustive study of the work of the jig on the galena-dolomite ore of this company is reported by Rabling (*57 A 309*). The jig was a standard 25-ft. size making concentrate from the first three hutches, middling from fourth and fifth and tailing from the sixth. Speed, 190 to 195 r.p.m.; vertical-stroke was varied by the operator between ⅜ and ¾ in.; horizontal, ¾ in.; depth of ragging, 3 in. The feed was the product between 9- and 2-mm. round-hole trommels. At the beginning of the testing work the results on 400 tons per day of original feed were as

Table 30. Hancock jig, Bonne Terre mill. (*After Rabling*)

Material	Before changes		After changes	
	Tons per 24 hr. total	Assay, per cent. Pb	Tons per 24 hr. total	Assay, per cent. Pb

in Table 33. In regular operations in this mill in 1919 the screens were as follows: sheet steel, 4-mm. aperture on compartment No. 1, 5-mm. on No. 2 with a row of 7-mm. holes at the tailing end, 6-mm. on No. 3, 7-mm. on No. 4 with one row of 8-mm. holes at the end, 9-mm. on No. 5 with 2 rows of 10-mm. holes 3 rows back from the discharge end. Life of screen was about 6 weeks for 4-mm., 7 weeks for 5-mm., 8 weeks for 6-mm., 9 weeks for 7-mm. and 12 weeks for 9-mm. A 5-in. bed was carried. Power consumption, 5 hp. at 195 strokes per min.; ¾-in. horizontal and ⅝-in. vertical throw. Capacity, 375 tons new ore per 24 hr. One man attended two machines. Lost time was less than 0.1 per cent., principally due to broken rocker-arm shafts. Water consumption, 500 gal. per min. Changes in length of stroke, character of bed and water quantity were left to the operator. Sizing test of feed as in Table 31. Feed contained 12 per cent. moisture. Assays, per cent. Pb; feed, 2.5; tailing, 0.75; concentrate from first hutch, 75.0; second hutch, 65; third and fourth combined, 20; fifth, 2. At the RIVERMINES MILL of the same company a 5-compartment jig.

3 × 25 ft., was fitted with punched soft-steel plates, 3 × 4 ft., with 5-mm. apertures on the first and second compartments, 6-mm. on the 3rd, 7-mm. on the 4th, and 8-mm. on the 5th. Life of screens was 30 days. Feed was all through 9-mm. and 10 per cent. through 10-mesh, and contained 40 per cent. moisture. 850 tons per day was treated including circulating load. Water consumption, 300 gal. per min. 3-in. bed. 190 strokes per min. 5 hp. Three machines per man. Lost time, due principally to changing screens, 2 per cent. Regulation of water and stroke were left to operator. Assays, per cent. Pb.: Feed 3.0; tailing, 0.5; concentrate, 70; middling, 4. At FEDERAL LEAD CO. MILL NO. 3, a 25-ft., 6-compartment jig with screen frame 32 in. wide was fitted with the following screens: First compartment, 3 ft. 9 in. long, 5-mesh brass wire; second and third, 3 ft. 1 in. each, 4-mesh brass wire; fourth, 3 ft. 6 in., 12-mm. punched-steel plate; fifth, 4 ft. 7 in., 9-mm. plate. Life of screens was 5 to 6 months. Feed: on 12-mm., 1.4 per cent.; 10-mm., 3.1 per cent.; 8-mm., 9.2 per cent.; 6-mm., 16.2 per cent.; 4-mm., 17.9 per cent.; 2-mm., 29.3 per cent; through 2-mm., 22.9 per cent., containing 43 per cent. moisture. Feed rate, 400 to 500 tons per day. 195 strokes per min., ¾-in. vertical and ⅝-in. horizontal throw. 4-in. bed. Water, 190 gal. per min. 5 hp. Two machines per man. Stroke regulation left to operator. 3 to 4 per cent. lost time, due to cleaning and changing screens and general repairs. Assays, per cent. Pb: Feed, 3; tailing, 0.65; concentrate, 70; middling, 3.5. At FEDERAL MINING AND SMELTING CO., Morning mill, standard 25-ft. Hancock jigs were used on both coarse and fine feeds. On the "coarse" jig the feed was all through 12-mm., 66 per cent. on 4-mesh, 26.6 per cent. on 6-mesh and 7.4 per cent. on 16-mesh, with 53 per cent. moisture. Screens were 5-, 7-, 9-, 12-, and 14-mm. round-hole punched-steel plates on compartments 1 to 5 respectively. Life of screens, 75 days. 6-in. bed was carried. 180 strokes per min., length variable. 5 hp. One man attended 2 jigs and 4 sets of rolls. Lost time, 0.05 per cent., due principally to changing screens. Length of stroke, quantity of water and character of bedding were regulated by operator. Results for April, 1917, are given in Table 34. "Fine" feed was all through 4-mesh; 9.6 per cent. on 6-mesh, 63 per cent. on 16-mesh and 27.4 per cent. through 16-mesh; 45 per cent. moisture. Screens, punched-steel plate, 3-, 3-, 3-, 5- and 7-mm. round holes on compartments 1 to 5 respectively, life about 75 days. 180 strokes per min. 5 hp. Attendance and lost time as above. See Table 34 for operations during April, 1917. ANACONDA ran extensive tests before replacing Evans jigs by Hancock jigs. The work was done on a 25-ft. jig with tray 20 ft. × 2 ft. 8 in. Speed, 190 to

Table 35. Hancock vs. Evans jigs, Anaconda Copper Co. (*46 A 217*)

	Natural feed, −8-mm. round-hole		Sized feed, −8-mm. +2.5-mm.	Classified feed, 11-mm. to 0.25-mm. quartz	Evans jig system (*c*)

a No assays. *b* None made.

195 r.p.m., vertical stroke ⅜- to ¾-in.; horizontal stroke, variable. No tailing was made. Concentrate was drawn from the first three hutches, middling from the fourth hutch was circulated, middling from the fifth and sixth hutches was re-ground. Results are given in Table 35. Further data from ANACONDA presenting the results of competitive tests between Hancock, Evans and Woodbury jigs are given in Table 36.

Franz jig (*13 CME 599*) is of the movable-sieve type with a screen 2 ft. 3 in. by 10 ft. (long). For jigging coarse (+2-mesh) lead-zinc ores screen was round-hole punched plate with 5⁄16-in. holes in first 2 ft., ½-in. holes for next 3 ft., ⅝-in. holes from 5 to 7.5 ft. and ¾-in. holes to end. Fine jig (−2-mesh, deslimed) used equal lengths of 3⁄16-, ¼-, 5⁄16- and ⅜-in. plate. Both fine and coarse jigs were run at 240 r.p.m., the fine with ¾-in. strokes and the coarse 1- to 1¼-in. Capacities: 120 tons per day, coarse; 80 tons, fine. The first three hutches of the coarse jig averaged 30 per cent. Pb; the first hutch of the fine jig, 35 per cent.

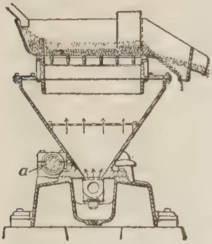

FIG. 22.—James jig.

James jig (Fig. 22), for metallic ores, consists of a movable sieve, usually less than 30 × 36 in., supported by means of a rubber diaphragm and two spring connecting rods on the drive shaft (*a*).

At NORTH RIVER GARNET CO. (*118 J 529*) the machines are run at 225 strokes per min.; the bed is about 3½ in. thick; screens are 6- to 30-mesh. Garnet is separated from hornblende and feldspar. Capacity is 10 to 50 tons per machine per 20 hr. depending on size of feed. About 2 hp. is consumed per sieve.

Hooper vanning jig (Fig. 23) consists of a shallow rectangular screen-bottomed tray open at one end, except for a shallow (1-in.) shoulder, suspended at the open end from a fixed shaft and at the closed end by an eccentric rod. The tray bottom slopes downward slightly toward the open end. A hopper-bottomed tank below the tray is filled with water to such a depth that the bed on the screen is submerged. The machine is run 240 to 330 @ 1- to 0.5-in. strokes, according to the fineness of the feed. Concentrate must be skimmed off the screen by hand. Hutch concentrate is discharged by spigot or by drag belt.

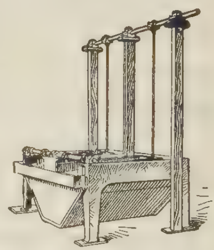

FIG. 23.—Hooper vanning jig.

This jig was developed at the NORTH RIVER GARNET CO. for separating garnet from hornblende and feldspar and has been successful in this service. (See Sec. 2.)

8. Movable-sieve (pan) jigs used in coal preparation

This type of jig is used widely in bituminous-coal cleaning but to a much less extent for anthracite. The best known are the Stewart, Shannon, Wilmot and James. They are used almost entirely for unsized feeds, 3½-in. or less maximum size, and, when the extent of overloading to which they are subjected is considered, do remarkable work. Hancock (*Iron making in Alabama, Geol. Surv. of Ala., 1912*) says that, in general, the pan-type jig is best for coarse bituminous-coal feeds and the piston type for fine.

Stewart jig (Fig. 24) is of the movable-sieve type with sieve basket suspended in a tank of water from two eccentrics. It has been used widely in coal treatment. An apron attached to the basket carries the upper or clean-

coal layer over the edge of the jig tank while the lower or refuse layer falls over the edge of the basket into the tank and is removed by mechanical means. The jig treats unsized feed. Water is supplied from a tank at the back of the jig through a flap valve that closes on the down stroke of the basket. The pan is always made 7 ft. long, width is variable.

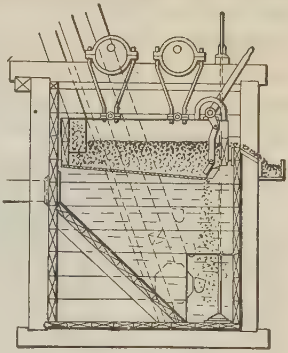

FIG. 24.—Stewart jig.

At twelve Illinois washeries reported by Lincoln (*Bul. 11 UI No. 9*) pan widths varied from 3½ to 6 ft. The feed rate on −3-in. coal ranged from 5 to 10 tons per ft. of width per hour and averaged 8 tons. On −1⅛-in. coal the capacity was about 7 tons per ft. of width per hour. The jigs were run 35 to 40 @ 4-in. strokes per min. At GRANBY CONSOLIDATED M. S. & P. Co. (*21 CA 367*) Cassidy, B. C., the jigs are 2-compartment, series type. Feed is 40 tons of −2-in. bituminous-coal screenings per hour. The bed in the first compartment is 12 to 14 in. deep and in the second, 10 to 12 in. Screens are 3/16-in. mesh. Hutch product is principally fine rock and clay. Performance is shown in Table 37.

Table 37. Performance of Stewart jig at Granby Cons. M. S. & P. Co. (*After Garman*)

Material	Ash, per cent.	Float		Sink	
		Per cent. weight	Per cent. ash	Per cent. weight	Per cent. ash
Feed, −2-in. raw coal........	22.80	56.0	9.38	44.0	43.43
Washed coal................	14.30	77.7	10.16	22.3	26.68
Refuse....................	67.05	2.5	16.00	97.5	68.16

Shannon jig is similar to the Stewart, but with the sides of the pan extended nearly to the bottom of the hutch in order to attain uniform rising current.

The average capacity of 4 × 6-ft. jigs at three Illinois washeries (*Bul. 11 UI No. 9*) was 47 tons of slack coal per hour, range 40 to 62½ tons. Speeds were 72 to 90 @ 3 to 3½-in. strokes per min. At PACIFIC COAL Co., Issaquah, Wash. (*28 UW 126*) the performance and the effect of change in length of stroke were studied. Results are given in Table 38. Determination of which of these results is best depends on the prices paid for coal of different ash contents. At this plant 15 per cent. ash was the standard aimed at, and on this basis test No. 3 would seem to be the best, since the slightly greater ash content of the cleaned coal as compared with test No. 4 is not enough to overcome the advantages of higher yield and higher recovery of combustible.

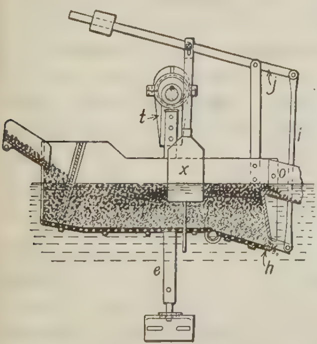

FIG. 25.—Wilmot jig.

American jig is similar to the Stewart, but the hutch water is pumped in and the water-inlet system is designed to reduce suction to a minimum. Baskets are usually 4 ft. wide and 6 to 7 ft. long. Speed in five Illinois washeries (*Bul. 11 UI No. 9*) treating unsized slack ranged from 35 to 50 @ 4-in. strokes per min., average 41. Capacity ranged from 9 to 12.5 tons of feed per foot of width per hr.

Wilmot pan jig (Fig. 25) consists of a sieve box suspended in a V-shaped

tank by straps (*e*) from two eccentrics (*t*), one at either side of the jig frame. Coal overflows at chute (*o*). The jig grate is hinged near the forward end and the hinged section (*h*) is connected by rods (*i*) and (*j*) to the float (*x*), which gives automatic control of slate discharge. The usual speed is 130 to 150 @ 1½- to 1¾-in. strokes per min. in treating anthracite. Grate apertures are 5/16 to ⅜ in. for pea and ½ to 9/16 in. for egg.

Performance on anthracite is shown in Table 39.

James coal jig (Fig. 26) is a modification of the James ore jig. The sieve is moved by a crank mechanism. The gate-and-dam method is used for discharging slate; coal is discharged by overflow. Valves are provided under

the sieves to lessen suction. High water level is maintained and water consumption kept down by discharging into tanks made integral with the jig tank, from which discharged material is removed by scrapers. The gate-and-dam discharge limits use to fine sizes.

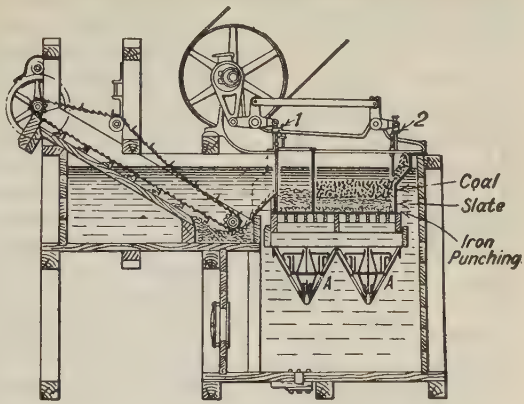

FIG. 26.—James coal jig.

Performance at LOCUST MOUNTAIN COAL Co. on barley-size anthracite ($-\frac{3}{16}$ $+\frac{1}{16}$-in. round hole) is reported by McNally (*18 CA 1089*). He found that the washed coal was cleanest (about 8 per cent. sink in 1.7-sp. gr. solution) at a feed rate of about 14 tons per hour while the refuse contained the least float at about 19 tons per hr. He also found that there was a straight-line increase in the ash content of the washed coal from 14 per cent. to 18 per cent. as the ash content of the feed increased from 16 per cent. to 37 per cent. During these tests the jig was run at 90 @ 2-in. strokes per min. Data on one series of tests are given in Table 40.

Feldspar jig is any type of coal jig bedded with crushed, sized feldspar for the purpose of jigging refuse through the bed into the hutch. Maximum size of feed is usually between ½- and ¾-in. Apertures in jig screens usually run from ¾ in. upward and size of pieces of cleaved feldspar used for bedding is about four times that of the largest pieces of refuse to be removed. At one plant (*59 A 409*) a jig handling -10 $+6$-mm. coal had 12-mm. screen and 30-mm. feldspar.

9. Hand jigging

Hand jigging is an indispensable operation in preliminary field testing of ores, ranking with panning and vanning; it is frequently practiced in treating ores in prospecting and small-scale development work when it is endeavored to make the mine pay its way; and in certain districts, notably parts of the mid-continent lead-zinc field, it is established as the only method of concentration on many of the small properties.

Equipment and operation. For field testing any small sieve such as a testing sieve, a bucket or tub of water, and small metal scraper or skimmer, are

all that are necessary. The screen is filled one-half to three-quarters its depth with the material to be tested, then, after careful submergence and thorough wetting, is held firmly in two hands with bottom horizontal and top just not submerged and moved up and down in such a fashion as will bring the material into partial suspension on the down stroke and allow it to settle back on the up stroke. This requires an accelerated down stroke and retarded up stroke. The usual speed is 60 to 100 strokes per min. After a small number of strokes, depending on the size of particles and relative specific gravities of the components of the bed, the impoverished surface layer may be scraped off and new feed added and the process repeated until the top of the middling layer becomes so high as to leave insufficient room for new feed. This layer is then scraped off and set to one side and con-

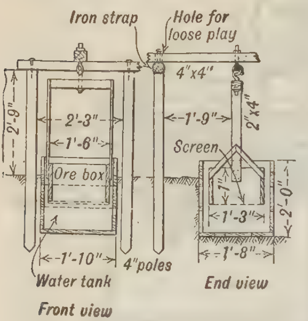

Fig. 27.—Simple hand jig.

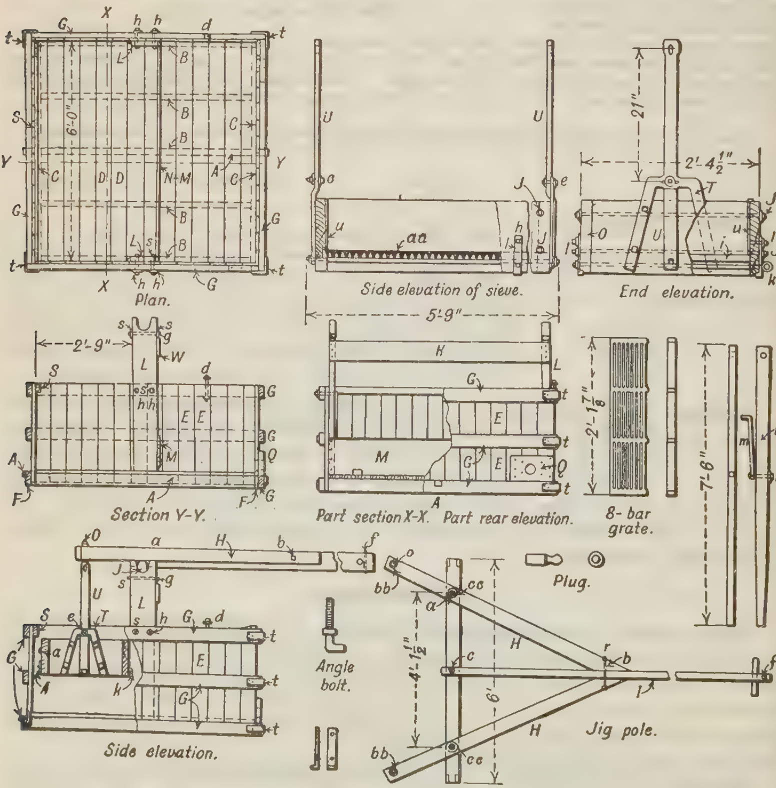

Fig. 28.—Joplin hand jig.

centrate is removed from the screen. Middling may then be put back to form the bed for further operations. The fine material that passes through the sieve and overflows the top is collected separately. If the jig screen is fine, this material is best cleaned up in a pan or plaque; if the screen is coarse, the fines may better first be re-jigged through a bed of coarser concentrate on a fine screen, in this work accenting the start of the up stroke and working with the top of the jig-sieve box always out of water. In this way considerable suction through the bed is induced and fine heavy mineral is thereby drawn through. Slime may be separated from this concentrate by decantation and be treated separately on a plaque.

A somewhat more elaborate testing jig may be made by suspending a jig sieve, say 12 × 12 in. and 6 to 8 in. deep by means of a rigid stirrup rod about 18 in. long, from a spiral spring of such strength that it is imperceptibly extended by the loaded jig sieve, yet extends readily under a downward pull by the operator and returns readily when the pull ceases.

When any extended operation is contemplated a more elaborate rig is needed. Figs. 27 and 28 show two forms that have been successfully used. The simpler form shown in Fig. 27 (*89 J 1265*) was used at an isolated copper mine in northern Transvaal; the form in Fig. 28 is typical of Joplin practice. This type is best used with a spring board, so arranged that the handle is about waist-high to the operator while jigging. The compartmented box is used to provide a quiet pool for slime settlement. Proportions are such that an 8-in. bed on the sieve, when submerged, just about balances the handle. Capacity of such a jig is from 1 to 3.5 tons feed per sq. ft. per 24 hr.

Elmore (*18 CA 1132*) says that a Joplin-type hand jig with 24 × 66-in. sieve in a 6-ft. × 6-ft × 33-in. tank can be built at not to exceed $60 (1920).

Performance. At SANTA BARBARA, Chihuahua (*87 J 910*), using a jig of the first type with a 3 × 3-ft. sieve, 0.25-in. aperture for coarse material and 0.12-in. for finer, the results shown in Table 41 were attained in treating 3000 tons of oxidized lead ore. One Mexican laborer made about 0.5 ton of combined screen and hutch concentrate per 9-hr. shift. Thirty jigs were arranged in two rows with a track for a tailing car down the center and room for ready access of wheelbarrows to all jigs. In the JOPLIN, Mo. district (*93 J 1079*) three men operating two rougher jigs and one cleaner jig of the type shown in Fig. 28 will treat 15 to 30 tons of coarsely-disseminated, non-clayey ore per 10-hr. shift. Feed is screened through 1-in. or 1.25-in. apertures; rougher-jig slots, $\frac{5}{8}$- to $\frac{3}{4}$-in., cleaner-jig, $\frac{1}{4}$- to $\frac{3}{8}$-in.; stroke, about 1 in. on rougher and $\frac{1}{2}$ in. on cleaner. If there is much clay in the ore it should be washed in a trough washer (Sec. 8, Art. 12) or the equivalent before jigging. Rougher jigs are run with no bed and each charge, after stratification, is divided by skimming into tailing, middling for sale to the mills, and concentrate. Hutch product collects in the jig box for re-treatment on the cleaner. On the cleaner the operator starts with a 2-in. bed and allows it to accumulate until about 6 in. thick, when it becomes too heavy to handle and is skimmed down to 2 in. again. The hutch product through the thin bed may have to be re-cleaned through the thick bed. Treating $-\frac{3}{4}$-in. WOLFRAMITE ORE with a quartz gangue on a jig such as shown in Fig. 28, using 10-mesh screen, the procedure was to charge 70 lb. of ore, jig for 1 min. (about 150 strokes) with an average stroke length of 1 in., longer at first and shorter at the end, shovel off tailing, then charge another 70-lb. lot and repeat. About 5000 lb. of ore carrying 5 per cent. tungstic acid was treated per day yielding 175 lb. of screen concentrate assaying 65 per cent. tungstic acid, and 200 lb. hutch product assaying 8 per cent. Tailing from the screen assayed 0.7 per cent. In another district, concentrating ferberite from quartz and granite (*101 J 717*); feed, $-\frac{3}{4}$-in., sieves, 2 to 4 sq. ft.; stroke, 0.5 to 3 in., speed about 40 strokes per min., and 2- to 3-in. bed, from 1 to 5 ton per 8-hr. shift was treated, including re-cleaning of concentrate to two grades, viz.: 50 to 63 per cent. tungstic oxide and 25 to 40 per cent. The hutch product was only slightly enriched. Water consumption per jig was about equal to the overflow through a 1-in. pipe. Table 42 shows the performance of a hand jig on BITUMINOUS COAL.

SECTION 10

SHAKING TABLES

Modern shaking tables are concentrating devices that consist of substantially plane surfaces, inclined slightly from the horizontal, shaken with a differential movement in the direction of the long axis, and washed at right-angles to the direction of motion by a thin film of water. The earliest form of shaking table was shaken in the direction of the slope, causing the heavy material to climb against the flow of pulp. Salzburg, Schemnitz, Halley and Gilpin County tables for heavy ores were of this class. All are now obsolete. The simplest and earliest form of typical side-slope table is the Rittinger bumping table (Art. 2). The separating action of a side-slope table is shown diagrammatically in Fig. 1; (*A*) is the feed side, (*B*) the concentrate end, (*E*) the tailing side and (*D*) the head-motion end. The deck tilts as indicated by the arrow, is reciprocated at right-angles to this slope by means of pulley (*P*), eccentric (*X*) and the flexible connecting rod (*R*) and is stopped suddenly at the end of the forward stroke by the bumping block (*G*). Feed is introduced at (*F*), slime flows directly down slope and leaves at (*S*), granular material is moved toward (*C*) by the bumping action and is washed by water introduced at (*W*). Tailing discharges at (*T*), middling at (*M*) and concentrate at (*C*). In modern types of shaking tables longitudinal cleats are fastened to the upper surface of the table deck or riffles are cut into the surface, the resulting riffles in either case being arranged variously. Some makers build the deck in two or more planes slightly inclined to each other. Decks of different makes differ in outline from the rectangular form, and head motions and methods of deck suspension have been greatly improved over the original Rittinger model. With a smooth-surfaced table such as the Rittinger the maximum size of feed that can be efficiently treated is less than 1-mm. For years the maximum size of feed treated on riffled tables was 2.5-mm. and in most mills it was less than this. With some of the present methods of riffling, however, base-metal ores are treated as coarse as 0.25- to 0.37-in. and coal as coarse as 0.5-in. has been handled successfully.

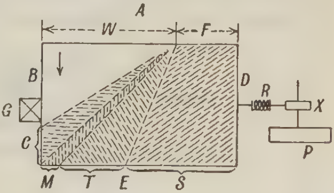

Fig. 1.—Sketch of action of a side-slope bumping table.

1. Principles of shaking-table action

Each particle on the plane inclined surface of a shaking table in operation is acted upon by two forces, *viz.:* (*a*) friction or adhesion between the deck and the particle and, (*b*) pressure of the moving water, and the particle moves in the direction of the resultant of these forces. In all tables the deck starts on its forward stroke at minimum velocity and adhesion between the deck and the particles in contact therewith is sufficient to overcome the inertia of the particles and cause them to move forward with the deck. Velocity accelerates to a maximum at the end of the forward stroke and the deck starts backward at this maximum velocity. Adhesion between particle and deck is insufficient to cause immediate reverse in direction of motion of the particles and they slide forward with the momentum gained on the forward stroke until this momentum is lost by friction against the deck surface. The particles then again move forward with the deck to the end of the forward stroke. The result is intermittent forward travel of each particle in contact with the deck from head-motion end toward concentrate end. If there is a layer of particles several grains deep on the deck, the deck motion is transmitted to the upper layers through the lower, but with some loss, so that the upper layers do not travel lengthwise so rapidly as the lower. If the particles in contact with the deck are of the same size but of different specific gravities, the respective momenta at the end of the forward stroke will be different, the momentum of the heavier being the greater, and the heavier will, therefore, travel further than the lighter before again coming to rest with respect to the table top. This conclusion, which is confirmed by experiment, assumes that the particles are substantially out of contact with the table top during this part of their motion. As soon as they resume contact retardation of the heavier particle is the greater in proportion to its weight (assuming equal coefficients of friction), just as its momentum at the instant of reverse was the greater, and the particles will thereafter be brought to the table velocity in the same time. Large particles of a given specific gravity similarly have more rapid forward travel than small particles of the same specific gravity. If, therefore, (P, Fig. 2), represents particles of heavy and light minerals of the same size, or particles of minerals of the same specific gravity but of different sizes, occupying at the same instinct substantially the same position on the deck of a shaking table, (H_H) may represent vectorially the forward velocity of the heavier or larger particle and (H_L) the lighter or smaller. The forces exerted by the wash water produce film sizing. (See Sec. 8, Art. 14.) If D_H and D_L are taken to represent vectorially the downstream velocities of the heavy and light particles of the same size or the small and large particles of the same specific gravity, respectively, the relative magnitudes of these velocities will be somewhat as shown. The resultant paths of the respective particles under the influences of the two sets of forces acting substantially at right-angles will be R_H and R_L respectively. By inserting some sort of division wall between the points where these paths cut the table edge, separation of particles P_H and P_L is made.

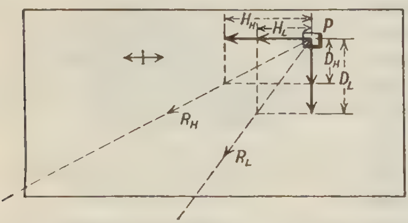

FIG. 2.—Analysis of forces in shaking-table concentration.

When the surface of the table is riffled the riffle grooves are so arranged that they grow shallower toward the concentrate end and in the best known form (Fig. 4) they taper off to nothing along a diagonal line running from the forward end of the feed box to a point near the corner formed by the concentrate end and tailing side. On a riffled table a further important phenomenon occurs that serves to increase capacity markedly above that of a non-riffled surface. As the solid particles carried along by the feed-water current flow out onto the surface of the riffled table, the velocity of the carrying current is lessened by reason of the increase in cross-section of the stream (Fig. 3, *a*) as between cross-section (*A-A*) and cross-section (*B-B*), and the bulk of the solid load settles out in the riffle. Here it is subjected to two sets of forces, both acting to produce segregation by stratification. The shaking motion of the table keeps the mass of particles in a loosened condition, free to move to a certain extent relative to each other, and under this condition the heavier particles and the small particles tend to work to the bottom of the mass. This is a familiar phenomenon that may be observed whenever a mass of grains of different sizes in a container is jarred repeatedly with sufficient force to cause movement of the individuals without sensibly lifting the mass as a whole. At the same time eddying, as indicated by the dotted arrows in Fig. 3, *a*, occurs in the riffles and since the smaller particles of the lighter mineral are more readily lifted by a water current of given velocity than are heavy-mineral particles of the same size, the light-mineral particles do not work down so far into the mass as the heavy. In a short time, therefore, the mass of grains is stratified in the riffles somewhat as is represented diagrammatically in Fig. 3, *b*, with both coarse and fine heavy mineral at the bottom, the fine, however, in the interstices of the coarse, and the light mineral above, more or less regularly arranged in layers with the coarsest on top. As this mass of grains is moved toward the concentrate side of the table the riffle groove in which it travels becomes progressively shallower. The result is the same as though the riffle cleats in Fig. 3, *b*, were successively sliced off at levels (*C-C*), (*D-D*), etc., thus exposing successively deeper layers of the stratified pulp to the cross wash of the water. This accentuates the separation that is effected on a smooth surface, as previously described; the riffles protect the heavy mineral from the action of the cross water, thus allowing a stronger cross-water current to be used, with consequent more rapid removal of waste and increase in tonnage handled. At the termination of the riffle cleats final washing out of the last of the fine gangue is done on a smooth surface, as previously discussed. The finest particles of both heavy mineral and gangue, that will not settle out of the feed-water current, pass directly across the table near the head-motion end and are discharged as slime (see Fig. 1). On an unriffled and to a considerable extent on a riffled table, the solid particles become arranged on the deck in a manner somewhat as indicated in diagrammatic sketch Fig. 3, *c*. Rows (*A*) to (*D*), inclusive, represent grains of con-

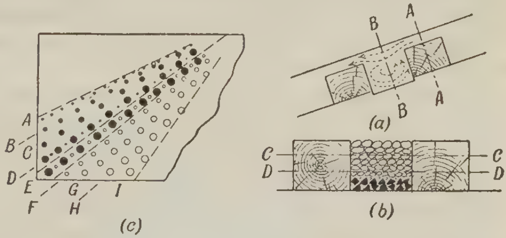

FIG. 3.—Behavior of particles on a diagonally riffled shaking table.

centrate. The grains in rows (*A*), (*B*) and (*C*) are substantially pure heavy mineral (indicated by full black circles); row (*D*) contains small grains of gangue (indicated by open circles) in addition to the large grains of heavy mineral. All very small grains of both heavy and light mineral go off in the slime. Row (*E*) contains the largest grains of pure heavy mineral and some small grains of pure gangue in addition to the large bulk of "mixed" grains, of intermediate specific gravity. Rows (*F*) to (*I*) inclusive contain the larger grains of pure gangue and the lighter grains of middling.

The ideal arrangement just illustrated is modified considerably by the character of the riffling, by irregularities in deck surface and water supply, differences in shape of grains of light- and heavy-mineral particles and of different grains of the same mineral, and by any irregularities in the motion imparted to the table deck.

Richards (*38 A 556*) found in treating "natural" feeds of quartz and galena on a Wilfley table that with −2-mm. feed there was marked retention of quartz between 0.7-mm. and 0.15-mm. sizes in the concentrate, while but little quartz of coarser and finer sizes was retained. With this same feed galena appeared in the tailing in amounts exceeding 1 per cent. at 0.2 mm. and the amount rose to 17.5 per cent. in the −0.08-mm. size. The slime from this run all passed 0.45-mm. and assayed 18.9 per cent. galena; there was no galena in the product on 0.36-mm., but 10 per cent. appeared in the 0.28-mm. size. Middling amounted to 21.5 per cent. of the total feed. The coarsest sizes assayed 75 per cent. galena and there was gradual diminution to a minimum of 3.68 per cent. galena at 0.20-mm. with a marked increase to 32.23 per cent. at 0.08 mm. and further increase to 90.5 per cent. in the −0.08-mm. size. In treating −1-mm., −0.5-mm. and −0.25-mm. feeds the results were similar except that the grade of total concentrate increased with increasing fineness, corresponding to decreased retention of intermediate-sized quartz; grade of tailing correspondingly increased, with accompanying decrease in grade of middling and slime. In every test maximum retention of quartz occurred at a size between one-quarter and one-third that of the largest grain in the feed, indicating that this retention is effected in the interstices of the concentrate layer on the table and is not the result of failure to move the material on a smooth plane. Richards' work likewise shows accordance with the ideal arrangement (Fig. 3, *c*) and the departure therefrom caused by using riffles. The particles in his concentrate are all distinctly smaller than those in his middling and the gangue in the middling is smaller than that in the tailing, but both middling and tailing contained much fine heavy mineral that on an unriffled table would have passed off in the slime and such mineral in the middling was coarser than that in the tailing. As the size of feed decreased and the amount of wash water necessary to remove coarse gangue from the concentrate likewise decreased, the amount of very fine mineral in the concentrate increased with correspondingly decreased tailing loss in the same sizes. The tests on "natural" feed indicate 0.15- to 0.2-mm. as a critical size at which galena losses in quartz tailing become excessive.

Feed. It follows from the foregoing discussion that in order to treat particles on a shaking table they must settle in water at a sufficiently rapid rate to come into contact with the table deck, or the mass of settled solids thereon; and they must have sufficient mass to travel forward, by reason of their inertia, for a short period of time after the table deck starts on its backward travel. In order to effect separation of one class of particles from another they must differ in size or in specific gravity or both. It would appear from Fig. 3, *c* that the most efficient separation of heavy from light grains can be made on a non-riffled surface when the heavy grains are smaller than the light, since small heavy grains and large light grains discharge from such a table the maximum distance apart. The limit of size difference is reached when the particle of heavy mineral is too small to remain in contact with the table top in the cross current required to wash down the large particles of light mineral. This limiting difference is not reached within the size range that it is possible to prepare by the most efficient hydraulic classification and hence the conclusion that classification is the best means of preparation of feed for unriffled shaking tables would seem to be justified. On a riffled table, on the

other hand, fine heavy mineral is protected by the riffle cleats from the cross-water current that removes the coarse gangue; 0.1-mm. galena is readily delivered at A (Fig. 3, c) while 1.0- to 1.5-mm. quartz is washed down to H, I.

2. Types of shaking tables

Tables are called sand or slime tables according to the size of material that they treat, and are classified as roughing or finishing tables according to the character of the service. Sand tables are always riffled with relatively deep riffles, over a majority of the surface at least, with the space between riffle cleats usually not more than ¾ in. to 1¼ in. wide; slime tables, on the other hand, are not riffled so deeply, and the space between riffle cleats is usually much wider than on sand tables in order to form pools of relatively quiescent pulp to induce settlement of solids. Slime tables always have a portion of the deck, at least, unriffled. But any sand table that has an unriffled portion may be used for slime and slime tables may be used for sands, if the settling pools are not too large. Roughing tables are usually riffled full length and the riffles are comparatively deep. These tables are thus enabled to treat large tonnages and yet save fine mineral with the coarse in the form of a low-grade concentrate, at the same time rejecting an impoverished tailing. Finishing tables, with a few exceptions, have an unriffled portion for cleaning out fine gangue from the concentrate streak; the riffles are shallower than on roughing tables, and, in general less resistance is offered to the cross travel of solids than on a rougher. While in some mills the same table with different operating adjustments is used for both roughing and cleaning, this is not, in general, good practice, and it is doubtful whether superior efficiency can be demonstrated for it in any case. Such practice has the advantage of lessening the stock of repair parts that must be carried, with consequent economy, but such saving will rarely compensate for the losses or reduced capacity incident to misuse of tables.

Rittinger bumping table was devised about the middle of the nineteenth century and was used to some extent in Germany. It was a plane-surfaced rectangular side-slope bumping table about 4 ft. long in the direction of motion and 6 to 8 ft. wide. The deck was suspended from overhanging supports by rods of adjustable length, and sloped 3° to 6° in the direction of the long axis. The deck was pushed in one direction by a cam acting against a spring, and, after release from the cam, was pushed smartly in the reverse direction by the spring until stopped by impact against a bumping block. The speed ranged from 70 to 100 @ 1-in. strokes per min. to upwards of 200. Feed was introduced along the short upper side near the end away from the bumping block and wash water was supplied along the remainder of the upper side. Division between concentrate, middling and tailing was made by means of adjustable fingers placed along the lower edge. In later forms two decks, side-by-side, were mounted on the same frame and shaken together. Capacity ranged from 0.75 ton of slime to 2.5 tons of sand feed per deck per 24 hr. Water consumption was excessive, ranging up to 30 tons per ton of feed, due to the fact that all movement of solids in the direction of discharge was effected by the water, the mechanical movement being utilized only to effect separation into bands at right angles to the direction of travel. The table was used as a finishing table for treating fine sand and slime. Low capacity, excessive water consumption and high repair costs combined to prevent its wide introduction and final adoption of the side-slope shaking table in the mills was deferred until about 1895, when the Wilfley table was first placed on the market.

3. Wilfley table

This table (Fig. 4) is a side-slope shaking table riffled over somewhat more than half the surface, the riffles terminating along a diagonal line extending from the forward end of the feed box to the corner formed by the tailing side and concentrate end.

Construction. The deck is built of redwood strips laid flat at 45° to the axes of four longitudinal beams; the whole is carried on two transverse steel trusses, each with two slipper bearings which rest in supporting bearings on the frame.

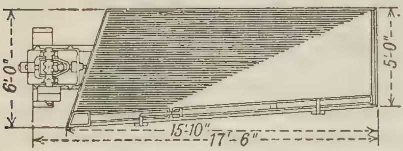

Fig. 4.—Wilfley table (right-hand).

Frame is built of steel or wood. The steel frame consists of a large, rigid through member composed of two 12-in. channels 15 ft. long, spaced 20 in. apart by cast-iron separators. The through member carries two circular machined seats in which rest cast-iron bolster yokes with suitably machined surfaces. The yokes carry cross members built up of lighter channels. In wood-frame tables, a 12 × 16-in. pine timber replaces the longitudinal channels and pressed steel is used for the cross members. The seats for the slipper bearings of the deck are bolted to the transverse deck-frame members. Transverse tilting is effected by power screws engaging bronze tilting nuts in the bolster yokes and actuated by suitable gearing from a hand wheel located at the feed side near the concentrate end. A permanent longitudinal tilt upward toward the concentrate end, ranging from ⅜ in. to 1¼ in. in the length of the table, is provided for; the normal tilt is between ⅜ and ⅝ in. When the longitudinal tilt is too steep, concentrate may refuse to climb and pack in the riffles. *Richards* cites an experience with two-mineral separation in which the lead content of zinc concentrate changed from 2 to 8 per cent. with change in longitudinal tilt from ⅝-in. to ⅜-in.

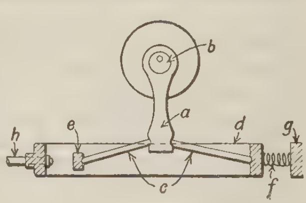

Fig. 5.—Diagram of Wilfley-table head motion.

Head motion is of the pitman-and-toggle type illustrated in outline in Fig. 5. The essential parts are the pitman (*a*), pulley-driven eccentric (*b*), toggles (*c*) and yoke (*d*). The forward toggle abuts against a fixed block (*e*) and lost motion is prevented by compression in spring (*f*) between the yoke and the fixed block (*g*). The yoke is attached to the table deck by rod (*h*). Horizontal movement of the outer end of the right-hand toggle for a given vertical displacement of the inner end is greatest when the divergence of the toggles from a straight line is a maximum, which is at the end of the forward stroke; it is least when the divergence is minimum, and this is at the end of the backward stroke. Hence with uniform rotation of the drive pulley the deck velocity increases from the beginning of the forward stroke to a maximum at the end of the stroke while the return stroke starts at maximum velocity and decelerates until the end. The backward stroke is effected entirely by the toggles, acting against the spring pressure and the inertia of the moving parts; the forward stroke is effected by the spring, but the spring tension is set to prevent lost motion so that the velocity of the forward stroke is controlled by the toggles. Graphical analysis of the motion is shown in Fig. 6, positions 1 to 8 inclusive being those occupied at eight equally-spaced moments of time in one revolution of the drive pulley. In the graph (Fig. 6, *c*) the slope of the tangent to the curve at any point is a measure of the velocity at that point and the curve clearly shows acceleration from 1 to 5, representing the forward stroke of the table, and de-

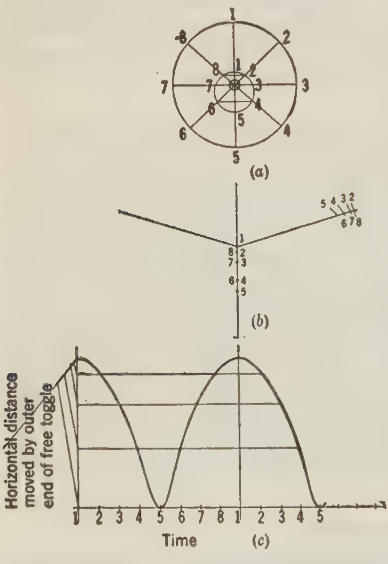

Fig. 6.—Analysis of motion of Wilfley table.

celeration from 5 to 1. To ADJUST THE SPRING properly, loosen until a slight knock is heard then tighten to just remove the knock. Further tightening increases wear and power consumption and may cause spring breakage. LENGTH OF STROKE and, to some extent, the SHARPNESS thereof, are controlled by vertical movement of the fixed toggle block, which is lowered to lengthen and sharpen the stroke and raised to shorten it. The usual range of STROKE LENGTH is from about 0.5 in. to 1.25 in.

DECK FRAME is covered with linoleum when delivered by the manufacturer and this is the usual covering, but canvas, rubber, pyroxylin-covered fabric (MINE-FAB), cement and glass have been used.

RIFFLES are usually formed on linoleum and similar surfaces by tacking on wooden cleats, but the riffle may be grooved into the linoleum or cast into glass or rubber. Softwood (sugar pine) attached riffles are usually used in finishing service, maple or oak in roughing service or with coarse abrasive feed. Riffles have been made by bending 16-gage galvanized iron into unequal-leg angle sections, using the short side as the riffle cleat and the long for the bottom of the riffle (*112 J 180*). These increased the capacity of a No. 9 Wilfley 25 per cent., the cost of laying was 20 per cent. less than for wooden cleats, and on the basis of the usual local average life of 5000 tons for soft-pine riffles the respective costs per ton of feed were $0.015 for wood and $0.008 for iron. STANDARD RIFFLING on a Wilfley table is formed as follows: A full-length cleat, ¼ in. wide, tapering from ½ in. deep at the head-motion end to a feather edge at the concentrate end is laid along the tailing side with the lower edge in the same plane as the outer face of the outer deck timber. The shortest riffle cleat, about 4 ft. long, ¼ in. wide, and tapering from ¼ in. deep at the motion end to a feather edge, is placed parallel to the first and partly under the feed box. Forty-four other riffles of the same width, spaced on about 1⅜-in. centers, are then placed between the first two. Their heights at the motion end are graduated between those of the first two cleats; they terminate along a diagonal line joining the thin ends of these cleats, and each is tapered gradually to a feather edge at this line. Brads penetrating at least ⅜ in. into the wood of the deck and spaced on about 6-in. centers should be used to hold down the cleats. In placing NEW LINOLEUM and riffles on a deck, first allow the linoleum to flatten out of its own accord in a warm, dry place, then set it on a clean, smooth deck with an overlap on the tailing side and concentrate end of about ¼ in. Tack lightly in place. Lay the longest riffle, mark the location of the shortest and of the diagonal line, then lay the remaining riffles, working upward from the tailing side, using a template to obtain the desired spacing. Finally tack down the edges of the linoleum and place quarter-round strips on the feed side to exclude water and pulp from the under side. Puffs will usually disappear after a few days' use and should not be tacked down.

Tables are built both right- and left-hand. RIGHT-HAND TABLES have the feed box and drive pulley at the right when the observer stands at the head-motion end and faces the table; LEFT-HAND, *vice versa.*

FEED AND WASH-WATER BOXES are open-topped troughs carried along the high side of the table deck. Feed box is attached to the deck and extends about one-quarter to one-third the length from the head-motion end. Wash-water box extends the remaining distance along the table and is supported on the table bed. Egress is by holes at the back (upper side) of the boxes and is regulated by fingers buttoned over the holes. The shaking motion keeps the heavy portion of the feed sufficiently in suspension to cause it to distribute and flow. Water is introduced by flexible hose through a hole in a cover board over the center of the water box, thus preventing splashing. An open water box is superior to perforated pipe as it permits ready cleaning of clogged exit holes.

Distribution of wash water along the concentrate end is effected on the usual form of table by a shallow cantilever wash-water trough along the end with drip holes near the lower corner. This is most unsatisfactory. The best method of keeping this end of the table washed is to cut the end back diagonally by shortening the tailing side 3 to 6 in., or water discharged from the feed-side water box may be diverted in part to the concentrate end by a proper arrangement of small cleats tacked to the unriffled surface.

SEPARATION OF CONCENTRATE FROM MIDDLING should always be made on the concentrate end where the movement of the discharging stream is parallel to the splitter edge. The tailing-middling split can be brought to the end also, with considerable advantage in some cases, by bringing the line of termination of riffle cleats up to about the quarter-point on the concentrate end. Fingers fastened to the deck are sometimes used to do away with constant tilting of the deck or shifting of the product pans. A finely-corrugated discharge lip on the concentrate end aids in effecting a clean cut between products.

Performance. Table 1 is a summary of operations of Wilfley tables on lead, zinc, copper and precious-metal ores. Table 3 shows the performance of tables on several different grades of classified feed at NEVADA CON. COP. Co. In most mills the Wilfley table is used on sandy feed, making clean

concentrate and a tailing to be re-ground and re-treated. Fig. 7 (*4 CA 732*) shows results of a test run on bituminous coal.

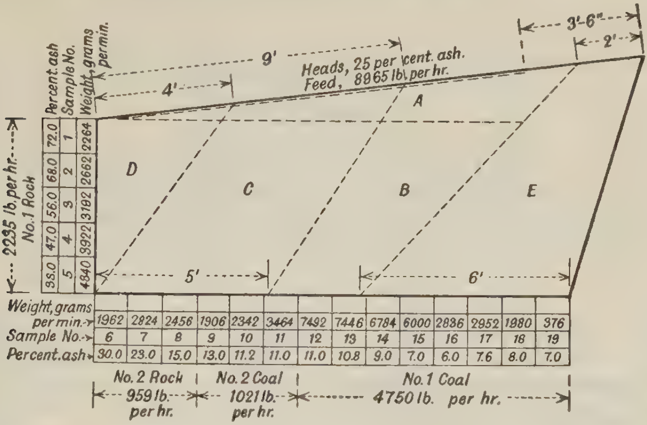

Fig. 7.—Performance of Wilfley table on $-\frac{3}{8}$-in. coking coal.

Capacity. On zinc-sulphide ores the tonnage treated ranges from 14 tons per 24 hr. on 0.8-mm. feed to 100 tons on 2.5-mm. feed; separating willemite, with closely classified feed, capacity varies from 6 tons with 0.4-mm. material to 12 tons at 2.3-mm. On lead ores, when both clean concentrate and finished tailing are sought, capacity varies from 10 tons on 0.5-mm. feed to 45 tons on 2-mm. size. Capacity treating native-copper ore all through 0.6-mm. and containing 40 per cent. slime is 15 to 25 tons per 24 hr. when making clean concentrate and finished tailing. Treating porphyry-copper ore, the capacity on material through 0.6-mm., when making finished concentrate and tailing, is 14 tons per 24 hr.; treating rougher-table concentrate capacity is 45 to 75 tons and when roughing -2.5-mm. feed, 200 tons. Separating auriferous pyrite from silicious gangue, capacity is about 25 to 30 tons per deck on 1-mm. sands, falling to 10 tons on 0.1-mm. sands and rising to 50 tons on 2-mm. material.

Size of feed rarely exceeds 2.5-mm. Wiggin (*46 A 232*) determined that 0.025-mm. was the smallest grain that could be saved with Anaconda ore. The coarser, sandy portion of 200-mesh slime is readily saved. Table 4 is a sizing-assay test of Anaconda table tailing

Table 4. Sizing-assay test of Wilfley-table tailing, Anaconda Copper Mining Co.

−0.07	3.10	1.25	17.13

when a roughly de-slimed feed was being treated. Table 5 gives similar results at Ray Cons. Cop. Co., except that the feed was not de-slimed. Here maximum loss of copper and maximum assay occur in the finest size; there is also a relatively high copper loss in the coarsest sizes.

Speed and stroke. Speed ranges from about 230 to 280 strokes per min., being close to 250 in the majority of mills. Length of stroke averages close to ¾ in. Within the range of practice presented, no distinct relation between stroke length and speed is established, but in general a short stroke corresponds to a high speed and *vice versa*.

Wash-water consumption ranges from 1.5 to 40 gal. per min., the high figure being in roughing service and the low corresponding to a very dilute feed pulp. Average consumption for average service is about 8 gal. per min.

Slope varies with size of feed, specific gravity of minerals, character of products desired, and the place that the products are split, as well as with the quantity of wash water. The usual slope with fine feeds is from ¼ to ½ in. per ft. and ¾ to 1 in. with coarse feeds. When roughing the slope may be as much as 2 in. per ft.

Power. Actual power consumption under average load is close to 0.6 hp. with a usual installation of between 0.75 and 1 hp. per table.

Lost time is very small and is principally due to shut-downs for replacing deck covering and repairing or renewing riffles. Mechanism difficulties usually correspond to high tonnages and long stroke or to attempts to run double decks with the standard head motion (see Garfield-table head motion, Art. 9).

Operating adjustments available on t e standard table are length of stroke, tilt, wash water, location of product splitters. In small mills where irregularity in feed conditions is frequently the rule, control of all of these is necessarily left with the operator. The tendency in large mills is to limit operator's adjustments to tilt and wash water and in some mills tilt is not adjustable and the operator controls wash water only. In some plants splitters are fixed in position and products must be brought to the proper points by shifting their position on the table deck by changing tilt and wash water. It is much better to have movable splitters and to take care of all minor shifting of the product streams by moving the splitters, leaving water and tilt as nearly undisturbed as possible.

Comparison with other machines. For results of competitive tests with other tables see the other tables.

As a result of a competitive test with a fine jig at Bunker Hill and Sullivan, Caetani concluded (*3 MM 54*) that the Wilfley table had twice the capacity of the jig, made a higher recovery and required less skilled labor and less water, power, and repairs. The table made a slime separation that a jig fails to make and there was less fall of material in passage through the machine. Jig concentrates were richer and the middling contained less free mineral. Tailing assayed about the same in both cases but the coarse part of the jig tailing was lower grade while the fine part was of higher grade than the Wilfley.

Buss table is a side-inclined shaking table which has the deck frame supported on a number of lath-shaped ash or hickory strips, pivoted at the lower end and standing inclined toward the motion end about 15° from the vertical. The head motion is a simple eccentric. On the forward stroke particles in contact with the table deck move forward and upward with it; on the reverse stroke the particles continue to move forward but, by reason of the fall of the deck, are out of contact with the deck during a part of their forward travel. The result is that forward travel is much more active than on tables

with the Wilfley type of motion. Riffles are full-length and converge slightly toward the tailing side. Height and taper of riffles, speed, stroke length, power and water consumption and capacity are about the same as on the Wilfley table.

Ferraris table is closely similar, except that the number of spring supports is less and the riffling is not carried full length but is cut off at right-angles to the motion along a line about two-thirds the distance toward the concentrate end of the table.

4. Butchart table

This table (also called NATIONAL TABLE) is a rectangular-deck, full- or partly-riffled table, differing from those previously described in that the riffles are bent diagonally toward the feed side about along the line of the "Wilfley diagonal" and run in this direction for a few inches, where they terminate or are again bent back substantially parallel to the tailing side. Diag-

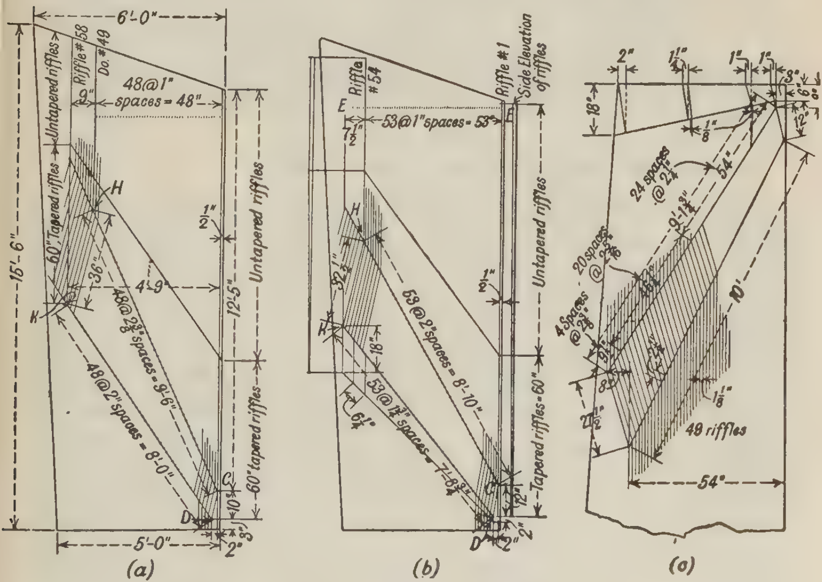

FIG. 8.—Butchart riffling.

onally-terminated riffling is used for cleaning; full-length riffling principally for roughing but also for cleaning. The "wave" in the riffles along the "diagonal" line is claimed to effect a rotary vanning motion that aids in bringing gangue to the surface of the beds in the riffles where it can be washed away. Fig. 8 shows plans of three forms of Butchart riffling. Either of types (*a*) and (*b*) may be changed to full-length by continuing the riffle cleats to the concentrate end in a direction parallel to the tailing side. Probably most Butchart riffling is mounted on Wilfley mechanisms, but W. A. Butchart manufactures a complete table with a head motion (Fig. 9) of the toggle type that is enclosed and runs in oil. This is a distinct advantage.

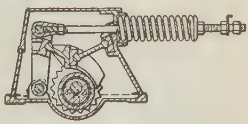

FIG. 9.—Butchart head motion.

Effect of full-length riffling is shown in Fig. 10. The coarsest heavy mineral discharges highest up on the concentrate end and there is a uniform decrease in size of heavy mineral in the concentrate as the tailing side of the table is approached. The gangue sizes, on the other hand, are distributed as on the Wilfley table. This arrangement of discharging grains is due to the fact that after stratification, which takes place as shown in Fig. 3, while the light minerals are washed away as on the Wilfley table, the heavy minerals are afforded the support of the riffles the full length of the deck, are not subjected to film-sizing and the only effective force acting to cause size segregation of these grains is eddying in the riffles. The eddying water lifts the finer particles more readily than the coarse and these particles are, therefore, carried over the riffle cleats and down slope, while the coarse particles travel along to the end of the table. The result is to spread the product bands at the discharge edges of the table and permit much closer and cleaner splitting than is possible with diagonally-terminated riffles. This is particularly true of the concentrate-middling split. On the other hand, the full-length riffles support fine gangue and carry it toward the concentrate end, with the result that more water must be used to get clean concentrate than on a table with partly plane surface, and there is more fine clean gangue in the middling.

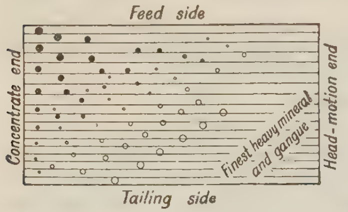

FIG. 10.—Distribution of minerals at discharge end of a shaking table rifled full length.

Performances at several mills are given in Table 6.

Maximum size of feed that can be handled depends upon the type of riffling. In roughing service, with tables riffled full-length, the maximum size of feed is probably about ⅜-in., but with such coarse feed, while a clean coarse concentrate can be taken, it is difficult, if not impossible, to make a satisfactory separation of middling from tailing. In finishing service, with diagonally-terminated riffles, the maximum size that can be satisfactorily treated is about the same as on a Wilfley table, *viz.*: 2- to 2.5-mm. Minimum size is the smallest that will settle in the cross-water current and will therefore be smaller the smaller the maximum-sized particle of feed. At the Bonne Terre mill of ST. JOSEPH LEAD CO., general mill concentrate was de-slimed at 100-mesh and the fines thickened and treated on a Butchart table. The concentrate assayed 80 per cent. Pb.; 95 per cent. passed a 200-mesh screen; tailing assayed 6 per cent. Pb. When coarse feed is treated it is necessary to have fine sand present. Attempts to enrich jig lead concentrate on the table failed until sandy table concentrate was added.

Riffling is varied according to the character of service and size of feed. Full-length riffling is used principally in roughing, but may be used also for finishing, especially when the ratio of concentration is low; diagonally-terminated riffles are used for cleaning. Riffle cleats are usually ⅛ in. high at the concentrate-discharge end, tapering from about ½ in., but when the feed is coarse, ratio of concentration low, or tonnage exceptionally high, the taper may be from 1 in. to ⅜ in., in order to provide concentrate-carrying capacity. With such deep riffles at the concentrate end, they are usually given a slight curve downhill near the end in order to keep sufficient water along this end to prevent banking. The average RISE OF RIFFLE CLEATS in the "wave" section is 1 in. in 4 in. of run parallel to the tailing side. The steeper the rise the cleaner the concentrate, other conditions being constant. Riffle cleats in roughing service or with coarse feed are usually of hard wood, oak or maple preferred; in cleaning, sugar-pine cleats are satisfactory. Life of oak riffles is three times that of pine.

Linoleum is the usual DECK COVERING, but soft rubber (old vanner belts) has been used at the Morenci branch of PHELPS DODGE and in the SOUTH-EAST MISSOURI lead district. Concrete has been used at Bonne Terre mill of ST. JOSEPH LEAD CO. Concrete mixture is 2 of sand (2-mm.) to 1 cement; it is laid on linoleum flush with the tops of riffle-nailing cleats 3⁄16 to ¼ in. high and is given a steel-trowel finish. Life of linoleum covering is 6 months to 3 years, depending upon the size of feed; rubber has a longer life, but new covers cost three to four times as much as linoleum. Concrete deck at ST. JOSEPH LEAD CO. has given very satisfactory service. It has the disadvantage of increasing the weight of the rapidly-reciprocating deck, with consequent increase in power consumption and wear.

Capacity on 2- to 3-mm. feed in roughing service is from 100 to 200 tons per 24 hr. which is about the same as that of the Garfield table (see Art. 9). In finishing work on 1.5- or 2-mm. feed the capacity on lead ores is from 30 to 65 tons per 24 hr. and in cleaning rough copper concentrate, through 8-mesh, ranges from 40 to 75 tons. Cole (*51 A 405*) reports 80

tons per day treating de-slimed Hancock-jig concentrate, −3⁄8-in., at Morenci, lowering the percentage of insoluble from 30 to 15.

Speed and length of stroke. The usual range in speeds is from 240 to 280 strokes per min. and average length is close to 1 in. The examples cited do not show any distinct relationship between character of feed and the stroke, nor between speed and stroke length, but in general the rule applies that coarse feeds require longer and slower strokes than fine feeds.

Wash-water consumption averages close to 10 gal. per min.

Lost time is estimated as close to 1 per cent. on the average and is due principally to replacement of deck covering and riffling.

Attendance. Operators control tilt and wash water in all mills reporting and at Morenci also control feed rate to a certain extent. The relatively low figures under "machines per man" in Table 6 are probably due to the fact that no more tables were installed calling for attention. Butchart riffling, particularly full-length, spreads the concentrate and middling bands out into wide fans which change position only slightly with changes in feed rate, hence control is easy and attendance should be small.

Butchart vs. Wilfley. Cole (*51 A 405*) reports the following 4-day test at Morenci.

Feed, de-slimed rougher tailing after re-grinding to pass 1.5-mm. Results as in Table 7, test A. Test B in the same tabulation shows the results of treating roughly de-slimed 20-

Table 7. Butchart *vs.* Wilfley table at Morenci plant, Phelps-Dodge Co.

mesh feed on a Butchart table with special deep riffles. On the basis of metallurgical results alone the advantage, if any, in these tests is with the Wilfley table on account of the fact that tailing is too high grade to discard in both cases and the operations must, therefore be judged on the concentrate taken out; but capacity and water consumption and necessarily, power, labor and maintenance are all in favor of the Butchart. Results of similar competitive work in treating lead ores in south-eastern Missouri were the same, the Butchart table yielding the same tailing and concentrate when treating 50 to 60 tons per 24 hr. of de-slimed 2-mm. feed as the Wilfley table yielded when treating 20 to 25 tons. (*57 A 350, 429*). In analyses of operation in both these fields the Butchart table is credited with elimination of all classification other than rough de-sliming, but this saving in treatment is rather due to the introduction of flotation, which removed from the tables the burden of making finished tailing.

Butchart table *vs.* **jigs.** Table 8 presents the results of a competitive run between a Butchart table and a Harz jig at the Detroit Copper Co. plant on primary feed passing

Table 8. Butchart table *vs.* Harz jig at Detroit Copper Co.

a 7-mm. screen, without de-sliming. (*51 A 405.*) At St. Joseph Lead Co., Bonne Terre, Hancock jigs gave better separation of middling from tailing than the table on -9 $+2$-mm. feed and tables were rejected for treating material coarser than 2-mm. (*57 A 429.*)

5. Card table

This table differs from the Wilfley table principally in that the riffles are cut into the linoleum and are triangular rather than rectangular in cross-section (Fig. 11). The cross-section of the riffles increases from the head-motion end to a maximum along a diagonal corresponding to the termination of Wilfley riffles, then decreases to nothing at the concentrate end. On tables for fine feed the riffles contract from maximum section at head-motion end to disappearance at the diagonal line. Riffles for coarse feed are about 2.5 in. apart, ⅝-in. maximum depth and $\frac{1}{16}$-in. minimum.

Fig. 11.—Cross-section of riffling on Card table.

Head motion is shown in Fig. 12. (*A*) and (*C*) are fixed pins and (*B*) a fixed toggle block. The motion of crank-shaft (*G*) is transmitted through the pitman and toggles to lever arm (*D*), thence by connecting arm (*F*) to lever (*H*), whose working arm (*E*) draws the table deck back against spring (*S*). The forward stroke is impelled by spring (*S*) but controlled by the mechanism chain. Length of stroke is varied by changing the position of pin (*P*) in lever (*D*). The deck motion is differential, of the same general character as the Wilfley, but Caetani (*3 MM 50*), discussing the choice of Card tables after competitive tests at Bunker Hill and Sullivan, says that the Card mechanism gave a sharper return stroke than the Wilfley and consequently greater capacity. The deck is roughly 5½ × 16 ft. There is a line of flexure in the deck along the diagonal from the feed corner, which permits the slime corner to be raised or lowered out of plane with the other half of the deck. When the deck is tilted up, crowding occurs along the diagonal of separation. The deck is usually set horizontally lengthwise.

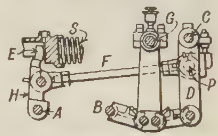

Fig. 12.—Head motion, Card table.

Performance. At Broken Hill South mill (*28 MM 8*) the table had a wood deck, sloped 1.75 in. in the width, and made 297 @ 0.75-in. strokes per min. Results on coarse unclassified feed are given in Table 9. A sizing test of a concentrate of similar assay, made

Table 9. Assays of Card-table products at Broken Hill South mill

	Product	Assays: Lead, per cent.	Silver, oz.	Zinc, per cent.
−16-mesh feed	Lead concentrate	63.8	23	7.8
	Lead-zinc middling	14	7.6	23
	Zinc tailing	2.8	3.0	16.5
	Quartz tailing	2.0	2.0	8.4
	Slime tailing	9.7	7.0	14.0
−24-mesh feed	Lead concentrate	52.8	20.0	12.7
	Lead-zinc middling	8.7	8.0	27.2
	Zinc tailing	2.9	2.5	14.0
	Slime tailing	8.8	6.6	13.0

on Card tables at the Central Mine, Broken Hill, is shown in Table 10 (*28 IMM 14*). This concentrate represents a recovery of about 20 per cent. of the silver, 34 per cent. of the lead and 3 per cent. of the zinc in the table feed. In planning the Bunker Hill and Sullivan, West Mill, extensive competitive tests were run, as a result of which the Card table was chosen. Caetani (*3 MM 50*) reports that the differences in performance were small but that the Card consistently recovered more silver than the other tables, probably because the wider concentrate streak, which is the result of full-length riffling, allowed a cut further down into the middling without too greatly lowering the grade of concentrate. The main factors in the choice were, however, mechanical. Great operating stability, by

Table 10. Sizing-assay test of Card-table concentrate, Central Mine, Broken Hill

Screen mesh, I.M.M.std.	Weight on screen, per cent.	Assays		
		Silver, oz.	Lead, per cent.	Zinc, per cent.

Whole....	100.0	33.4	63.8	4.6

reason of the broad concentrate streak, was noted. The table stood up to 20 per cent. overload without important loss in efficiency, but overloading caused sand tailing to discharge with the slime. The feed was classified. Capacity on different-sized feeds was as given in Table 11. Speed, 250 @ ¾- to ⅞-in. strokes per min.; hp., 0.5; wash water, 7.5 to 9

Table 11. Capacity of Card tables at Bunker Hill and Sullivan, West mill

Classifier-spigot product, number	Coarsest material		Per cent. through 100-mesh	Tons per 24 hr.
	Mesh	Per cent. retained		
1	40	16	13	18
2	40	2	22	10
3	60	2	65	5
4	80	2	91	3

gal. per min. On coarse feed assaying 15 per cent. lead, tailing assayed 2 per cent., concentrate 72 and middling 14; on finer feed assaying 13 per cent., tailing was 1.5 per cent., concentrate 70 and middling 12.5.

Table 10 shows one of the results of full-length riffling in the high zinc content of the coarse sizes of concentrate. On a table riffled full length the coarsest particles of the heavy minerals ride highest, reversing the ideal Wilfley-table arrangement. On the Central-mill tables the coarse blende was at the upper edge of the middling streak and was cut into the concentrate. The large percentage of fine lead in this concentrate is the result of the V-shaped riffles. The eddying characteristic of rectangular riffles (Fig. 3) is largely absent in these, with the result that fine heavy mineral is retained higher on the table and goes, in greater quantities, into the concentrate.

Table 12 shows tailing made on classifier-spigot products at Mary Murphy mine (*12 CME 21*).

6. Deister sand table

This was the first serious competitor of the Wilfley. Sketch of deck and riffling is shown in Fig. 13. The deck motion is parallel to the riffles, which, therefore, terminate on a line diagonal to the motion. On this ground the table was subservient to the Wilfley patent (now expired). The deck rises about ⅜ in. beginning about 7 in. back from the concentrate-discharge end thus causing the concentrate to climb against the flow of wash water. The deck is supported on extended ball-and-socket bearings. Tilt is effected by sliding wedges located under the seats of the bearings on the feed and tailing sides and actuated synchronously by a hand wheel or lever. The table is built both single-and double-deck.

Head motion for single-deck tables is a combination of a quick-return slide-crank mechanism and a bell lever. (See Fig. 14.) The fly-wheel driving pulley (*a*) is mounted eccentrically to crank shaft (*b*) which carries a slide crank (*c*) engaging a pin (*d*) that is attached to pulley (*a*). Roller (*e*) is eccentrically mounted and free to revolve on shaft (*b*) and actuates the long arm of the bell lever (*f*) which is pivoted at (*g*) and carries on the short arm the yoke (*h*) which attaches to the drawbar of the table deck. The action of the slide-crank mechanism is shown in Fig. 15. Starting with a given point on the surface of the drive pulley in position 1, the time intervals required for this point to move from

1 to 2, 2 to 3, etc., are equal. But in the same time intervals the shaft (*s*), actuated by slide crank and pin from the driving pulley, moves through different angular distances and the total angular movement of this shaft during the time that the chosen point on the drive pulley moves from 1 to 5 is less than that moved through while the same point moves from 5 to 1. With a uniform rate of motion of the drive pulley the rate of revolution of the crank will, therefore, be non-uniform. Eccentricity of the drive-pulley center with respect to the center of the crank shaft is varied by means of slotted arm (*i*) (Fig. 14) by which the sleeve bearing of pulley (*a*) may be so rotated as to cause the center to approach or recede from the center of shaft (*b*). Sharpness of differentiation between forward and back strokes increases with the distance between the two centers. The relation of the eccentricity of roller (*e*) to the position of pin (*d*) is such that when the roller is depressed the table deck is thereby started back at the instant of maximum angular velocity of shaft (*s*) (Fig. 15).

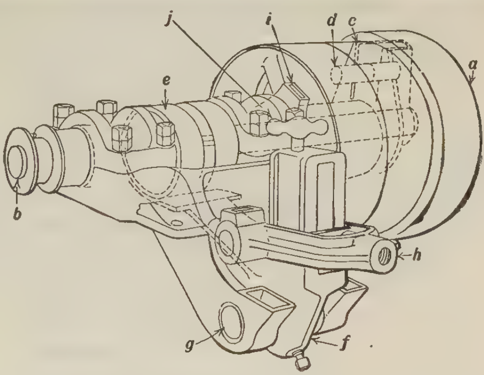

Fig. 14.—Deister head motion.

Length of stroke is varied by moving yoke (*h*) (Fig. 14) along the short arm of the lever (*f*) by means of hand wheel (*j*). This change is made without changing the sharpness of the return stroke except in so far as increasing length without changing speed increases velocity. The action of this head motion is strong and positive and causes material to progress rapidly. A serious disadvantage is the exposure to grit. On double-deck tables the heavy head motion described in Art. 9 is used.

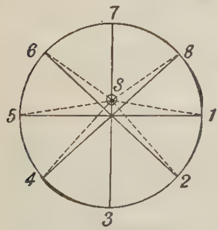

Fig. 15.—Analysis of Deister head motion.

Riffling varies somewhat with the character of the feed. The typical riffling shown in Fig. 13 has ¼-in. cleats spaced 1 in. center to center. When treating unclassified feed and fine sands the lowest riffle cleat, the 9th, 18th and 27th, etc., therefrom, and a cleat near the feed box are made higher than the others (*e.g.*, 0.5 in. against 0.25 in.) in order to form pools to aid settlement of fine material. The riffle cleats are not tapered, but the upper surface is set level longitudinally and an effect of taper is gained by raising the plane of the deck near the discharge end, as described. Pool riffling may be used, although it is unnecessary, on closely classified relatively coarse feeds. Tables are rated as right-hand when the feed box is to the right of an observer facing the table at the head-motion end. The drive pulley is on the side opposite the feed box.

Performance. At Miami Copper Co. No. 2 sand tables running at 240 to 256 @ 1⅛- to 1¼-in. strokes per min. and treating the sand from the first spigot of a hydraulic classifier taking − 20-mesh feed made 38.6-per cent. (Cu) concentrate, 1.21-per cent. middling and 0.64-per cent. tailing from a feed assaying 3.96 per cent. At Old Dominion 30 tons per 24 hr. of − 0.6-mm. feed assaying 2.78 per cent. Cu was treated per table; concentrate assayed 10.5 per cent., middling 2.5 and tailing 0.7. Table 13 shows performance on different classes of feed at Nevada Cons. Cop. Co. Table 14 gives performances in finishing service on a classified feed and compares the performance of standard riffling with a Schwarz glass top. Sizing-assay tests of tailing show that the glass top retained the coarser mineral better than does the standard riffling, but lost a greater part of the fine mineral.

Capacity ranges from 10 to 100 tons per deck, depending on the size and character of feed and whether in finishing or roughing service. The usual range of feed size is from 2-mm. to 0.15-mm. sands. Wash-water consumption is 3 to 10 gal. per min. per deck. Power consumption is about

0.75 hp. for single-deck and about 1 hp. for double-deck machines. The average SPEED recommended by the manufacturer is 215 @ 1- to 1.25-in. strokes per min.

Table 14. Performance of Deister No. 2 sand table with linoleum top and standard riffling and the same table with Schwarz glass top, both treating classified feed, all through 0.833-mm.

Test number	Standard riffling						
	Feed		Concentrate		Middling		Tailing
	Tons per 24 hr.	Assay, per cent. Cu	Tons per 24 hr.	Assay, per cent. Cu	Tons per 24 hr.	Assay, per cent. Cu	Assay, per cent. Cu
1	17.70	2.17	0.47	48.97	0.96	4.51	0.67
2	13.50	2.37	0.59	36.87	2.06	1.27	0.70

Test number	Glass top						
	Feed		Concentrate		Middling		Tailing
	Tons per 24 hr.	Assay, per cent. Cu	Tons per 24 hr.	Assay, per cent. Cu	Tons per 24 hr.	Assay, per cent. Cu	Assay, per cent. Cu
1	17.20	2.01	0.56	42.22	2.14	0.89	0.63
2	11.40	2.18	0.41	45.06	2.66	0.75	0.53

Note—In both tests the assay of −100-mesh tailing was higher on the glass top as was also the percentage of total copper contained in this size.

7. Deister slime table

The No. 3 table is shown in Fig. 16. The deck tilts toward the tailing side and also toward the head-motion end. The deck surface is in two distinct planes, that on the feed side of riffle (*a*) being higher than that on the tailing side and less-steeply sloped. Riffle cleat (*a*) and the cleat along the tailing-discharge side are ½ in. high while the other riffles are but $\frac{1}{16}$ to $\frac{1}{32}$ in. The deck covering is carried up along the back board on the head-motion end. The result is that relatively quiescent pools of pulp are formed at (*b*) and (*c*) in which the fine solids are given a chance to settle after which they progress up a grade of about ⅛ in. per ft. toward the concentrate end. The low riffles afford needed support for the finest concentrate and middling against the force of the wash water while tailing is carried in the current over the lowest riffle. The table is supported on extended ball-and-socket bearings.

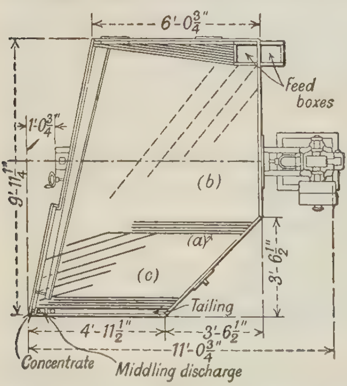

FIG. 16.—Deister simplex slime table.

The bearing seats along the feed and tailing sides are supported on sliding wedges, oppositely faced on the two sides and connected by suitable levers to a hand wheel, movement of which causes tilting. The head-motion is of the variety shown in Fig. 14, for single-deck tables, or of a heavier variety for double-deck tables. The table is rated RIGHT-HAND when the feed box is on the right of an observer facing the head-motion end and *vice versa*. The drive pulley is usually on the same side as the feed box.

Performance. Copper. At OHIO COPPER CO. a table treating primary-slime feed assaying 1.31 per cent. Cu, 90 per cent. −200-mesh, recovered 42 per cent. of the copper in a concentrate assaying 19.2 per cent. The feed rate was 5.6 tons per 24 hr.; speed, 265 @ 7⁄16-in. strokes per min.; deck, enameled linoleum. At BURRO MOUNTAIN concentrator of Phelps Dodge Co. flotation tailing was treated at the rate of 29 tons per 24 hr. making concentrate assaying 11 per cent. Cu and 16.5 per cent. insoluble and tailing assaying 0.47 per cent. total Cu, 0.26 per cent. oxide from feed containing 0.78 per cent. total Cu, 0.26 per cent. oxide. Table 15 shows performances in tests at NEVADA CONSOL. COPPER Co. Vanner recoveries corresponding to the second and third tests were 30 and 50 per cent. and the concentrates contained 41 and 28 per cent. insoluble respectively. **Lead.** At the Morning mill of the FEDERAL MINING AND SMELTING Co. this table treated a feed assaying 10.8 per cent. Pb at the rate of 4.3 tons per 24 hr. Speed, 275 to 295 @ 5⁄8- to 1⁄2-in. strokes respectively per min. Concentrate averaged 55 per cent. Pb and recovery was about 72 per cent. **Complex lead-zinc-silver ore.** At Midvale (Utah) plant of U. S. S. R. & M. Co. the table treated 4.5 tons per 24 hr. per deck of material all passing 200-mesh, in a pulp containing 75 to 80 per cent. water. Speed, 258 @ 3⁄8- to 1⁄2-in. strokes per min. Assays of feed and products are given in Table 16. Power for double-deck table, 1 hp. Water consumption, 2.4 to 3.5 gal. per min. per deck. One man attended 10 machines and controlled operations by varying tilt and wash water. **Gold-pyrite.** Daily performances in a 13-day test on slime feed at the GOLDFIELD CONSOLIDATED COMBINATION mill are given in Table 17. There is no distinct relation in this series of tests between the operating variables and metallurgical results. At LIBERTY BELL a table roughing out concentrate treated 10 to 14 tons of 100-mesh feed per 24 hr., running at 240 @ 1⁄2-in. strokes per min. and consuming 24 gal. of water per min. One man attended 33 machines, controlling opeartions by means of tilt and wash water. At HEDLEY GOLD MINING Co. 50 tons of −200-

mesh slime was treated per 24 hr. on 12 machines run at 190 r.p.m. Power, 0.8 hp. per machine; water consumption, 1.7 gal. per min. One man attended 12 tables and 24 vanners. **Tungsten.** Tungsten Mines Co. treated 10 tons per deck per 24 hr. of a mixed feed consisting in part of cone-spigot discharge from original slimes and in part of the overflow of a hydraulic classifier grading tailing and middling from other tables and vanners. Feed contained 90 per cent. water; wash-water consumption was 8.3 gal. per min. for two decks; power consumption, 1.5 hp.; speed, 280 @ ⅜-in. strokes per min. One man attended 10 machines, controlling wash water only. Assays, per cent. WO_3: Feed, 0.5 to 1.0; concentrate, 40 to 60; tailing, 0.3.

Feed-pulp consistency. The effect of pulp consistency on capacity and saving of fine mineral was investigated by Bland (*107 J 1116*) with the result given in Table 18. In the

Table 18. Deister No. 3 slimer: Effect of feed-pulp consistency. (Feed all through 200-mesh)

Feed-pulp consistency, per cent solids.	Per cent. of concentrate passing 0.0125-mm. aperture	Assay of concentrate, per cent. WO_3	Feed-rate, tons per 24 hr.

8	0	63	4.8
6	0	59	12.0

tests with thick pulp, only a small portion of the deck was used, hence Bland recommends working with thick pulp with resulting small capacity per deck, cutting off the unused

portion of the deck and multiplying decks in order to save power and floor space and thus compensate for decreased capacity. He also recommends close control of pulp dilution in order to insure regular operation and advocates dry sizing of feed to effect this, citing practice at New Jersey Zinc Co. (See Sec. 2).

8. Deister-Overstrom diagonal-deck table

This table has a roughly rhomboidal deck, shaken substantially in the line of the short diagonal, and riffled parallel to the direction of motion. The deck surface is in one plane. Two sizes of deck are used (Fig. 17), a long and narrow one for roughing service and a shorter and broader deck for finishing. The shape is varied on the theory that on the coarse sizes the longitudinal component of travel is proportionally greater and greater length must, therefore, be afforded to permit sufficient washing, while on fine material the transverse travel is proportionally most rapid and width of deck must be furnished to allow the reciprocating motion time to move concentrate to the concentrate-discharge end. The long table is made narrow in order to afford prompt removal of tailing while permitting the table to be run on a flat slope. The concentrate end of all tables is cut off on a backward bevel so that wash water from the water box will flow over the concentrate end and do away with a spray pipe along this end. The deck is inclined against the travel of concentrate, 0.75 to 1.25 in. in its length for sand feeds and 0.25 to 0.5 in. for slimes. Tapered riffle cleats of the usual dimensions (0.25 in. wide ranging up to 1 in. in depth at the head-motion end, according to the service) are used on roughing- and sand-table decks; pool riffling, effected by the addition of a number of broad V-topped riffle cleats, are used on the slime table. In south-eastern Missouri grooving has been substituted for riffle cleats in some places; grooves tapering from ⅛ to $\frac{1}{32}$ in. on the coarse-sand tables, ⅛ in. to nothing on the intermediate tables and $\frac{1}{16}$ in. to nothing on slime tables.

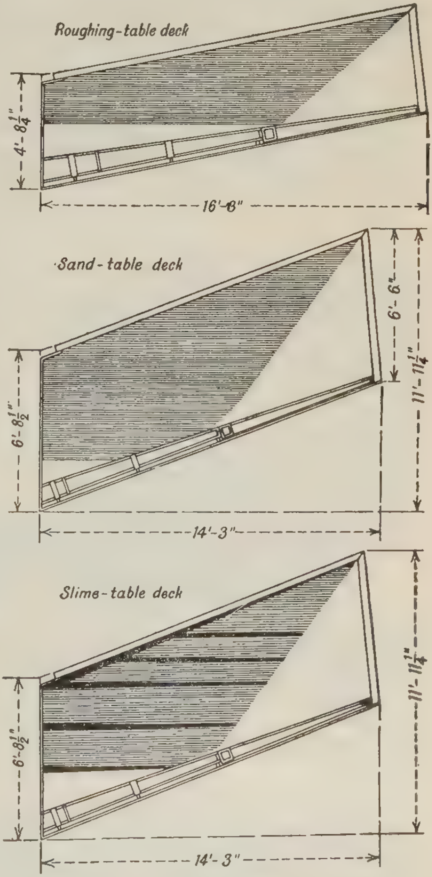

Fig. 17.—Deister-Overstrom table.

It is endeavored to make the depth of grooves at the discharge end equal to the diameter of the gangue particles to be separated.

The deck is supported on slide bearings carried on a tilting frame of light structural steel which, in turn, rests on a heavy, built-up through member that carries the head-motion. Transverse tilting is effected by sliding wedges actuated by a hand-wheel. The head-motion is usually the same as shown in Fig. 14. As a result of testing work at Bunker Hill and Sullivan, Caetani (*3 MM 50*) brands this as the best of all the head-motions tested and Robie (*116 J 403*), writing about the tables at the Northern Ore Co. also commends it.

The shape of the table deck results in increase in the cleaning area along the diagonal separating line and longer time of treatment of partially enriched material. Long narrow decks require long feed boxes.

In south-eastern Missouri practice they are made one-third the total length of the deck on coarse-sand tables, one-half on intermediate-sand and three-fifths on slime.

Performance at several mills is shown in Table 19.

Table 19. Performance of Deister-Overstrom tables

See Table 1. *g* 35 tons 10-mesh sands to 10 tons 100-mesh sands. *h* 20-mesh middling from roughing table. *R*-1 Single-deck, rougher. *S*-1 Single-deck, sand. *Sl*-1 Single-deck, slime.

Feed-pulp consistency ranges from 60 to 80 per cent. water. In south-eastern Missouri work it was found (*96 J 57*) that pulp consistency was an important factor in obtaining a proper bed on the table, and the best consistencies were 10 : 1 (by volume) for coarse feed, 12 or 15 : 1 for medium sands, and 15 or 18 : 1 for slime. Results of test work at Connecticut Zinc Corporation are given in Table 20. It is interesting to note

Table 20. Performance of Deister-Overstrom table at Connecticut Zinc Co., Oronogo, Mo.

Test number	Tons per 24 hr.	Feed		Concentrate		Tailing		Middling	
		Per cent. Zn	Per cent. Pb	Per cent. Zn	Per cent. Pb	Per cent. Zn	Per cent. Pb	Per cent. Zn	Per cent. Pb

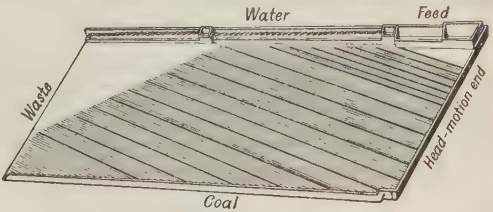
5	48	3.64	0.065	59.40	0.21	1.64	0	8.82	0.064

Notes—Test 1, Feed ranged from "very coarse" to slime. Test 2, Feed coarse. Test 3, Typical feed, mixed coarse and fine. −60-mesh material in feed assayed 5.64 per cent. Zn, tailing 2.46 per cent., concentrate 58.10 per cent. Lead concentrate in this test assayed 61.30 per cent. Pb, 9.29 per cent. Fe and 6.20 per cent. Zn. Adjustment difficult, concentrate streak wandered badly. Test 5, −60-mesh in feed assayed 5.10 per cent. Zn, in tailing 2.84 per cent. and in concentrate 60.60 per cent. Wash water, 6.25 gallons per min. Continuous shifting of concentrate streak, requiring much adjustment. Tonnage of middling return per 24 hr., 21; length of middling cut, 73 in.

in connection with the assays of the −60-mesh material that the fine size in the concentrate was considerably richer than the coarse while the reverse was true on a competing table, which, however, used but half the quantity of wash water and made a lower-grade tailing. The use of the relatively large amount of wash water to clean fine gangue out of the concentrate resulted in also sweeping fine blende into middling and tailing.

Deister-Overstrom coal-washing table is similar to the ore-concentrating table, but has an extra-large deck, 16 ft. 10 in. long by 8 ft. 4 in. wide, riffled as shown in Fig. 18. It treats screenings as coarse as −0.5-in. and as fine as −⅛-in. The deck is tilted longitudinally and is 2 to 2.5 in. higher at the waste end for coarse feeds, ⅞ in. for fine. The average transverse tilt is about ⅞-in. per ft. with coarse feed and ⅝-in. with fine. Capacity is claimed to be 8.5 to 10 tons of feed per hour with a water consumption of 1.8 tons per ton of feed. Speed, 245 to 260 @ 1- to 0.75-in. strokes per min. Power consumption, 1.5 hp. This table, a large-size Wilfley table (MASSCO) and a large-size Plat-O table, are being used to an increasing extent for washing the finer sizes in both anthracite and bituminous-coal washeries.



The high cleats (black) in the upper portion of the deck are ¾ in. deep, tapering to 0 in. The other high cleats are ⅝ in. at the head-motion end and taper to 0 in. All low cleats are carried ¼ in. until the plane of the upper surfaces intersects the plane of the tops of the ⅝-in. cleats, when all taper alike.

FIG. 18.—Riffling of Deister-Overstrom deck for coal washing.

Griffin (*26 CA 217*) gives Table 21 as representative of the capacity of the table on anthracite. The lesser figures in each case correspond to an operation in which maximum ash removal is attempted. In one breaker the capacity of a table on barley size was 50 to 60 tons per day (8 hr.) when producing cleaned coal containing 10 to 11 per cent. ash; when the feed rate was increased to 85 tons per day the ash content of the cleaned coal ran up to 12 to 14 per cent. Table 22 shows the performance of the table when treating dif-

Table 21. Capacity of Deister-Overstrom table on anthracite

Size of coal	Tons of feed per hour per table
No. 1 buckwheat	15–20
No. 2 buckwheat (rice)	12–18
No. 3 buckwheat (barley)	6–14
No. 4 buckwheat	4– 6
Slush	2– 5

ferent sizes of anthracite in the same breaker. At another breaker six tables treating No. 4 buckwheat produced 200 tons per day of cleaned coal containing 13 to 14 per cent. ash from a feed containing 25 to 30 per cent. ash. Another table treating two tons per hour of −3/64-in. +20-mesh (No. 4 buckwheat) containing 29 per cent. ash produced clean coal that averaged 9.5 per cent. ash for one month's operations. Treating anthracite at Hudson Coal Co. the tables have a capacity (*66 A 422*) of 10 to 12 tons per hr. on No. 1 buckwheat down to 3 to 4 tons an hour on slush (−3/64-in.) The tables are run at about 275 @ 3/4-in. strokes per min. Table 23 shows average results when treating de-slimed material passing 3/64-in. round-hole screens and sizing 88 per cent. on 60-mesh, 8 per cent. on 100-mesh, 3 per cent. on 200- and 1 per cent. −200-mesh. At one of the Madeira-hill breakers six tables treating rice and barley coal handled 400 tons per 8 hr., made a coal product containing 12.5 to 13 per cent. slate, and a slate product containing 9.25 per cent. coal. The respective calorific values were 12,663 and 3636 B.t.u. per lb. Water consumption was two tons per ton of coal. Ashmead estimates labor and power cost at $0.04 per ton with power at $0.015 per kw.hr. and labor at $0.50 per hr., and total cost at $0.10 per ton. At Granby Consolidated M. S. & P. Co. (*21 CA 368*) Deister-Overstrom tables treated 4 to 6 tons per hr. of −3/16-in. slack from jig-washed bituminous coal and 6 to 7 tons per hr. of washed-coal conveyor drainings. Performance is shown in Table 24. Table 25 shows the results of a number of tests on a quarter-size laboratory table treating Washington bituminous coal and coal-washery products (*Bul. 28 UW*). The tests on −3/8-in. raw coal are all unpromising. The tests on −3/16-in. raw-coal screenings are better, but whether because the table treats this size better or because the ash was more completely freed is not apparent. Probably both facts aided. Some of the tests on refuse showed some promise for the production of mine fuel, but not for salable coal. At the Renton Coal Co., Renton, Wash. (*19 CA 741*) five Deister-Overstrom coal-washing tables treating −3/16-in. reclaimed subbituminous sludge handled approximately 40 tons of feed per hour and reduced the ash from 28 or 30 per cent. to 16 or 18 per cent. with high recovery. Reduction to 10 per cent. is possible by putting more coal into the refuse.

Table 22. Performances of Deister-Overstrom table on different sizes of anthracite

Size of coal	Pea	No. 1 buckwheat	Rice	Barley
Feed rate, tons per hour	20.2	19.3	18.0	14.4
Clean coal produced, tons per hour	13.2	11.2	12.1	10.5
Ash in feed, per cent.	38.5*a*	43.3	35.8	33.5
Ash in cleaned coal, per cent.	5.7*a*	15.4	15.0	17.5

a Equivalent to 5.4 per cent. of feed.

Shaking tables will treat coal as coarse as $-\frac{3}{4}$-in. but performance is better on $-\frac{3}{16}$-in. or smaller. Anthracite feeds must, in general, be smaller than bituminous. For treating fine sizes, power and water consumption per ton treated are both markedly less than that of jigs.

Empire table is a rectangular-deck diagonally-riffled table with 4 × 10-ft. deck suspended by means of 3-ft. rods from an overhanging frame. The rods are inclined from the vertical as in the Ferraris screen and the head-motion is a simple eccentric. The stroke is exceptionally long, ranging from 2 to 5 in. and correspondingly slow, 135 to 160 per min. The long, slow stroke keeps the bed loose and gives high capacity. The long stroke and coarse feed cause tremendous wear on riffle cleats; Wiard (*112 J 417*) says that ordinary linoleum and soft-wood cleats last only one to two weeks in such service. Gross (*102 J 428*) states that the table has been operated to give high capacity on 0.5-in. feed; it will not handle slime (*107 J 453*). At St. Joseph Lead Co., Bonne Terre mill, a table making 168 @ 3.5-in. strokes per min. treated 65 tons per day of de-slimed − 10-mesh feed (6.5 per cent. on 14-mesh, 13.2 per cent. through 100-mesh) containing 50 per cent. water. Power consumption, 0.5 hp.; wash water, 10.5 gal. per min. Assays; per cent. Pb: Feed, 8.0; tailing, 0.4; concentrate, 78.0; middling, 9.0. Gross also describes the treatment of 30-mesh gold-silver ore at the rate of 37 tons per 24 hr. on a 4 × 10-ft. deck making 135 @ 5-in. strokes per min. Power consumption, 0.5 hp.; wash water, 10 gal. per min. Assays: Feed, 0.2 oz. Au, 8.4 oz. Ag; tailing 0.03 oz. Au, 1.9 oz. Ag; concentrate, 0.54 oz. Au, 21.4 oz. Ag.

9. Garfield table

This is essentially a Wilfley table with riffles carried straight across from head-motion to concentrate end over the full surface of the table. It is used exclusively for roughing service.

Construction. When specially built and not merely a Wilfley table with modified riffling, the deck is made rectangular, 4 ft. × 12 ft., and the head-motion, although of the same type as the Wilfley, is heavier in order to handle the heavier pulp loads. The table is frequently double-decked, the additional deck carried about 8 in. above the regular deck on heavy cast-iron stanchions attached to the lower deck. Head-motion for double-deck tables is twice the size and several times heavier and more rugged than the Wilfley motion. The riffles are deeper and wider than the Wilfley. At Utah Copper Co. (*112 J 415*) riffle cleats were 1.5 in. face to face, $\frac{3}{4}$ in. deep at the head end tapering to $\frac{1}{8}$ in. at the line corresponding to the Wilfley diagonal, and extended thence to the concentrate side at uniform depth. The bottom face of the riffle cleats is beveled to allow the side faces to stand vertically at the steep inclination of the table. Riffle cleats are usually hardwood, maple or oak. Linoleum is the commonest deck covering but wears rapidly and in some mills cast-iron plates with riffles cast on are let in near the feed corner to take the excessive wear at this point.

Test 1, 129 tons per 24 hr. Test 2, 91 tons per 24 hr. Test 3, 65 tons per 24 hr.

of tonnage on performance. This test shows maximum recovery of grains between 0.15- and 0.2-mm. at all tonnages with a sharp drop in recovery in the sizes below 0.15-mm. Low recovery in the coarser sizes is apparently due to included grains. The efficiencies of the respective concentrating operations, based on copper contained in free mineral, were 73.3 per cent., 79.5 per cent. and 82.8 per cent. By increasing speed and length of stroke, CHINO raised capacity to 200 tons per deck without marked loss in recovery as compared with RAY results. Since tailing is to be re-ground in any case, such overcrowding of the table would seem justifiable. SIDE TILT in roughing is usually held constant and variations in feed conditions are taken care of by varying the WASH WATER. Consumption of wash water ranges from 3.5 to 12 gal. per min. Dirty water is usually used. POWER CONSUMPTION is slightly higher than for the Wilfley table on account of the heavier bed of solids on the table; power consumed by double-deck tables is 25 to 33 per cent. in excess of that for single deck.

10. Overstrom Universal table

This is a one-plane table, roughly rectangular in plan, about 18 ft. 6 in. by 5 or 6 ft., with diagonal riffling. The deck is supported on leaf springs of hickory set so that the long transverse axes center at a point on the center line of the head-motion shaft extended beyond the feed side, thus giving the deck a horizontal twisting motion. These springs are inclined backward slightly, as in Ferraris and Buss tables. The riffle cleats, however, are curved in such a manner that they are substantially tangent at any given point to the motion of the deck at that point.

Head-motion. Differential reciprocating motion is obtained by mounting an eccentrically-loaded pulley loosely on a shaft carried on extended deck sills. Motion resulting from revolution of the pulley is constrained to the horizontal by gravity and the spring supports; horizontal movement is stopped by a bumper at the forward end of the stroke and controlled by a spring on the back stroke. Length of stroke is controlled by a canvas pad of variable thickness inserted between a bumping strut on the deck frame and the bumping post. Sharpness is controlled to some extent by varying the spring tension. SIDE TILT is adjusted by a screw-controlled multiple wedge under the feed side. POWER CONSUMPTION varies between about 0.25 hp. light and 0.75 hp. loaded, average is about 0.5 hp. CAPACITY is claimed to range from 20 to 300 tons per 24 hr. according to the character of feed and kind of service.

Performance. Results of a test at NEVADA CONSOLIDATED COPPER CO. are given in Table 28 and of another at RAY CONSOLIDATED COPPER CO. in Table 29. At the latter

Table 30. Performance of Overstrom Universal table on classified feed at Arthur plant, U. C. Co. (1917)

Legend	Spigot number					
	1	2	3	4	5	Average
Average tons per day	21	22	17	18	34	22
Feed, per cent. Cu	1.00	1.20	0.99	1.29	1.28	1.17
Feed, per cent. Fe	2.46	2.06	1.88	1.86	1.39	1.87
Tailing, per cent. Cu	0.35	0.34	0.30	0.28	0.25	0.30
Middling, tons	3	3	4	4	6	4
Middling, per cent. Cu	0.84	1.12	2.00	0.73	0.70	1.08
Concentrate, per cent. Cu	14.63	13.02	17.30	25.38	24.47	18.96
Concentrate, per cent. Fe	29.39	24.39	26.97	24.18	21.66	25.32
Concentrate, per cent. insoluble	15.80	27.76	18.72	15.29	22.22	19.96
Ratio of concentration	21.87	14.78	24.85	24.90	23.40	21.43
Recovery, per cent	66.83	73.54	70.54	79.15	81.56	75.70

12.57 per cent. Cu, 22.5 per cent. Fe and 39.9 per cent. insoluble; and tailing assaying 0.57 per cent. Cu and 0.65 per cent. respectively, representing recoveries of 56.8 and 54 per cent. At Detroit Copper Co. (Phelps-Dodge, Morenci), treating de-slimed sand (0.2 per cent. on 8-mesh, 5.69 per cent. through 65-mesh) at an average rate of 70 tons per 24 hr. the table made concentrate assaying 9.06 per cent. Cu, 23.9 per cent. insoluble and tailing carrying 0.51 per cent. Cu from feed assaying 1.02 per cent. Cu. On finer sand (0.14 per cent on 20-mesh, 13.1 per cent. through 100-mesh) average tonnage per 24 hr. was 47; average assays: Feed, 0.87 per cent. Cu; middling 0.74 per cent.; tailing, 0.41 per cent.; concentrate, 11.6 per cent. Cu, 27.2 per cent. insoluble. At Old Dominion Copper Co., treating flotation tailing at an average rate of 39 tons per 24 hr. in a pulp containing 20 per cent. solids, assays were as follows: Feed, 0.35 per cent. Cu; tailing, 0.32 per cent.; middling, 0.43 per cent.; concentrate, 4.65 per cent. Cu; 23.2 per cent. insoluble. This table was operated at 265 @ 11⁄16-in. strokes per min. and used 3.8 gal. wash water per min.

11. Plat-O table

This is a substantially rectangular diagonally-riffled table with deck about 14 ft. long by 6 ft. wide at the head-motion end and 5 ft. wide at the concentrate end. The deck is in two planes joined by a sloping surface along the separating diagonal, the higher plane being at the concentrate end. For some conditions three planes or plateaus are used (Fig. 19). The methods of riffling are various, according to the character of the feed, but in general the riffle cleats are wide with relatively narrow spaces. They are carried at full depth from

the head-motion end to the plateau, and taper in riffle depth is obtained by the rise in deck surface at this point. On the concentrate side of the rise in deck surface riffle cleats are omitted on slime and fine-sand tables, wafer cleats are carried to the end of the coarse-sand table and higher cleats on the roughing table. When the concentrate plateau is unriffled the upper surface

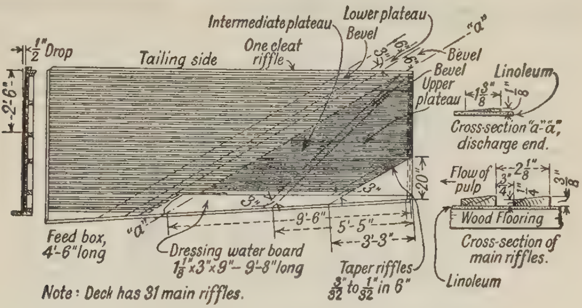

FIG. 19.—Plateaus and riffling on a Plat-O table.

of the riffle cleats and the surface of the plateau are in the same plane. This gives the effect of a one-plane table with shallow grooved riffles widely spaced. The amount of rise at the plateau and the slope vary; a typical figure is $\frac{3}{8}$-in. rise in 12 in. measured along the line of the riffles. Linoleum is the usual deck covering, but rubber may be supplied on roughing tables treating coarse feed at high tonnage rates. The head-motion is the same as illustrated in Fig. 20 and is carried in a covered tank-like housing that allows it to be run nearly submerged in oil and completely protected from splash and grit. The deck is supported on self-oiling dust- and grit-proof slipper bearings and is tilted by means of an adjustable multiple wedge under the feed-side slippers. A special table for coal washing is rectangular, 7 ft. wide by 14 ft. long. The manufacturer recommends 290 @ $1\frac{1}{16}$- to $1\frac{3}{16}$-in. strokes per min. for slime treatment, 290 @ $\frac{3}{4}$- to $1\frac{3}{16}$-in. for fine sand, 275 @ $\frac{7}{8}$- to 1-in. for roughing 8-mesh feed, 240 @ $1\frac{1}{8}$- to $1\frac{1}{4}$-in. for roughing $\frac{1}{4}$-in. feed, and 285 @ $\frac{7}{8}$-in. for $-\frac{3}{4}$-in. coal.

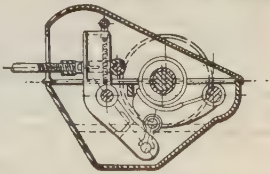

FIG. 20.—Head motion for Plat-O table.

Performance. Copper. COPPER RANGE CONSOLIDATED treats 15 tons per 24 hr. of −35-mesh feed assaying 0.5 per cent. Cu and containing 80 per cent. moisture. Concentrate assays 45 per cent. and tailing 0.22 per cent. The table is a standard Wilfley with plateau and Plat-O riffling, linoleum deck cover and pine riffle cleats. Speed 245 @ $\frac{3}{4}$- to $\frac{7}{8}$-in. strokes; water, 5.6 gal. per min.; 0.3 hp. One man attends 106 machines. At RAY CONSOLIDATED COPPER CO. a Plat-O rougher treating −5-mm. primary feed gave results shown in Table 31. Judgment of this result from the viewpoint of mill economics requires consideration of the relative value of table and flotation concentrate (the latter obtained by treatment of re-ground table tailing), which is out of place here. The tabulation shows a consistent decrease in recovery and relative decrease in tonnage of concentrate with increase in feed tonnage. Grade of tailing is dependent rather on tonnage than on grade of feed while grade of concentrate is rather dependent on grade of feed and independent of tonnage treated. At the BURRO MOUNTAIN concentrator of Phelps Dodge Co. a Plat-O table treated flotation tailing de-slimed in Allen cones at the rate of 39 tons per 24 hr. in a pulp containing 22 per cent. solids. Feed assayed 0.667 per cent. total Cu, 0.150 oxide; concentrate, 11.28

per cent. total Cu, 35 per cent. insoluble; tailing, 0.446 per cent. total Cu, 0.143 per cent. oxide. Recovery was 34.5 per cent. based on total Cu and approximately 42 per cent., based on sulphide. At the same plant a roughing table treated 147 tons per 24 hr. of 14-mesh feed in a pulp containing 45 per cent. solids. Feed assayed 2.136 per cent. total Cu, 0.261 per cent. oxide; concentrate, 14.658 per cent. Cu, 15.86 per cent. insoluble; tailing, 1.200 per cent. total Cu, 0.228 per cent. oxide. Recovery of total Cu was 47.8 per cent.,

Table 31. Performance of Plat-O rougher at Ray Consolidated Copper Co.

Tons of feed per 24 hr.	Assays, per cent. Cu			Recovery, per cent.	Ratio of concentration
	Feed	Concentrate	Tailing		
137	1.39	14.4	0.82	43.5	23.8
190	1.16	13.9	0.78	34.7	34.5
210	1.17	12.7	0.82	32.0	34.0
214	1.26	12.8	0.89	31.5	32.2
243	1.25	12.7	0.90	30.2	33.7
287	1.29	13.9	0.93	29.9	36.1
312	1.29	13.6	0.96	27.5	38.3

sulphide about 52 per cent. At the Bisbee test mill of Phelps Dodge Co., a Plat-O table treating flotation tailing (70 per cent. through 200-mesh) in a pulp containing 22 per cent. solids handled 53 tons per 24 hr. Feed assayed 0.26 per cent. total Cu, 0.05 per cent. oxide; concentrate, 5.80 per cent. total Cu, 27.2 per cent. Fe and 36.8 per cent. insoluble; tailing, 0.19 per cent. total Cu, 0.05 per cent. oxide. This represents a recovery of 27.8 per cent. of total copper and 34.1 per cent. sulphide. At the Morenci plant of Phelps Dodge a single-deck linoleum-covered table with maple riffles, running at 280 @ ¾-in. strokes per min., treated 60 tons per 24 hr. of flotation tailing assaying 0.45 per cent. Cu and made tailing assaying 0.38 per cent. and 11-per cent. concentrate. The table consumed 0.5 hp. One man attended 23 tables. At Old Dominion Copper Co. a Plat-O slime table treating flotation tailing at the rate of 41 tons per 24 hr. in a pulp containing 20 per cent. water made concentrate assaying 3.56 per cent. Cu and 32.2 per cent. insoluble and tailing assaying 0.33 per cent. Cu from feed containing 0.38 per cent. Cu. The table was run at 283 @ ¾-in. strokes per min. and used 4.8 gal. wash water per min. Results of eight weekly test periods at Anaconda roughing 8-mesh feed are given in Table 32. Increasing speed in this test and placing cap riffles on top of the main riffles cut down the grade of tailing while increase

5	22	3.45	0.065	57.40	0.32	1.23	0.010	2.94	0.020

Notes—Test 1, Feed varied from very coarse to fine slime. Test 2, Feed very coarse. Test 3, Feed coarse and fine, typical −60-mesh material in feed assayed 5.42 per cent. Zn; in tailing, 2.07 per cent. and in concentrate, 58 per cent. Lead concentrate in this test assayed 64.50 per cent. Pb, 5.60 per cent. Fe and 9.40 per cent. Zn. Test 5, −60-mesh material in feed assayed 5.23 per cent. Zn, in tailing 2.77 per cent. and in concentrate 55.50. Wash water 3.25 gallons per minute. Tonnage of middling return, 12.5 per 24 hr.; length of middling discharge 42 in.

plateau with thin riffle cleats extended to the concentrate-discharge end. Commenting on the test work the company metallurgist stated that the table was very stable in operation, handling fine material as well as coarse at a given setting and requiring but little attention; that the enclosed head motion was a great advantage and that oil consumption was much lower than with an exposed head motion. Robie makes similar comment (*116 J 403*) on the Plat-O rougher at the NORTHERN ORE Co., and Mette (*109 J 1314*) in writing of the NEW CORNELIA test mill. He ascribes stability to height of rise to plateau, noting greater stability with ⅜-in. rise than with ¼-in. Stability is an important item in the choice of tables in that it lessens the necessary attendance and thereby lowers the labor charge against table operation.

Coal. The manufacturer states the capacity of the coal-washing table to be 5 to 8 tons per hr. on feed through ¼-in. screen, 7 to 10 tons with ⅜-in. screen, 10 to 12 tons with ½-in., 12 to 14 tons with ⅝-in. and 14 to 16 tons with ¾-in. and claims removal of 90 per cent. of the free refuse.

12. Rotary shaking table

Many forms have been proposed but none has made its way into the mills. The PINDER CONCENTRATOR is one of the soundest attempts. It is substantially a side-inclined end-shake diagonally-riffled table curled around a vertical axis. A plan of the deck is shown in Fig. 21. The deck is supported on extended ball-and-socket bearings spaced around the periphery and is shaken with a differential reciprocating motion around the central axis by means of a typical toggle head-motion with drawbar attached to the deck periphery. Lost motion is controlled by a spring. The deck is adjustably concave, 10 to 12 ft. diameter. Speed and stroke length are the same as for rectangular tables. Feed pulp is introduced at (*a*) and is distributed by feed box (*b*) along the upper side of the full-riffled section, *viz.:* about 10 ft. In the riffles stratification takes place in the usual fashion, due to the shaking action. Gangue is carried down slope to the tailing discharge at the center by cross-wash water fed around the periphery. Centrifugal force is claimed to be effective to throw the

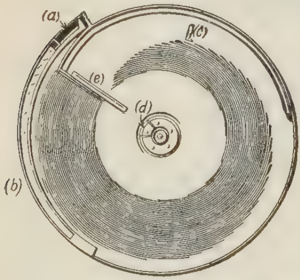

FIG. 21.—Pinder circular-deck shaking table.

heavier particles of concentrate further toward the upper side than they normally appear on a diagonally-riffled table. Concentrate is cut out through an opening in the deck at (c). Middling travels to the end of the longer riffles where it is washed down to pen (d) by spray water from pipe (e).

13. Campbell bumping table

This table (Fig. 22) is used in bituminous-coal washeries to separate coal and the heavier impurities. It consists of a suspended movable trough or deck about 2½ to 3 ft. wide by 9 to 11 ft. long, sloped from a minimum of 7° at the lower end to a maximum of about 12° at the upper end. The bottom of the trough is transversely riffled. The deck is shaken about 75 times per min. by an eccentric, the length of stroke being about 5 in. for coarse coal (−3¾ + 1¾-in.), 2½ in. for medium (−1¾ + ⅜-in.) and 1¼ in. for fine coal (−⅜-in.). A bumping block (b) causes the backward stroke to end suddenly, thus impelling material on the deck to travel toward the back (upper end). Feed is introduced at (c) and wash water at (d). Slate works up slope against the flow of water and discharges at (e) while coal is washed over the lower end into trough (f).

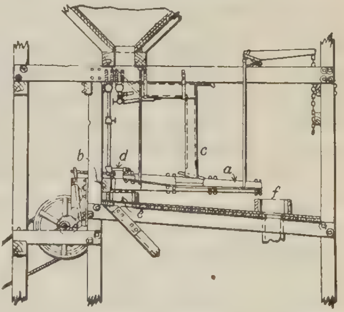

Fig. 22.—Campbell bumping table.

At one Illinois washery (*11 Bul. UI No. 9*) seven tables treated 40 tons per hr., roughly sized as above. Capacity of 3 × 11-ft. tables at Cambria Steel Co. (*23 CA 289*) is 5.75 net tons of raw coal per hr. with a water consumption of about 2200 gal. per hr. One 15-hp. motor drives 12 tables and 12 screw feeders. Performance at this plant is shown in five sets of typical analyses in Table 35.

Table 35. Performance of Campbell bumping table at Cambria Steel Co.

Run number	Raw coal, per cent.			Washed coal, per cent.			Refuse, per cent.			Recovery of combustible, per cent.	Reduction, per cent.

14. Operation of shaking tables

Applicability. A separation can be made on shaking tables between any two minerals or substances that differ in specific gravity to an appreciable extent, but unless the difference is greater than 1.0, separation by reason of specific gravity alone will be relatively crude and imperfect. Completeness and ease of separation increase with difference in specific gravity; a difference of 3 or 4 is sufficient for rapid treatment and substantially complete recovery. When there is a decided difference in shape of particles as, for instance, exists in the case of coal and slate, the heavier particles in this

case being tabular while the light are rounded, separation is aided thereby and can be successfully performed even though the difference in specific gravities does not greatly exceed 1.0. Particles of the same specific gravity but of different sizes, all very fine, can be separated to a certain extent, thus removing accidental grit from finely-ground abrasives or washing small quantities of slime from granular products.

Size of feed. It is essential that particles settle to the table deck in order to be collected as concentrate, hence the lower size limit is determined by the velocity of the cross water and by the movement of the table. The necessary water velocity depends on the size of the particles that are to be washed down the slope. No established mathematical relation exists between the smallest size of concentrate particle and largest size of tailing particle that can be treated together. It depends, of course, on the relative specific gravities and shapes of particles, the nature of the table surface, character of feed and other more or less indefinite factors.

Wiggin determined that chalcoyprite smaller than 0.025-mm. could not be economically treated on the shaking tables at ANACONDA. Bland found that in treating tungsten slime, 40 per cent. of the concentrate would pass a 0.0125-mm. screen when feeding pulp containing 29 per cent. solids at 2.4 tons per 24 hr. while all of this material was lost when a pulp containing 8 per cent. solids was treated at 4.8 tons per 24 hr. (Table 18.) Beringer (*24 IMM 411*) investigated the effect of shake on the settling rate of cassiterite by fastening to a Buss table 2-oz. phials containing cassiterite grains of various sizes suspended in water and noting the time required for the grains to settle. With the table making 270 @ ¾-in. strokes per min. 0.045-mm. particles settled in 60 sec., 0.035-mm. in 90 sec., 0.030-mm. in 120 sec., and 0.025-mm. in 150 sec. Corresponding sizes with the tables at rest were 0.025-, 0.020-, 0.015- and 0.010-mm. The average minimum size of grain in Buss-table concentrate was 0.05-mm. Johnson and Heinz (*107 J 558*) report sizing tests on blende tailing in the JOPLIN DISTRICT, showing 2.7 per cent. zinc in the sand between 0.833- and 0.295-mm., 2.2 per cent. in that between 0.295- and 0.147-mm. and 9.4 per cent. in the material passing a 0.147-mm. screen. Similar results reported by Wright (*TP 41 USBM*) are given in Table 36. As a general rule governing this subject, it may be stated

Table 36. Sizing-assay test on Joplin table tailing.

Screen aperture	Weight, per cent.	Assay, per cent. Zn	Total zinc, per cent.
On ⅜-in.	15.22	0.77	12.25
3-mm.	47.56	0.96	47.61
1.5-mm.	23.96	0.76	18.95
0.46-mm.	10.41	0.71	7.68
Through 0.46-mm.	2.84	4.55	13.51
Totals	99.99	0.96	100.00

that the granular or sandy portion of material passing a 200-mesh (0.074-mm.) screen is readily settled to a shaking-table deck and moved along by the table motion and that good recoveries can be made on such material if the accompanying gangue is not so coarse as to require excessive wash water or excessive tilt to remove it. Watt (*57 A 371*) states that reciprocating (shaking) slime tables do excellent work saving galena coarser than 300-mesh and make good recovery of finer galena. In a test on a feed in which 94 per cent. of the lead passed a 200-mesh screen the concentrate assayed 76 per cent. lead and represented a recovery of 65 per cent.; 89 per cent. of the lead in the concentrate would pass 200-mesh; 98.5 per cent. of the lead in the tailing would pass 300-mesh. Caetani (3 *MM 50*) concluded from testing work at BUNKER HILL AND SULLIVAN that on such material reciprocating tables will do better work than vanners.

The upper size limit is just as indefinite as the lower. On tables that pass concentrate across a smooth cleaning plane it is practically impossible to make clean concentrate and finished tailing when the particles are larger than 2-mm., and difficult when they are larger than 1-mm. Full-riffled roughing tables will treat unsized material passing a ⅜-in. aper-

Table 37. Performance of Wilfley table on "natural," sized and classified feeds

a Proportioned to full-size table on basis of comparative area of small table and tonnage treated thereon.

ture and deliver a small band of clean coarse concentrate along the upper riffles and a considerably impoverished tailing between the forward edge of the slime streak and the corner of the table deck. The Empire table is reported to have made clean concentrate on ½-in. base-metal ore, and coal this size can be treated on any of the shaking tables, if properly riffled, but both of these operations are of roughing character. In the great majority of plants treating base-metal ores, roughing-table feed has passed a 2- or 2.5-mm. screen.

Preparation of feed for shaking tables. There has been much discussion on this point and the general opinion at present probably is that classified feed is best, "natural" feed is poorest and sized feed occupies an intermediate position. This conclusion is based upon Richards' interpretation of the data presented in Table 37 (*38 A 556*), which shows the results of a series of runs with a laboratory Wilfley table on an artificial mixture of quartz and galena, prepared variously, as indicated, for table treatment. (A similar series with cupriferous pyrite and quartz gave similar results.) Professor Richards' conclusion was as follows:

> "While the sized-product feed appears to have done better work than the classifier-product feed, if we give full weight to the great performance of Run No. 12, we can agree that this has fully off-set the slight falling-off of runs Nos. 13 to 17, and that the classifier-feed work is fully up to the sized-feed work on the Wilfley table, and with a perfect classifier the work will be better done than with screens."

But if Run No. 12 is properly weighted with the other classified-feed runs and compared with the sized-feed runs similarly weighted, it appears that the average assay of tailing from classified feed is 0.43 per cent. PbS and that from sized feed 0.19 per cent.; that the respective percentages of middling are 13.6 and 15.4, and that the grades of concentrate are substantially the same. It would appear, therefore, on the face of these tests, that preparation of a given lot of finely crushed material by sizing would result in more efficient table treatment of the products than preparation by hydraulic classification. This conclusion has been reached by other experimenters from data similar to Richards; one of these (Bland, *107 J 1112*) even going so far as to advocate dry grinding in order to effect the careful sizing necessary. Hancock (*24 MM 87*) citing Cox, Porter and Gibbon (*14 CMI 490*) says that treatment of a "natural" feed yielded 64.4 per cent. recovery, the mean recovery on the same ore sized into six lots and separately treated was 63.9 and on classified feed was 66.7 per cent. Ellis (*7 MMt 156*) compared the treatment of de-slimed natural feed, classified feed and sized feed, prepared from Coeur d'Alene ore. The results are shown in Table 38. They would justify very little expense for any preparation other than de-sliming.

Table 38. Comparison of classified, sized and natural feeds for shaking tables. (*After Ellis*)

Recovery	95.1	92.7	94.6	90.9	93.4	90.8

As a practical matter in the mills, classification is superior to sizing as a means of preparation because close fine sizing, as was practiced in Richards' tests, cannot be done in the mills as cheaply as classification; cannot, in fact, be done economically at all. Hence most practice has followed Richards' conclusion.

In Richards' tests while slimes are charged against the runs on natural feed, they do not appear, although, of course, present, as charges against the other runs. Supplementary treatment of these products is contemplated in all cases.

Since Richards' work was done, the growth of roughing-table practice has brought treatment of natural feeds on shaking tables into prominence again. Elaborate test work at Miami and Inspiration in 1912 and 1913 showed that careful treatment of natural feed on roughing tables with subsequent enrichment of the rough concentrate after classification yielded better metallurgical results and would probably yield better economic results, than most careful and elaborate preparation of the whole feed by classification prior to tabling. With ores adapted to concentration by flotation, there can be no doubt that classification of the original table feed is wholly unnecessary from a metallurgical standpoint and is uneconomic. Limiting the upper size of roughing-table feed by means of a screen or a mechanical classifier is all that is necessary.

Capacity of full-riffled tables such as the Garfield, Butchart, Deister No. 2, and Plat-O in roughing service is 100 to 200 tons per 24 hr. on feed through 2- or 2.5-mm. screens. It may be pushed to 300 tons with a feed as coarse as 4-mm. maximum, but at considerable sacrifice of recovery. Cleaning rough concentrate from full-riffled tables, practically any of the usual sand tables (Butchart, Card, Deister, Deister-Overstrom, Plat-O) will treat from 40 to 75 tons per 24 hr. When feed is coarse, riffles extended to the concentrate-discharge end will aid in keeping up capacity. Treating classified or de-slimed feed and making both clean concentrate and tailing, capacities range from about 10 tons per 24 hr. on 0.5-mm. material to 40 to 45 tons on 1.5- to 2-mm. feed. In general, the capacity on lead ores will be higher than on copper or zinc. These same tonnages will apply to recovery of auriferous pyrite from quartz sands, but this is essentially roughing service, as re-treatment of tailing by cyanidation is always contemplated and frequently the concentrate is also cyanided. Slime tables in finishing service treat from 3 to 6 tons each per 24 hr.; roughing auriferous pyrite from quartz the capacity rises to from 10 to 15 tons, and treating flotation tailing (also essentially roughing service) from 30 to 60 tons per 24 hr. per deck is handled in some mills. Results of tests on Joplin zinc ores *(57 A 456)* are shown in Table 39.

Table 39. Effect of size of feed on capacity, recovery and grade of concentrate, Joplin ore

Table number	Size of feed			Assays, per cent. Zn			Recovery, per cent.	Operating data	
	All pass, . . mm.	Per cent. on following screen	Per cent. through 0.074-mm.	Feed	Concentrate	Tailing		Speed, revolutions per minute	Length of stroke, inches
1	2.36	0.40	2.48	4.83	58.2	0.88	83.1	239	1
2	0.59	36.55	2.08	4.70	61.8	0.66	86.9	242	1·
3	0.59	15.73	3.96	5.0	58.78	0.78	85.8	242	1⅛
4	0.59	4.21	5.98	4.78	53.92	0.57	89.0	243	⅞
5	0.59	1.0	8.30	5.0	58.0	1.03	80.8	245	1
6	0.29	5.04	17.02	5.22	54.05	1.50	73.3	245	¾
7	0.59	0.16	13.18	5.01	55.44	1.16	78.5	270	9/16
8	0.59	0.45	14.75	5.07	45.16	1.37	75.0	270	9/16
9	0.59	1.04	8.71	5.17	49.6	1.66	70.2	274	⅝
10	0.29	0.70	26.29	5.55	50.82	1.90	68.3	276	¾

Note—In all cases but No. 9 the tailing was noticeably coarser than the feed. In 1, 5, 8, 9, 10, more than 30 per cent. of the total zinc loss was in −200-mesh material. Feeds were successive spigot products and final overflow of a series of 9 hydraulic spitzkasten. Tonnage per table ranged from about 20 per 24 hr. on table 1 to 2 tons per 24 hr. on Table 10.

Speed and stroke are properly related, a low speed and long stroke being suitable for coarse feeds and the reverse for fine, but in the examples cited

in the preceding pages, which comprise a fairly representative cross-section from practice, this relation is decidedly obscure. On the other hand Wright (*TP 41 USBM*) gives results shown in Table 40 to illustrate the effect of wrong *vs.* right stroke-length and speed. The average in roughing service is: Garfield, 256 @ 1-in. strokes per min.; Butchart, 261 @ ⅞-in.; in sand-

Table 40. Tests on effect of speed and stroke-length on zinc ores

Test number	Revolutions per minute	Stroke, inches	Feed, per cent. Zn	Tailing, per cent. Zn
1	220	¾	9.25	0.9
	175	1¼	9.25	3.05
2	244	⅞	7.75	1.25
	224	½	7.75	3.20

finishing service: Butchart, 274 @ ⅞-in.; Wilfley, sands coarser than 1-mm. maximum, 255 @ ⅞-in.; sands finer than 1-mm. maximum, 249 @ ¾-in.: in slime service (Deister slimer only included), 273 @ ½-in. Wright gives practice in Joplin district as follows: Coarse feed (1.5- to 2-mm. maximum), 220 to 240 @ ¾-in. to ⅞-in. strokes; medium sands, 240 to 260 @ ⅝- to ¾-in.; fines, 250 to 280 @ ½- to ⅝-in.; ungraded feed through 1.5- or 2-mm. screen, 230 to 250 @ ¾- to ⅞-in., depending on rate of feed. He states that if stroke length or speed is too low, galena packs in the riffles at the head-motion end of the tables and gradually works down into the tailing. Study of details in the various examples of operation will, however, show that variations from the averages are in all cases so great as to throw individuals of any one class into another class. The stroke for slime tables must be much sharper than for sand on account of the greater relative tendency for fine particles, once in contact with the deck surface, to stick. Stroke should, therefore, be correspondingly short in order to prevent agitation of the mass of pulp on the table, thereby preventing settlement.

Water consumption in roughing service ranges from about 50 to 350 gal. per ton treated; in finishing service on sands it is usually between 300 and 400 gal. per ton, on slimes from 600 to 3000. Water and transverse slope are interdependent and both are dependent on the size of feed. The requirements are that solids shall settle in the riffles, that the pulp shall be sufficiently fluid to allow stratification, that there shall be sufficient velocity of cross flow to carry off the upper strata as the riffle support is withdrawn and that there shall be sufficient agitation in the riffles to keep fine gangue from settling as readily or as far as the fine mineral. Granular pulps containing 25 per cent. solids and slime pulps containing as high as 30 per cent. are sufficiently fluid to allow stratification and are sufficiently lively in the riffles, hence feed pulps may be of these consistencies. Wash water must be supplied in sufficient quantity to form a freely moving film on the deck deep enough to cover the largest particles. Beyond this point transport of material may be gained either by increasing volume at the same slope or increasing velocity by increasing slope. To increase transporting power by increasing slope is economical of water, but it narrows the bands of the various products at the concentrate end and makes accurate splitting difficult. This is allowable in roughing practice, which employs steep slope and minimum water, but when clean products are desired, as in finishing practice, more water is used. Water consumption in slime treatment is exceptionally high on account of the fact

that the tonnage of slime per table is low, a certain minimum amount of water is necessary to keep a uniformly moving film flowing and finally fine particles adhere tenaciously to smooth deck surfaces and require prolonged washing to remove them.

Power consumed averages close to 0.6 hp. per single-deck table and that installed between 0.75 and 1 hp., except that the Garfield table under heavy loads consumes close to 1 hp. Double-deck tables require from 50 to 75 per cent. more power than single-deck.

Attendance averages about 30 tables per man in finishing service and 50 in roughing service but as many as 135 tables per man in finishing service are reported from one mill (Calumet & Hecla) and 106 at another. The number of tables that one man can run depends, of course, on the difficulty of the job. The most difficult service is making finished tailing and concentrate on sand tables with fluctuating feed. The operator in such service must continually change transverse tilt, wash water and (if possible) the position of the product splitters. In roughing service with full-riffled tables the tilt may be fixed, if the feed supply is steady, wash water is rarely changed, and control is effected almost entirely by shifting the product splitters. In this case one man can attend almost any number of tables, the practical limit being the number that he can keep properly lubricated and running.

Lost time practically never exceeds 1 per cent. of possible running time. The principal cause is renewal of riffling and deck covering. In heavy roughing service soft-wood riffle cleats may last only one or two weeks and linoleum the same number of months but lost time is cut down by use of hardwood or metal-protected riffles and rubber or concrete decks or metal plates inserted near the feed box, at the point of greatest wear. In ordinary service soft-wood riffle cleats will last from six months to a year or upward and a linoleum deck for two to four years. If head motions are of proper size and protected from grit they will last almost indefinitely with occasional re-babbiting of bearings and replacement of renewable wearing parts.

Riffling. The principles underlying correct riffling are as follows: Riffles must be deep enough at the head end to hold all of the solid particles in the feed that can settle out of suspension in the cross flow of feed water, in order to give opportunity for stratification of this material. They must decrease gradually in depth toward the concentrate-discharge end to permit gradual shearing off of the impoverished upper layers by the cross flow of wash water. If the surface is unriffled at the concentrate end the termination of the riffles should lie along a diagonal line extending from near the corner formed by the tailing side and concentrate end to a point on the feed side one-fourth to one-half the distance toward the concentrate end. Such diagonal termination of the riffles results in catching and moving toward the concentrate end such particles of concentrate as are unable to withstand the full flow of wash water on the unriffled surface. If the feed to such a table contains coarse grains of free mineral that tend to go into the middling, extension of occasional thin riffle cleats to the concentrate end, particularly near the feed side of the deck will result in removal of these particles without holding back much fine gangue. Wright (*100 J 642*) recommends termination of riffles along a curve convex to the concentrate side instead of along the usual straight diagonal, in order to hold concentrate higher on the deck and to spread the concentrate band wider and thus make the cut between concentrate and middling sharper. Garber (*111 J 788*) recommends carrying broken extensions of the regular riffling to a second advanced diagonal for the treatment of complex ores. If

the lower end of the diagonal is brought to the concentrate end 2 to 4 in. above the lower corner, the concentrate-middling split can be made on the end of the table where the waggle of the discharging stream is parallel to the cutting edge, with corresponding increase in sharpness of cut as compared with corner cutting. If the middling streak is narrow the middling-tailing cut can also be made on this end. Such riffling, however, requires that the transverse tilt be less and more wash water must, therefore, be used. If the concentrate end is cut back diagonally to the feed side, say 6 in. in the width of the deck, the same end is served without the necessity of flattening the table when running and, in addition, the concentrate end is kept wet by wash water supplied at the feed side. When high tonnages or coarse feed are treated, shallow riffles should be extended from the separating diagonal to the concentrate end for the full width of the deck in order to hold up concentrate with the steep slope necessary to carry off the tailing. This will result in somewhat lower-grade concentrate than otherwise, but increases recovery. The WIDTH OF RIFFLES is determined in part by the size of the largest grains of feed and in part by the demand as to grade of tailing, other conditions remaining the same. Width must be sufficient to prevent jamming of coarse particles with consequent clogging of a riffle and this means that it should be more than three times the diameter of the largest grain. Agitation due to swirling is a maximum in narrow deep riffles, hence these will result in clean concentrate, but at the expense of higher-grade tailing. Steep-sided riffles produce more agitation than those with slanting sides. Hence riffles for slimes should be shallow, relatively widely spaced and have slanting sides. Richards calls attention to the fact that riffle cleats fastened onto a plane surface cause the plane of the roughing surface and that of the cleaning surface to intersect at an angle along the diagonal of riffle termination, thus forming a valley in which the grains pile up and hinder separation. He recommends grooving the riffles into a plane surface to overcome this effect and this has been done in some tables (Card) and its equivalent has been effected in the plateau arrangement of the Deister-sand and Plat-O tables.

Cost of tabling. HOLLINGER (*51 A 124*) 5¢ per ton of feed; ALASKA GASTINEAU (1917) two treatments on Garfield tables plus two on Wilfleys, total $0.051 per ton of feed; at GOLDFIELD CONSOLIDATED (*89 J 1230*), $0.054 per ton. The principal element of cost is labor and where, as in a flotation mill, table attendance can be made part of the flotation operators' duties, the cost of tabling is substantially negligible.

SECTION 11

VANNERS

1. Principles of vanner concentration

Vanners are concentrating machines adapted to the treatment of fine sands. They consist essentially of an endless belt with upper surface horizontal transversely and inclined longitudinally, all carried on a frame that oscillates in the plane of the belt. The belt is usually made of rubber and the upper surface travels slowly uphill. Feed is introduced about one-quarter of the distance from upper to lower pulley, heavy mineral is discharged as concentrate over the upper pulley and light mineral is washed over the lower pulley. The simple, non-differential shaking motion effects stratification of the solids in the semi-fluid pulp, the heavier and smaller particles working down to the bottom of the mass. The uphill movement of the supporting surface transports the settled solids upstream against the downward flow of the overlying layer of impoverished pulp and wash water.

Apart from the stratification induced by shaking (see Sec. 10, Art. 1) the effectiveness of the vanner depends on the adhesive force between finely divided solid matter and the smooth wet supporting surface. It is not proved quantitatively that this force is greater in the case of sulphide particles than in the case of gangue minerals, but qualitative proof all points in this direction. If this hypothesis is true, difference in the surface energy at the wetted contacts between sulphide-rubber (*e.g.*) and gangue-rubber is far more responsible than difference in specific gravities between the two classes of minerals in effecting the adhesion that results in concentration. It is worthy of note in this connection that more than one of the early patents that led up to modern flotation practice specified rubber as a substance showing preferential adherence to sulphide particles over gangue, (Sec. 12, Art. 3), and also that several oil-selection processes depend upon increasing the selective adhesion of sulphides to vanner belts by coating either belt or sulphide with oils. (Elmore, Luckenback, Schwarz.)

TYPES OF VANNERS

There are four types, characterized by the direction and character of shake and direction of slope, viz.: (*a*) oscillating side-shake, end-slope; (*b*) oscillating end-shake, end-slope; (*c*) differential end-shake, side-slope; (*d*) gyrating, end-slope. The first are the oldest and most used, the Frue, Johnson and Isbell being typical representatives; the Embrey, Craven and Triumph are of the second class; the Luhrig, Weir-Meredith and Monell are of the third class and the Senn the fourth.

2. Side-shake vanners

Frue vanner (Fig. 1) has an endless rubber belt (*a*), usually 6 ft. wide but sometimes 4 ft., mounted to pass around four large rollers or pulleys *b*), (*c*), (*d*), and (*e*) known respectively as head roller, tail roller, dipping roller and tightening roller, all carried on a shaking framework (*f*) which is in turn supported on a plurality of lath-like hickory or steel springs (*g*) suitably seated on the framework (*f*) and main frame (*h*). Intermediate small-diameter rollers (*i*) (best made of brass) prevent the upper run of the belt from sagging. The plane of the upper surface of the tail and intermediate rollers below the feed box cuts the head roller about 0.5 in. below the top, thus making the slope of the belt between the feed box and head roller steeper than below the feed box. The intermediate rollers above the feed box conform to the steeper slope. The framework (*f*) is shaken by means of three straps (*j*) actuated by simple eccentrics synchronously mounted on shaft (*k*) which is carried on the main frame.

A cone pulley (*l*) on this same shaft drives a shifting pulley on the flexibly-mounted shaft (*m*), on the forward end of which is a worm (*n*) engaging a worm wheel that is flexibly connected by means of a spiral spring with the shaft of the head roller, thus effecting upslope travel of the upper run of the main belt. The rate of travel is changed by moving belt (*p*) by means of hand wheel (*q*). The feed box (*r*) with a suitable pulp-distributing sole is carried on standards attached to the shaking framework (*f*). Wash water is applied from box (*s*) and a suitable spray for removal of concentrate is mounted under the head roller. Tailing is discharged over the tail roller. The belt is caused to travel straight on the head and tail rollers by swinging the tightening roller forward on the side toward which the belt is desired to travel, by means of hand wheels (*t*). Adjusting bolts on the tail-roller boxes may also be used to guide the belt. Longitudinal tilt is adjusted by means of bolts (*u*) but the machine must be stopped to make this adjustment accurately.

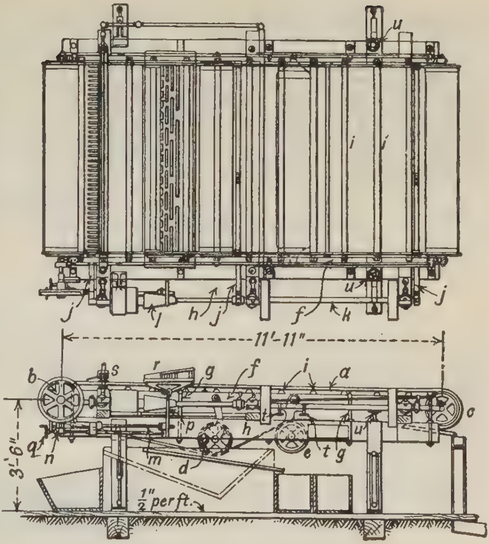

Fig. 1.—Frue vanner.

Performances are given in Tables 1 to 4.

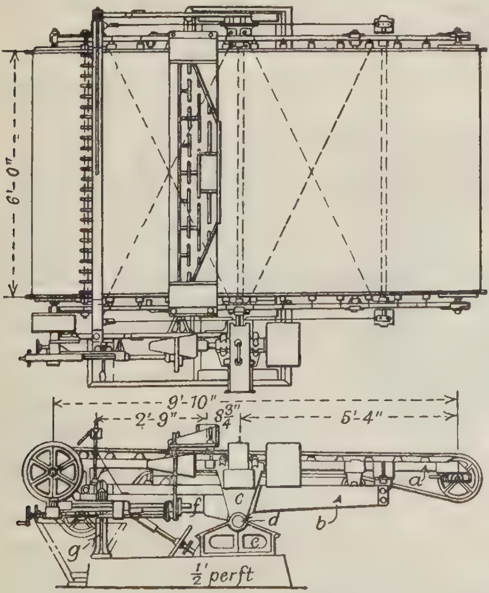

Fig. 2.—Isbell vanner.

Isbell vanner (Fig. 2) is a mechanical improvement on the Frue vanner. The shaking framework (*a*), which is of steel, is supported at the ends of two longitudinal leaf springs (*b*) which are bolted at their centers to

brackets (*c*) clamped to the transverse supporting shaft (*d*). This shaft rests, in turn, on a main transverse framework (*e*). An arm (*f*), likewise clamped to shaft (*d*) is attached to a power screw operated in floor stand (*g*), thus permitting ready variation in longitudinal tilt as one of the operating adjustments. Side shake is effected by means of a single eccentric, which permits ready adjustment of stroke length. Belt travel is effected in a manner similar to that of the Frue except that the flexible connection between worm wheel and head-pulley shaft is obtained by means of flexibly-connected cranks on the respective shafts. The method of mounting the shaking frame produces rectilinear motion of points on the belt surface, as compared to the curved path of the Frue.

Performances are given in Table 1.

Note—Speed in all tests: 196 @ 1-in. shakes per minute. Feed, 96 per cent. through 0.07-mm. screen.

Johnston vanner (Fig. 3) differs from the Frue and Isbell principally in the method of support of the shaking frame, which is hung by means of inwardly-inclined adjustable suspension links (*a*) from standards (*b*). This method of suspension produces an undulatory motion of the belt which, taken with the usually slower speed and longer stroke, prevents the formation of sand banks along the flanges.

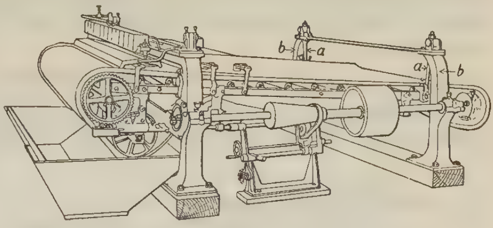

Fig. 3.—Johnston vanner.

Performances are given in Table 1.

3. End-shake vanners

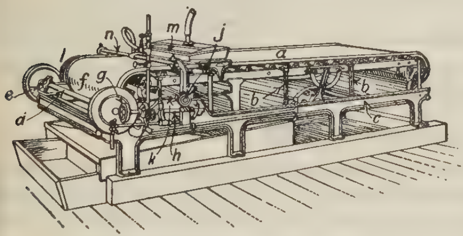

Fig. 4.—Triumph vanner.

Triumph vanner (Fig. 4) is of the oscillating end-shake end-slope variety. The shaking frame (*a*) is carried on lath springs (*b*) which, in turn, rest on main frame (*c*). Shake is transmitted through rods from eccentrics (*e*) mounted on drive shaft (*d*). The belt (*f*) is driven through a power chain composed of the friction disk (*g*), shaft (*h*), worm and gear (*j*), and shaft (*k*), carrying at the other end a pinion that drives gear (*l*). Feed sole (*m*) is mounted on the shaking frame and wash-water spray (*n*) on the main frame. The **Embrey vanner** is similar.

Performances are given in Table 1.

4. Differential end-shake, side-slope vanners

Luhrig vanner, Weir-Meredith and Monell vanners and the Bilharz-Stein shaking tables are all of the general type shown in Fig. 5, consisting of a shaking frame carrying an unflanged endless traveling belt 3 ft. 6 in. to 5 ft. wide by 12 ft. from center to center of head and tail rollers, all supported by means of rods from a tilting mechanism carried on the main frame. Differential end shake is transmitted from a suitable head-motion (see descriptions of shaking tables, Sec. 10) mounted on the main frame. Belt travel is effected by suitable connection of the head roller with the drive shaft. Pulp is fed from a distributing box near the tail roller and along the upper edge of the belt and suitable wash-water sprays are provided along the remaining length to the head roller. Tailing discharges along the lower edge opposite

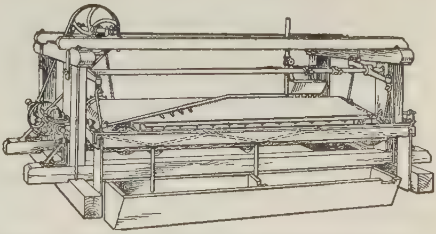

Fig. 5.—Differential, end-shake, side-slope vanner.

and somewhat forward of the feed box, middling along the same edge forward of the tailing, and concentrate at the lower edge near the head roller. This class of vanner makes three products as opposed to the two usually made on vanners.

5. Gyrating vanner

Senn vanner (Fig. 6) is of the end-slope variety but the shaking frame (*a*) oscillates both endwise and sidewise on ball-bearing supports (*b*). Sidewise shaking motion is transmitted from drive shaft (*c*) through eccentric (*d*); end shake is effected through eccentric (*e*), cranks (*f*) and (*g*) and rod (*h*). Belt motion is transmitted from the drive shaft through friction cones (*i*) and worm (*j*) to gear (*k*) on the head roller. Gyratory movement is depended upon to cause rapid stratification in a thick pulp and allow higher capacities than are usual with vanners. (See Table 1.)

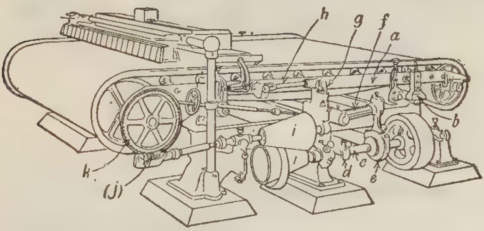

FIG. 6.—Senn vanner.

6. Operation of vanners

Removal of concentrate from the belt is normally effected by a spray directed at the face of the belt about half-way between the head and dipping rollers. Water consumption here is upward of half of the total for the vanner.

A rotary brush placed in the same position, driven from the vanner mechanism and followed by a padded roller is said (*106 J 713*) to have improved recovery as well as removed concentrate with less consumption of water. Explanation of increased recovery would lie in the maintenance of a clean rubber surface in place of a surface made "slimy" by clayey and colloidal materials in the feed pulp. Use of a 3-in. wood roller, placed so as to just touch the belt and a short distance below the head roller, is described (*106 J 1040*) as causing discharge of the bulk of the concentrate at a higher elevation than usual, allowing collection of most of the concentrate from a battery of vanners at a central point by means of launders running just below the rollers. In most mills concentrates are hoed out of boxes intermittently but some use a continuous spigot discharge. With such discharge a device similar to the Shackleford washer shown in Fig. 7 is necessary, if excessive dilution of concentrate is to be avoided. This washer is merely a ratchet-shaped rake (*a*) attached by means of rigid straps (*b*) underneath the dipping roller. The side shake of the vanner effects movement of solids to one side of the concentrate box, where they are discharged through spigot (*c*). Water level is maintained constant in the box by ball valve (*d*) and overflow (*e*).

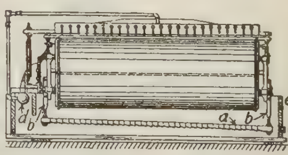

FIG. 7.—Shackleford vanner-box cleaner.

Important factors affecting performance are: Feed, shake, slope, belt travel, kind of belt and amount of wash water.

Size of feed. The maximum rarely exceeds 1.5-mm., the average maximum is between 0.6- and 0.8-mm. It is probable that the vanner should never be fed with material coarse enough to be treated on shaking tables, since the latter will treat sands with an efficiency equal to that of vanners and at much greater capacity.

Caetani (*3 MM 54*), after thorough testing of vanners, shaking tables, round tables and frames at Bunker Hill and Sullivan concluded that reciprocating (shaking) tables were superior to vanners for fine sand but that the latter were superior in every way on 200-mesh slime. Nowadays flotation will treat such material from sulphide ores much more efficiently than either machine.

A vanner will save finer mineral than can be saved on shaking tables because mass is not an essential in the moving of particles toward the concentrate discharge on vanners while it is on tables. The essential requirement, if a particle is to be caught on a vanner, is that it settle to the belt surface. Once there it adheres with relatively greater force the less its size and it is safe to say that a vanner will save any mineral particle that comes into contact with the belt, provided that very fine particles are not admixed with so much coarse sand that the amount of wash-water necessary to keep back the sand is sufficient to wash away the fine mineral.

The ability of a vanner to save mineral lost by a table is indicated in Table 5 (*106 J 711*) showing the performance of a Senn vanner treating Wilfley-table tailing. The feed to both

machines was of practically the same size, but substantially 80 per cent. of the vanner concentrate passes a 200-mesh screen as compared to about 25 per cent. of the table concentrate. The fine table concentrate was very rich, meaning very heavy, and therefore of sufficient mass to settle on and be moved along the table deck, while the large amount of slime value caught on the vanner would not settle and move with the concentrate on the Wilfley.

The size of grains affects the vanner adjustments. The usual practice is to treat fine feed with flat slope, slow belt travel and little wash water, and coarse feed *vice versa*.

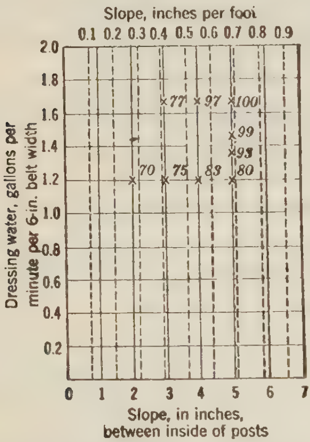
Richards (*TB 361*) recommends steep slope, rapid belt travel and little water for fine feed and gentle slope, much water and a long, slow shake for coarse. Gahl's work at Detroit Copper Co. (*40 A 517*) indicated steep slope, rapid belt travel and more than the usual amount of wash water to be best for slime treatment on smooth-belt vanners. Results are indicated graphically in Fig. 8.

Pulp consistency is usually between 80 and 90 per cent. water except on the gyrating vanner where it varies from 60 to 80 per cent.

Caetani recommends (*3 MM 48*) as high as 95 per cent. water in slime pulps, stating that thicker pulps increase capacity at the expense of efficiency. Gahl, on the other hand, found

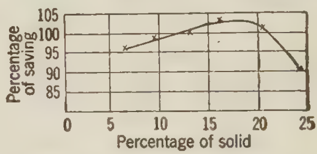
that maximum saving was obtained with between 15 and 20 per cent. solids in the feed, recovery increasing slowly to the maximum, then falling off rapidly with increased pulp thickness. His results are shown graphically in Fig. 9. The tests at the COMBINATION MILL on fine sand pulp (Table 6, tests 2 and 3) show that increase in percentage solids from 15.4 to 36.8 per cent., with increase in slope (and probably in belt speed) raises recovery, but at the expense of a decrease in grade of concentrate.

The pulp consistency should be such that the bed of pulp on the belt is sufficiently fluid to allow fine particles to settle readily. If the feed is too thick, the bed FELTS, *i.e.*, compacts into a semi-solid mass, if there is much clayey slime present, after which excessive wash water must be used to keep sand out of the concentrate, and practically no fine mineral can get through to the belt surface. The only remedy is to loosen the bed with a broom or scraper, sacrificing most of the mineral contained, and start afresh with thinner feed, slower belt travel or steeper slope. Felting is most common on side-shake vanners, less so with Johnston than with Frue and Isbell; it is less frequent on end-shake and least frequent on gyrating. Consequently end-shake vanners can be run with thicker feeds than side-shake, while gyrating can be run with very thick feed on account of the relatively perfect fluidity of the bed.



Figures at co-ordinate points are recoveries expressed in percentages of the maximum recovery attained in the series of tests. Belt speed, 120 in. per min. 220 @ 1-in. strokes per min. Feed: 13 per cent. solids; 90 per cent. −200-mesh; 1.40 per cent. Cu; 9.5 tons dry per 24 hr.

FIG. 8.—Relation of slope, wash water and recovery on smooth-belt vanners.



Saving is expressed in percentage of saving made with a pulp containing 12 per cent. solids. Slope, 0.54 in. per ft. 209 @ 1-in. strokes per min. 2.2 gal. wash water per min. Feed: 91 per cent. −200-mesh; 1.48 per cent. Cu; 7.93 tons solid per 24 hr.

FIG. 9.—Relation between pulp consistency and recovery on smooth-belt vanners.

Mineral of high specific gravity can be saved with steep slope, slow travel and much water as compared to mineral of low specific gravity; gangue of high specific gravity will require steeper slope, slower travel and more water than gangue of low specific gravity. If the ratio of concentration is low, concentrate will come over in a thick sheet with entangled gangue unless the machine is run with steep slope, rapid belt travel and much water. An ore with a high ratio of concentration, on the other hand, needs slow, careful treatment to save the small amount of mineral and discard the large amount of gangue, hence the machine is run at low slope and slow belt travel with little water.

Capacity varies with size of feed and character of ore, as well as with character of service, *i.e.*, roughing or finishing.

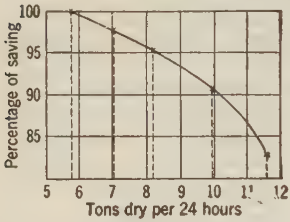
Note—Feed, 96 per cent. through 0.07-mm. screen.

Table 3 gives capacities of a Frue vanner in finishing service on galena ore at Bunker Hill and Sullivan Mining Co. Capacity of 1 to 2 tons per hr. on slime is in accord with results at Anaconda, shown in Tables 4 and 7. Five to six tons per 24 hr. is close to the average on fine sands containing slimes. A general rule on such material is 1 ton per 24 hr. per ft. of belt width. Caetani recommends 0.6 ton per 24 hr. per ft. as maximum. In roughing service, making finished tailing only, the capacity is 10 to 20 tons. The Senn vanner at Phelps Dodge Co., Morenci plant, treated as high as 150 tons per 24 hr. of feed through 3-mm. Chilian-mill screens in roughing service but it is probable that shaking tables would be a better installation for such work in general. Fig. 10 (Gahl, *ibid.*) shows variation in recovery on a corrugated-belt vanner with variation in feed rate.



Saving is expressed in percentage of the saving made on a similar vanner with the same adjustments at 5.77 tons solid per 24 hr. Feed: 14.7 per cent. solid; 90 per cent. − 200-mesh; 1.31 per cent. Cu. 210 @ 1-in. strokes per min. Slope, 0.82 in. per ft. Belt travel, 120-in. per min.

Fig. 10.—Relation between recovery and feed rate on a corrugated-belt vanner.

Preparation of feed. Controversy has raged concerning whether the feed to vanners should be classified or unclassified. Proponents of the first method argue that the vanner is a film sizer (see Sec. 8, Art. 14) and that it will, therefore, do its best work when the particles of valuable mineral are smaller than the gangue particles, but not so much smaller that the mineral is washed away in the current necessary to move the gangue.

Richards (*TB 363*) plots the results of a sizing-sorting test on the tailing of a well-run vanner treating −0.75-mm. quartz-pyrite ore, and shows the average ratio of size of quartz to that of pyrite to be about 10 to 1. He concludes that the finer pyrite should have been removed from the feed by classification. Hancock (*24 MM 80*) holds that since film sizing results in putting together in the tailing fine heavy mineral and coarse light mineral it is wrong to feed material that has this composition to a vanner, hence he advises against classification. He cites Gilbert's experiments (*PP 86 USGS*; see Sec. 20, Art. 1C) showing the relation between size transported and stream velocity over a smooth surface to show that fine mineral is transported in suspension in a current necessary to roll coarse gangue. He thinks that with a vanner operated under a given set of conditions the size of mineral in concentrate will be close to a definite mean figure, that tailing will contain both coarser and finer particles, and that these will be saved by another vanner, differently run, treating the tailing of the first. Beringer's results (*24 IMM 411*) showing that cassiterite in a vanner concentrate made by re-treating vanner tailing fell into two definite size groups, viz.: from 0.050- to 0.075-mm. and from 0.010- to 0.015-mm., confirm this view. McDermott (*24 IMM 447*) maintains that suspended fine material flows, with the water, over and through the interstices between coarse grains in the bed of pulp on the vanner and that retardation of the flow by coarse grains effects settlement. Removal of coarse would, in his opinion, cause the fine pulp to progress in waves and at higher velocity, with less settling time available and more disturbance of settled particles due to the impact of waves. He notes, also, that the capacity of a vanner is increased three to four times over that as a slime vanner, when coarse material is present. The weight of practice has been to treat unclassified feeds. In California gold mills 40-mesh stamp product was sent to vanners after amalgamation on plates; in Cornish tin practice vanner feed comes directly from stamps or is the tailing of tables taking feed direct from stamps; in American base-metal practice vanner feed has almost always been hydraulic classifier overflow, which, while it contains grains of gangue coarser than the largest grains of mineral, is not a true classified product (see Sec. 6, Art. 1).

Richards' and Beringer's results seem to point rather to series treatment of unclassified pulp on different machines than to classification with accompanying dilution of products. All of the work shows that one machine cannot be expected to make clean concentrate and substantially complete recovery on unclassified feed, notwithstanding the upper size limit, and that the difficulty will increase markedly with increase in this size.

Shake is dependent on both length of stroke and number per min. Side-shake vanners are usually run at between 180 to 200 @ 1-in. strokes per min.,

except that the Johnston is run more slowly (120 to 140) with a stroke between 1 and 2 in. End-shake vanners usually make from 200 to 240 @ 1-in. strokes per min. Side-slope vanners run at 160 to 200 @ ¼- to ¾-in. strokes per min. and gyrating at 140 to 160 @ ½-in. to ¾-in. strokes.

The amount of shake has an important bearing on the minimum size of grain that will settle on a belt.

Beringer (*24 IMM 411*) investigated the effect of shake on rate of settlement of cassiterite grains. He found that on a Frue vanner run at 180 strokes per min. 0.035-mm. particles required 60 sec. to settle in a 2-oz. phial while 0.025-mm. particles settled the same distance in the same time when the phial was at rest. Complete results are given in Table 8. Corresponding sizes on a shaking table were 0.005- to 0.010-mm. larger (see Sec. 10, Art. 14). He concluded that cassiterite between 0.030- and 0.060-mm. would be saved on a vanner without difficulty. Study of a vanner concentrate made in a CORNISH mill showed that most of the mineral lay between 0.015-mm. and 0.050-mm. Coarser mineral had already been taken out by shaking tables. Another vanner, treating unclassified feed directly from stamps saved mineral ranging from 0.010- to 0.120-mm., but there was a very small proportion below 0.010-mm. On the other hand, the smaller the particle the stronger the adhesion between it and the belt surface. Therefore the important matter in saving fine material is to get it down to the belt and the shake should be the minimum that will maintain the bed in a fluid condition. With the vanner adjusted to a given shake, decrease in speed with consequent decrease in violence of shake will result in carrying sand into the concentrate.

Table 8. Rate of settlement of cassiterite grains on a Frue vanner. (180 strokes per minute)

Time, seconds	Size of particles that settle, mm.	
	Phial at rest	Phial attached to vanner
60	0.025*a*	0.035
90	0.020	0.030
120	0.015	0.025*b*
150	0.010	0.025*a*

a, b The particles marked 0.025*a* are slightly smaller than those marked 0.025*b*.

The COMBINATION MILL tests (Table 6, tests 4, 10, 11 and 12) indicate that a long, slow shake as opposed to a short, rapid one results in increased capacity and higher grade of concentrate with the same recovery and that, if grade of concentrate is held constant, capacity is increased or recovery can be increased, if the feed rate is held constant.

Slope is closely dependent upon speed of belt, steep slope corresponding to high belt speed and *vice versa.* With side-shake vanners slope ranges from 0.15 to 1 in. per ft. and is usually steeper with coarse feed or where clean concentrate is desired than with slime feed or in roughing service. Richards' average for all service (*Peele* 1684) is from 0.28 to 0.31 in. per ft.

Prof. Richards has consistently recommended steep slope and high speed for slime feed, probably on the theory that with the correspondingly thin bed of pulp, mineral particles had a short and relatively unimpeded path to the belt, and Gahl's results shown in Fig. 8, confirm this view. Tables 4 and 7, presenting ANACONDA test work also illustrate this practice. The COMBINATION MILL tests (Table 6, tests 1, 4 and 8) show that increase in slope permits increase in tonnage treated. End-shake vanners have been used frequently to clean up concentrate from side-shake and, therefore, show a steeper average slope than side-shake. Richard's figures (*Peele,* 1684) are 0.6 in. per ft. Side-slope vanners are set at ½ to ¾ in. per ft. side slope and from level to ½ in. per ft. rise toward the head-roller end. The Senn vanner is recommended to be tried at ⅝ in. per ft. slope to allow high belt speed and thick feed pulp. If, under these conditions, fine mineral goes into the tailing, the slope must be flattened. Corrugated belts are usually set on a steeper slope than smooth belts in order to cut down the amount of wash water necessary.

Belt speed determines the rate at which settled concentrate is removed and also the amount of wash water that must be used to produce clean concentrate. Belt speed and wash water are the two adjustments most depended upon by vanner operators for controlling results. High belt speed tends to keep fine mineral out of the tailing but also drags coarse gangue into the concentrate unless considerable wash water is used and this increase in water currents flowing down the belt may defeat the purpose of high belt speed by

keeping fine mineral in suspension. The average speed for side-shake vanners is between 36 and 48 in. per min., with higher speed when a rough concentrate is sought and lower when particularly clean concentrate is desired. Corrugated belts may be run at lower speeds than smooth on account of the fact that fine mineral settles in the corrugations and is protected from the wash-water; they must be run slowly when coarse sand is present on account of the difficulty of washing this down-slope. Speed of belt on end-shake vanners averages 60 in. per min. according to Richards (*Peele* 1684) and in the Anaconda test work (Table 7) ranged from 80 to 216 in. per min. It is worthy of note, however, that in this work a speed of 80 in. per min. at 0.33 in. per ft. slope produced results substantially equal to those obtained at 216 in. per min. with a slope of 1.5-in. per ft.

Luhrig vanner at BROKEN HILL was run at 180 ft. per min. belt speed, this high speed being necessary in order to move the concentrate through the required horizontal distance before it was washed across the relatively narrow smooth belt into tailing or middling launders.

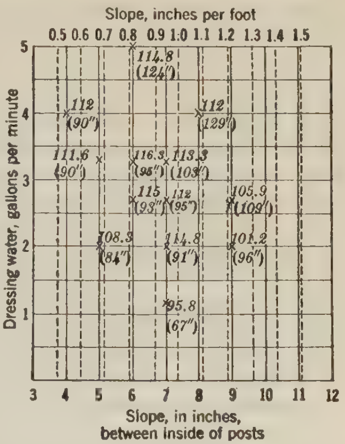
Wash-water consumption per machine is low, ranging from about 1 to 5 gal. per min., including both dressing water (added on top of belt) and water added to remove concentrate from the belt. The maximum water consumption per ton corresponds to attempts to make high-grade concentrate from finely ground low-grade feed. Side-slope vanners use more water per minute than end-slope. The LUHRIG requires from 5 to 10 gals. Wash-water consumption per ton of ore treated is less on vanners than on shaking tables in the same service. The SENN vanner uses much less water per ton of feed than side- and end-shake on account of its large capacity.

Depth of bed is a resultant of all adjustments. Flat slope, high belt speed, coarse feed, thick pulp and small amount of wash water all tend to produce a thick bed of pulp on the belt and *vice versa*. Richards recommends 0.25 in. maximum thickness (*Peele* 1685). Beds up to 0.75 in. thick are used when crowding vanners in roughing service but are too thick for finishing. Channeling of bed, either by reason of side banks or center banks will cause dirty concentrate or rich tailing or both.

Side banks. Frue and Isbell vanners are peculiarly liable to formation of hard banks of sand along the flanges. These creep up into the concentrate and also increase tailing loss. They are formed by any knock or irregularity in the shaking motion such as by a loose or worn eccentric or connecting rod or end play in small supporting rollers or in end rollers. A bank on one side may be formed because the belt is not level transversely or because the supports of the shaking frame are not parallel. Parallel longitudinal ridges will form if the bed is too thick. The REMEDIES are to increase water, decrease belt travel or increase slope. The Johnston vanner, on account of the more gentle and tilting side motion, is comparatively free from side banking and end-shake vanners are, of course, entirely free.

Belt is usually smooth rubber with two plies of canvas and a flanged edge 1 in. to 1.25 in. high. Belts with transverse 60° corrugations spaced 8 to 32 to the inch have had considerable vogue in treating relatively coarse feeds. Fig. 11 (*40 A 517*) shows comparative results with corrugated- and smooth-belt vanners on slime feed. Corrugated belts permit low belt speed but require large quantities of wash water to hold back gangue. This difficulty increases with the size of the corrugations. Tailing is generally lower than on smooth belts but concentrate is correspondingly lower grade. Table 9 gives comparative results on a silver ore. *Richards* reports running a corrugated belt on a Johnston vanner at 5 in. per min. without excessive tailing loss. Canvas belt, usually painted with some water-proof compound, has been used for fine slimes but it is difficult to wash out fine gangue from the uneven surface without also removing fine mineral. Belts should be kept sufficiently tight to prevent sagging of the upper surface between the support-

ing rollers. End rollers are adjustable lengthwise to permit tightening. An egg-shell surface, pitted with shallow depressions about 0.6 by 0.1 in. has been made. The life of rubber belts is from 2 to 6 years, if protected from abuse. Belts are frequently injured by hoes used in digging concentrate out of collecting boxes. This may be obviated by placing a light guard in front of the belt or by using some kind of automatic discharge. Old vanner belts make good covers for shaking tables or liners for chutes and launders.



Saving is expressed in percentage of the saving made on a standard vanner with smooth belt: 229 @ 1-in. strokes per min., 5-in. slope between posts, belt travel 123 in. per min. Corrugated belt, 190 @ 1-in. strokes per min.; feed: 12.64 per cent. solids, 91 per cent. −200-mesh; 1.4 per cent. Cu.; 8.43 tons dry per 24 hr. () Figures in parenthesis are belt travel in inches per minute.

Fig. 11.—Comparison of smooth- and corrugated-belt vanners on slime feed.

Attendance necessary varies with service and regularity of feed and wash-water supply. In finishing service one man can attend to 30 to 40 machines, if feed and water supply are regular, but when dirty reclaimed water is used and the wash-water supply consequently clogs, or if the feed is irregular, one man will have difficulty with 20 machines. In roughing service a man can handle 100 machines without difficulty. The vanner is a complicated machine, when judged by other concentrators; it requires skilled operatives and repairs are frequent.

Efficiency of vanners is always low. Recovery rarely exceeds 50 per cent., even on rich galena slimes; it ranges between 20 and 35 per cent. in finishing service on copper slimes, and rises to 60 to 75 per cent. when making rough copper concentrate.

Table 9. Comparison of corrugated-belt and smooth-belt vanners on silver ore (*21 A 280*)

Test number	Smooth belt				Corrugated belt

Average	100	100	100	100	146.3	86.2	125.3	67.4

End-shake *vs.* side-shake vanners. Theoretically the concentrate from an end-shake vanner should be of lower grade and the tailing of higher grade than the corresponding products of a side-shake machine on account of the fact that feed and wash water are brought to the belt in streams and these have greater transverse distribution on a side-shake than an end-shake machine, hence ridges will form on an end-shake machine up which sand will travel between the wash-water streams while fine mineral will be carried into the tailing in the streams rushing down the valleys between these ridges. Exact comparative data are not available but Tables 4 and 7, giving results on the same kind of feed, show that as between a Frue vanner with corrugated belt and an end-shake machine, the result is the reverse of that to be expected and the end-shake machine produced a higher average grade of concentrate and lower grade of tailing than the side-shake.

Frue *vs.* Johnston vanners. Table 10 presents a comparison between these types of vanners in the old mill of Nevada Cons. Cop. Co. The Frue corrugated vanner is distinctly superior to the Johnston in grade of concentrate and grade of tailing but the capacity is markedly less; there is little to choose between the smooth-belt machines, such advantage as there is lying with the Johnston. All smooth-belt machines were much overloaded.

Table 10. Comparison of Frue and Johnston vanners at Nevada Consolidated Copper Co., 1909–10

Row number	Frue vanners, Sections 1 and 2							
	Assays, per cent.				Recovery, per cent.	Tons per 24 hr.	Water consumption, gallons per minute	
	Feed, Cu	Concentrate		Tailing, Cu			Above belt	Below belt
		Cu	Insoluble					
1	1.28	19.2	34	0.43	68	8	3.4	4.0
2	0.97	18.8	30	0.53	47	12	2.7	3.1
3	0.92	16.1	38	0.70	25	9	1.8	2.6

	Assays, per cent.				Recovery, per cent.	Tons per 24 hr.
	Feed, Cu	Concentrate		Tailing, Cu		
		Cu	Insoluble			
1	1.58	17.9	36	0.56	67	11
2	1.00	16.5	34	0.52	50	12
3	0.93	16.4	36	0.67	29	11

Notes—Speed: Frue, 192 @ 1-in. strokes per minute; Johnston, 120 @ 2-in. First row, all sections, corrugated belts; other rows smooth. Feed to first row was middling from Wilfley tables treating products from first three spigots of hydraulic classifiers treating reground middlings; second row took middling from Wilfleys treating primary slimes; third row took thickened slime from these same Wilfleys and slime from the re-grinding circuit. Assays are averaged from shift samples; each figure represents 25,000 cuts on Frues and 58,000 on Johnstons, 3900 and 3000 copper determinations respectively and 430 and 1000 determinations of insoluble.

SECTION 12

FLOTATION

1. Introduction

Definition. Flotation is a method of wet concentration of ores in which separation of mineral from gangue is effected by causing the mineral to float at or above the surface of a body of liquid pulp while the gangue becomes or remains submerged. The method operates, in general, only on particles smaller than 0.5- or 0.3-mm. diameter. The minimum recoverable size probably includes the finest particles produced in grinding ore. Minerals that float readily are those of metallic, resinous or adamantine luster, such as the base-metal sulphides; those that readily sink are the vitreous or earthy gangue minerals; but separation by flotation is possible between minerals of the first class, and some of the minerals of the second class can be floated away from others of that class. Thus galena can be separated from blende; fluorite, calcite and apatite can be separated from quartz and most other silicates; coal can be separated from slate, and mica from other silicates.

Types of processes. Flotation processes are of three different varieties, namely, (*a*) film flotation, (*b*) oil-buoyancy flotation, (*c*) froth flotation. In film flotation the separation is made at the upper or air surface of a body of water; in oil flotation, at the interface between a mass of oil and a mass of water; in froth flotation, by means of a froth floating on the surface of a body of pulp.

Only froth flotation is of commercial importance, but understanding of the phenomena of film flotation and oil flotation is necessary to a proper understanding of froth flotation.

2. Film flotation (Skin flotation)

If a sulphide ore is crushed dry and sized through, say, 0.3- or 0.2-mm. and brought gently onto the surface of a body of still water, a certain number of the particles will float. The floating particles will usually contain a materially higher proportion of sulphide mineral than was present in the original ore. Each floating particle or group of particles appears to rest in a dimple in the water surface. The actual condition is the same as that of the floating needle in the familiar parlor trick and is illustrated in Fig. 1*c*. A clean glass needle of equal length and weight will not, ordinarily, float. This difference in behavior between the two substances is specific and is due to a difference in surface characteristics that can be described as RESISTANCE TO WETTING. Metallic surfaces are generally more resistant to wetting than non-metallic. Metallic substances, therefore, if treated as above, generally float; non-metallic become wet and sink. If the crushed ore described above is wetted and then drained, as, for instance on a vanning plaque, the sulphide minerals dry more rapidly than the gangue, and if a film of water is thereafter flowed gently over the drained mass, a part of the solids, sulphides predominating, will float on the water surface.

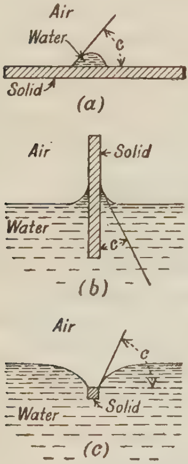

FIG. 1.—Contact angles, gas-liquid-solid.

Theory of film flotation. When a drop of a liquid, such as water, is placed upon a solid surface, *e.g.*, a piece of metal, the drop assumes a position shown in cross-section in Fig. 1*a*. The angle (*c*) between the solid surface and the tangent to the water surface at the apparent meeting point of water and solid, in a plane passing through the center of the water drop and at right-angles to the solid surface, is called the ANGLE OF CONTACT. This angle is specific within certain limits for the contacts of different liquids and solids. For water against solid surfaces of metallic luster it is generally larger than against solid surfaces of vitreous or earthy luster; it is generally larger for water than for oil against any given solid; and the difference in the angle for water against two different solids, as say, quartz and galena, may be affected by small amounts of solutes in the water. Other examples of the apparent contact angle formed when the three phases, solid, liquid and gas, meet are shown in Figs. *1b* and *1c*.

Existence of a contact angle is challenged by some physicists, or, at least, a zero angle is claimed to exist in all cases of a three-phase contact such as is pictured in Fig. 1. It is claimed that when the condition pictured exists a fourth phase consisting of a film on the solid surface intervenes between it and the two fluids. Experiment indicates this to be a fact. If the solid is platinum sheet, cleaned carefully in alkali and strong sulphuric acid and burned to remove the last trace of grease, a drop of water will not stand on its surface; if inserted into water as in Fig. 1*b* and then withdrawn, it is uniformly wet; the adhering water does not draw together in drops; and the platinum will not float as pictured in Fig. 1*c*. The same is true of clean glass or quartz. It is difficult to similarly clean metals other than platinum, or metallic sulphides, and at the same time insure against surface oxidation, but mineral surfaces produced from the center of lumps of pure mineral, with every precaution against surface contamination, behave more like clean platinum than like the solid in Fig. 1. Dean and White (*124 P 410*) found that the air-water contact angle against sulphides cleaned with sodium hydroxide and pyrogallol was zero immediately after the cleaning, but that after a period varying from a few minutes to several days, according to the specimen, a definite contact angle was again found. Calcite and garnet behaved similarly, but recovery (contamination) was slower and more erratic. From the practical standpoint, however, contact angles between water and various minerals, ranging from a few degrees to 90° or more, do exist, and the differences are sufficiently definite to permit commercial utilization.

Contact angle is the result of equilibrium of a system of forces, mutually exerted by the molecules of the three phases in contact, whose effective

resultants lie in the contact surfaces. Fig. 2 is a vector diagram of these forces at any point (O) on the periphery of the drop pictured in Fig. 1a. The actual directions of the forces OA and OD are not known, but they must act in opposite directions. The equation of equilibrium is $OA = OD + OB \cos C$, from which it follows that $OA > OD$. If OA and OD are assumed reversed in direction, the equation becomes $OD = OA + OB \cos C$, and $OD > OA$. Neither conclusion can be confirmed, because of inability to measure the interfacial force or surface tension of solids against other phases. Surface tension of liquids against gases and against other liquids can, however, be measured. The surface tension of a liquid against a second liquid, whose tension against a gas (air) is less than that of the first, is generally less than that of the first against the gas. Further, the surface tension of molten solids, such as salts and metals, is much higher than that of substances liquid at ordinary temperatures. Hence, it is not unreasonable to suppose $OA > OD$ and that the directions of the vectors in Fig. 2 are correct. (For an exhaustive discussion with many experimental data see Coghill and Anderson, *TP 262, USBM*.)

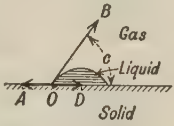

FIG. 2.—Forces at 3-phase contact.

Experiment shows that the relative magnitudes of OA and OD are different for water against different minerals. Table 1 presents determinations on several common constituents of ores. Values under the caption "Minimum value = θ" represent the angle maintained on the higher edge of a drop rolling down an inclined surface of the mineral and those under caption "Maximum value = θ'" are those on the lower or advancing edge. Sulman applies the term HYSTERESIS OF CONTACT-ANGLE to the difference between the two values.

Table 1. Contact angles of ore minerals with plain water. (*After Sulman*)

Mineral	Contact angle		Difference or hysteresis
	Minimum value = θ	Maximum value = θ'	
	degrees	degrees	degrees
Chalcopyrite	37.0	87.0	50.0
Stibnite	24.0	62.8	38.3
Rosin blende	47.0	81.0	34.0
Magnetite	21.7	80.8	69.1
Marcasite	56.5	83.5	28.0
Iron pyrite	25.5	87.0	61.5
Quartz	19.5	58.5	39.0
Calcite	39.6	85.5	45.9
Garnet	58.2	94.5	36.3
Galena No. 1	35.0	73.0	38.0
Galena No. 2	41.6	70.0	28.4
Molybdenite	12.6	62.5	49.9
Chalybite	45.2	90.0	44.8
Glass	33.0	39.5	6.5

Effect of differences in contact angle on flotability of two pieces of the same size, shape and weight is shown in Fig. 3. Fig. 3a shows a particle against which the liquid makes a contact angle nearly 90°. The vertical component of (T), available to counteract (W) (weight of solid in liquid), is nearly as great as (T) itself. In Fig. 3b, the contact angle is small and, although (T) is the same as before, the effective component is much less.

Hence the first particle may float and the second sink. This was for many years taken as the complete explanation of the separation possible by film flotation. But reference to Table 1 shows that on the basis of magnitude of contact angles alone, the advancing angle being the effective one, the order of floatability would be garnet, chalybite, chalcopyrite and pyrite, calcite, marcasite, rosin blende, magnetite, galena, stibnite, molybdenite, quartz, glass. This order is distinctly not in accord with experience, as is shown by Table 2. From this table the order of floatability, at the most favorable size for comparison (−1.168 +0.833-mm.) is sphalerite, galena, chalcocite, calcite, dolomite, quartz, siderite.

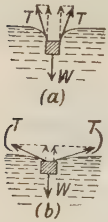

FIG. 3.—Forces in film flotation.

The order of magnitude of the hysteresis of the contact angle is claimed by Sulman (*29 IMM 44*) to gage the order of floatability more correctly. The minerals in Table 1, arranged on this basis are: magnetite, iron pyrite, chalcopyrite, molybdenite, calcite, chalybite, quartz, stibnite, galena, garnet, rosin blende, marcasite, glass. While this arrangement likewise does not agree with actual experience as to floatability, as presented in Table 2, it approaches it more nearly. Sulman's argument is plausible. He says that hysteresis of the contact angle increases the range of equilibrium of the forces causing flotation of the particles, and thus allows the system to adjust to changes in direction and magnitude of the forces caused by disturbances of the water surface. An unchangeable contact angle, he properly maintains, would give a system incapable of such adjustment.

Table 2. Flotation of dry, unoiled minerals at a clean water surface. (*School of Mines, Columbia University*)

a Sizes in mm. *b* Flotation was obtained by placing the pieces on top of a glass dome, 1 in. diameter, projecting 5⁄16 in. above the water surface, and allowing them to slide down onto the surface. Percentages were obtained by counting the number of pieces that floated out of 100 tried.

Effect of dissolved substances on contact angles is shown in Table 3. Minerals in the order of magnitude of advancing angles are: chalcopyrite, rosin blende, marcasite, galena, iron pyrite, molybdenite, stibnite, garnet, quartz, magnetite and glass. In order of hysteresis range they are: Molybdenite, iron pyrite, galena, chalcopyrite, stibnite, marcasite, rosin blende, garnet, magnetite, quartz and glass. Both of these orders are in consistent accord with general experience as to the greater floatability, on acidified water, of sulphides than gangue, and the second probably approaches the truth more closely in detail than the first. The remarkable things to note, however, in comparing Tables 1 and 3, are the marked and consistent drop in all contact angles produced by the acid in solution, and the fact that the drop averages 19.2° for the sulphide minerals as against 54.8°, nearly three times as much, for the gangues. There is a similar proportionate drop in the hysteresis. The possible benefit of dissolved substances on film flotation is referred to by Macquisten (U. S. patent 865,194).

Glass..........	4.0	4.0	0.0

Oiling of mineral particles changes both contact angles and hysteresis. Oiling is a phenomenon similar to water-wetting, when performed in the presence of air (i.e., on dry pulp), but differing therefrom in the fact that while all contact angles are low, those on particles of metallic luster are lower than those on gangue particles. Hence when oil is incorporated with a dry pulp there is some tendency for the sulphide particles to become wetted more completely than the gangue. But the tendency is not sufficiently sharp and definite to be useful. When, however, oil and water are brought simultaneously to the surfaces of mineral and gangue particles, out of the presence of air or other gas, a relatively sharp differentiation in behavior occurs, as illustrated in Fig. 4. The oil makes a small contact angle with sulphide mineral and displaces water from the sulphide surface, while the reverse is true at the gangue surface and the latter becomes or remains water-wet. When dry-oiled particles are brought into contact with water a similar tendency exists and the water to some extent displaces oil from the gangue surfaces and wets them, while it is repelled from sulphide surfaces to an even greater extent than when these are unoiled.

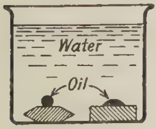

FIG. 4.— Behavior of oil and water at gangue and mineral surfaces.

Sulman and Picard (*The theory of concentration processes involving surface tension, Exhibit Minerals Separation North American Corp.* vs. *Magma Copper Co.*) gave the results presented in Table 4 for contact angles of oiled minerals with acidified water. These are to be compared with those for unoiled minerals in Table 3. The order of decreasing floatability based on advancing contact angle is: chalcopyrite, stibnite, rosin blende, specular iron, marcasite, galena, molybdenite, garnet, quartz, magnetite. Based on hysteresis the order is: Chalcopyrite, galena, marcasite, specular iron, molybdenite, stibnite, rosin blende, garnet, quartz, magnetite. Excluding the specular iron, these results accord fairly with experience. Table 5 presents results with oiled sulphides comparable to those with unoiled minerals in Table 2.

Wood dry-feed film-flotation machine (1,088,050/1914) is typical of the dry-feed machines (Fig. 5). It consists of two tanks (A) and (P), filled with water. A roller (C), covered

a Sizes in mm. *b* Method of effecting flotation is described in note *b*, Table 2. Mineral was oiled with about 2 per cent. oleic acid by weight, applied in benzol solution, from which the benzol evaporated leaving oleic acid as a film-coating on the solid.

with corrugated rubber belting and submerged with its center well below the surface of water in the tank (*A*), rotates in the direction indicated. As the roller emerges from the body of liquid, it carries with it, covering its upper surface, a thin layer of water. Dry ore is fed onto the surface of the revolving roller, in a thin sheet by means of the shaking feeder (*G*), the gangue minerals tend to wet and sink into the grooves, while the minerals of metallic luster tend to float. When the floating and submerged minerals are carried over to the point where the surface of liquid in the tank intersects the surface of the roller, the floating mineral rides out onto the water surface because of the fact that the surface film is continuous over the tank and the roller. The gangue minerals remain submerged and finally fall off and settle to the bottom of the tank. At the opposite side of tank (*A*) is another roller (*I*). An endless rubber belt (*K*) passes over this roller, thence in turn over pulley (*R*), and guide roller (*M*). A gentle current is maintained from

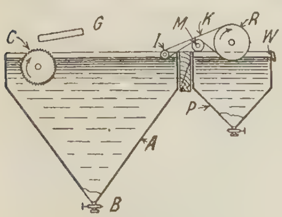

FIG. 5.—Wood skin-flotation machine.

(C) toward (I) by reason of the constant addition to the surface film at (C) and constant removal at (I) by the traveling belt (K). The surface film is continuous from the liquid in tank (A) to the liquid in tank (P) over the surface of belt (K). Due to the disturbance at the point where belt (K) passes below the surface of the liquid in the tank (P), the less tightly held material in the film is shaken out and settles to the bottom of tank (P). This material constitutes the middling of the process and is re-treated on gravity-concentration apparatus. Tailing is discharged through valve (B). Floating concentrate overflows lip (W), the level of liquid in tank (P) being maintained so as to overflow a thin sheet of liquid at this point.

In an earlier patent, 984,633/1911, Wood states that in certain instances a small quantity of oil will increase selection.

The machine as built had a feed roller 3 ft. wide, required about 0.25 hp. and is said (*44 A 684*) to have had a capacity of from 1000 to 2000 lb. per hour.

Other dry-feed film-flotation machines differ in no way in principle from the Wood machine.

Nibelius (486,495/1892). Vertical gravity feed. Radial skimming current induced by rising current of water at the center of the separating box. Re-treatment of float concentrate in successive shallow troughs with side overflow and short vertical drops between.

Brumell (678,860/1901). Fixed inclined feed. Lateral skimming current induced by a special submerged fitting on the water-supply pipe.

Allen (688,279/1901). Vertical gravity feed onto water in an inclined launder, discharging, so as to cause ripples, into a spitzkasten. The spitzkasten discharges tailing and a rough concentrate, the latter by inclined launder onto the surface of water in a shallow box with several submerged weirs, where middling is shaken out by ripples caused by the weirs.

Wheelock (734,641/1903). Fixed inclined feed by means of special chutes. Lateral skimming current induced by perforated pipe at the surface near the back of the separating spitzkasten. Re-treatment of concentrate by vertical fall along the lip of the first spitzkasten onto the surface of the second.

Davis (816,303/1906). Vertical gravity feed onto the surface of a rising stream. Compartmented trough with special knife-edge skimmers at each compartment to cut out suspended matter just below the surface.

Behrend (973,467/1910). Feed sifted onto the surface of water in a cone with a radial skimming current induced by a radially-discharging pipe at the center.

Behrend (979,820/1910). Vertical gravity feed by shaking tray onto a horizontal current in a compartmented trough with film-thinning boards over the partitions.

Wood (984,633/1911). Vertical gravity feed onto water on a slightly-inclined plate with provision for discharge of sunken material. The film from the plate flows onto the surface of water in a spitzkasten. Overflow passes over a steeply-inclined screen for final cleaning of concentrate.

Wood (987,209/1911). The film in a tray receiving the feed flows tangentially, at an acute angle, onto the surface of pulp in a cone fitted with curved-screen skimmer opposed to the surface current in a way to lead the film into a central overflow.

Smith (1,014,977/1912). Shaking feed onto a steeply-inclined plate, thence onto a film in a slightly-inclined launder leading to a spitzkasten. Overflow by launder to a further spitzkasten. Repeated re-treatment of concentrate. Provision for varying the slope of connecting launders, resulting in variation in height of fall onto the surface of the pulp in successive spitzkasten.

Jeffrey (1,052,061/1913). Feed distributed at center of cone by sliding from a spherical segment onto a radially traveling film on a flat conical surface. Radial current guided by underside of spherical segment.

Smith (1,136,622/1915). Vertical gravity feed through screens of increasing aperture placed above a launder or launders carrying the separating film. Inclination of feed screen opposed to that of separating launder.

Rowand (1,159,713/1915). Dry feed to traveling oiled belt on which preferential oiling of sulphides in air is expected. Subsequent presentation of solids at a water surface by submergence of the belt. Belt continuously oiled by dipping into a tank containing oil.

Munroe (1,230,081/1917). Inclined fixed feed onto lateral current in spitzkasten, induced by making upper portion of back of spitzkasten circular in vertical section.

Macquisten wet-feed film-flotation machine (865,194, 865,195, 865,260/1907) is one of the best known types of wet-feed machines.

Fig. 6 shows the essential features, *viz.*: a rotating rifled tube (b) 1 × 6-ft., set horizontally, with central opening at the inlet end and full opening at the discharge end into a pointed box

(*d*), with overflow lip. Water level is maintained in box and tube about 3 in. above the bottom of the tube so that a film of water about 1/32 in. deep overflows the discharge lip. Liquid pulp is introduced through the feed trough (*a*). The tube makes 30 r.p.m. The solids in the pulp are thus raised above the surface of pulp in the tube, water drains away, most rapidly and completely from particles of metallic luster, and, as the material slides back, the minerals of metallic luster float, in part, while the gangue minerals submerge. This operation is repeated many times as the pulp passes through the machine. Slime tends, in large part, to pass through in suspension and thus gets no chance to separate. A gentle surface current (about 10 ft. per min.) is maintained from feed to discharge end. When the submerged solids reach the tank they sink and are withdrawn as tailing.

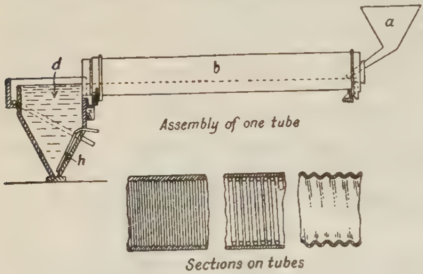

FIG. 6.—Macquisten skin-flotation machine.

Floating concentrate passes over the lip. Tailing is re-treated in another tube. At the MORNING MILL (*43 A 692*) 175 to 200 lb. of zinc concentrate assaying 48 per cent. zinc were floated per tube per 24 hr., representing a recovery as high as 85 per cent. Three tons of solid per 24 hr. was passed through four tubes in series. The feed sized about 9 per cent. on 40-mesh and 11 per cent. through 200-mesh. The feed pulp carried from 14 to 20 per cent. solids.

Macquisten states in patent 865,194 that acid, alkali or soluble salt or other substance like petroleum may be used to modify the surface tension of the separating liquid or to alter the surface condition of the particles.

DeBavay wet-feed film-flotation process (864,597/1907; 912,783/1909). The apparatus used in Australia is described by *Hoover* and differed from that shown in the patents.

The process described in the patents consists in first digesting pulverized ore with a solution of alkaline carbonates or bi-carbonates or carbonic acid or any other reagent in order to remove surface coatings from the sulphide particles, or it may be removed by trituration. The pulp is then de-slimed, suspended in new water and flowed in a thin film over an inclined plane onto the surface of a body of water in a tank or trough where the mineral floats. The feed should be between 40- and 80-mesh. The strength of the washing solution is from 0.5 to 10 per cent. when alkaline carbonates are used.

In the process as described by *Hoover*, tailing from gravity concentration, crushed to pass about 40-mesh, was first de-slimed, then fed into a mixing tank and agitated for a considerable time with cold sulphuric-acid solution, about 0.2 per cent. strength, in a pulp containing 15 to 20 per cent. solids, the acid solution was decanted, the settled solid washed twice with fresh water, then thoroughly agitated with water containing about 0.02 per cent. chlorine and from 2 to 3 lb. per ton of ore of a mixture of 1 part of castor oil and 4 parts of low-grade kerosene. The oiled pulp was elevated by a monteju onto a series of separating cones of the type shown in Fig. 7. Concentrate floated from (*A*) to (*B*), gangue sank and discharged through (*D*). The floating material was principally froth. This is not true of the process described in the patent.

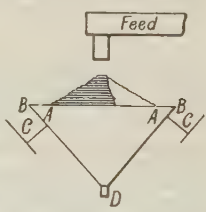

FIG. 7.—DeBavay separating cone.

Other wet-feed film-flotation machines comprise a variety of methods of bringing the solids in a wet pulp to the surface in order that the sulphides may preferentially drain and then float.

Sulman and Picard (793,808/1905). Oiled pulp is sprayed by means of jets, revolving disks, or otherwise onto the surface of water.

Sulman, Picard and Ballot (879,985/1908). Three methods of bringing solids to the surface are described: (*a*) specially riffled reciprocating table, the exposure taking place as the

solids climb the riffles; (*b*) air jets applied to material on the surface of a reciprocating table; (*c*) concave vanning belt, which drains on alternate sides at each reciprocation.

H. L. and E. A. Sulman (902,018/1908). Fixed buddle with two scraper arms carrying rubber scrapers to "dry" the solid, followed by perforated arms to distribute a liquid, as acidified water, onto the dried surface. Thick feed.

Brown (1,081,360/1913). Pulp, with or without "a substance to enhance the flotation of the mineral particles" is successively raised above the surface of water in a tank and then submerged, by means of a traveling belt.

Stevens (1,116,642/1914). Oiling with a small quantity of a mineral oil in a warm, acid pulp, presenting the pulp to air and then to the surface of a liquid by any method.

Livingston (1,147,633 1915). Oiled, acidified pulp flowed through the bottom of a ribbed revolving drum. Internal spray pipes to furnish a liquid film for flotation of the drained mineral and a longitudinal concentrate-overflow launder submerged in the pulp along the center line of the drum. Several variations.

Stone (1,156,041/1915). Oiled, acidified pulp fed intermittently at an acute angle, with as little agitation as possible, to a liquid (water) surface by means of a plurality of small movable mechanically-operated trays. The trays are mounted on a carriage so that they alternately submerge with a load of feed and emerge empty on the return trip for another load.

Haultain (1,218,400/1917). Pulp, with or without oil or inorganic agents, fed successively by pluralities of inclined, fan-shaped trays onto water surfaces in settling tanks. Air jets to set up skimming currents.

Spearman (1,377,937/1921). Grinding in the presence of water and a small quantity of a non-frothing oil followed by separation on an inclined screen on which floating mineral discharges as oversize and sunken material as undersize. Specifically for graphite.

Bonnell (1,399,539/1921). Oiled pulp raised to a smooth or riffled apron by air-lift and flowed onto the surface of water in a spitzkasten. Succession of apparatus with both series and circulating treatment. Some froth flotation here also, depending upon oil and ore.

Spearman (1,491,110; 1,491,111; 1,497,804; 1,509,266/1924). Freely-flowing oiled pulp is sent in a thin layer over an inclined porous membrane discharging gas, thence onto the surface of water in a spitzkasten from which a skin float is withdrawn by suction while tailing sinks. The process is claimed to be particularly suitable for separating graphite from mica in refining graphite concentrate.

Use of film flotation has not been great. It has been extensively experimented with in the treatment of graphite ores and was used for floating sphalerite in Broken Hill and at one mill in the Coeur d'Alenes.

3. Oil flotation

Bulk-oil flotation and OIL-BUOYANCY FLOTATION are other names for the same method. The process depends upon the interfacial forces at the contact of a mass of oil and water for selecting and holding sulphide mineral, and upon the buoyancy of the oil in water for the levitation of the selected sulphide. Operation of the process consists in mixing relatively large quantities of oil with finely-ground ore, either before or after admixture with water, then allowing the mixture of ore, oil and water to stratify. Following such procedure, if the oil is of lower specific gravity than water (or pulp), a load of solid, predominately metallic mineral, is carried at the interface between the oil and water, and by overflowing the oil layer with a thin layer of the underlying water, this mineral load can be separated from the settled gangue.

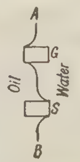

FIG. 8.—Selection at oil-water interface.

Theory of oil flotation. The fundamental phenomenon of selection is illustrated in Fig. 4. The conditions existing in a freely-flowing pulp into which a mass of oil is being mixed are illustrated in Fig. 8. *AB* represents an oil-water interface and (*G*) and (*S*) gangue and sulphide particles respectively. When a gangue particle is presented at the interface, the contact angle of water against a gangue surface in the presence of oil being small, the oil-water interface assumes the position shown and the force of surface tension acts to throw

the gangue particles back into the water. On the other hand, when a sulphide particle is similarly presented, it is the oil-sulphide contact angle that is small and the direction of the forces at the oil-water interface in the neighborhood of the sulphide particle is, therefore, such that the sulphide is held or moves toward the oil. *Bancroft* says (p. 83):

"The solid particles tend to go into the water phase if they adsorb water to the practical exclusion of the other liquid; they tend to go into the other liquid phase, if they tend to adsorb the other liquid to the practical exclusion of the water; while the particles tend to go into the dineric interface in case the adsorption of the two liquids is sufficiently intense to increase the miscibility of the two liquids very considerably at the surface between solid and liquid."

Levitation of the selected solid occurs when the specific weight of the system composed of selected solid and oil is less than that of the water or pulp in which it is submerged. The amount of oil theoretically necessary depends, therefore, on the specific gravities of the oil and pulp and the quantity of sulphide mineral to be lifted.

Assuming an ore containing 4 per cent. of mineral having a specific gravity of 5, the amount of oil having a specific gravity of 0.9 theoretically necessary to just float the mineral is 575 lb., if the specific gravity of the pulp is taken as 1.0, *i.e.*, the same as water. The reasoning follows: 4 per cent. of mineral to be floated equals 80 lb. The weight of this mineral in water is $80 - (80 \times 62.5)/(5 \times 62.5) = 64$ lb. or 29,030 gm. Each cubic centimeter of the oil assumed weighs 0.9 gm. and can buoy just less than 0.1 gm. submerged weight of mineral. It requires, then, to lift 29,030 gm. of mineral $29{,}030 \times 10$ or 290,300 cc. of oil, which is 76.7 gal. or 575 lb.

Practically, the oil is not completely utilized in levitation, some gangue is raised, some mineral is lost, and finally air is entrained in the process of mixing the oil and this entrained air aids levitation markedly. The net result is that less than the theoretical quantity of oil is necessary.

Oil-flotation processes may be grouped as dry-oiling and wet-oiling, depending upon whether the oil is added to dry or moist ore or to an aqueous pulp; and further with regard to whether any special means is employed to increase the viscosity of the oil.

Elmore wet-oiling oil-flotation process (643,340; 676,679 and 689,070/1901; 692,643/1902) is the best known of the oil-flotation processes. The operation consists in first producing a freely-flowing pulp by mixing pulverized ore with water in the proportions of 6 to 10 of water to 1 of ore, by weight; adding thereto a relatively large quantity of oil, up to more than a ton of oil per ton of solids; adding also sulphuric acid; mixing the ingredients in a trough provided with stirring blades on a horizontal shaft; then passing the mixture to a spitzkasten. The pulp level in the spitzkasten is kept at such a height that a slight overflow of pulp liquor is maintained. Under these circumstances the oil layer on the surface of the pulp should be one-half inch or less in thickness. The mixing should be so limited in violence as not to break the oil into minute globules. Oil is recovered from concentrate by washing with solvents, filtration, centrifugation, etc. The actual oil loss per ton of ore is said to have been between 10 and 20 lb. per ton of ore treated.

Other wet-oiling oil-flotation processes using non-thickened oils are described in the following patents:

Glogner (736,381/1903). Treatment of gravity graphite concentrate. Pulp containing 25 to 33 per cent. solids is thoroughly stirred in a closed vessel with petroleum in an amount equivalent to 50 per cent. of the graphite by weight. The mixture is then sprayed with water, allowed to stand for settlement, and finally skimmed to remove the floating graphite.

Orr (758,464/1904). Pulp mixed with oil by agitation of a water wheel and by flow in a pipe is discharged upwardly by a submerged pipe in a spitzkasten. Overflowing oil with concentrate is filtered through charcoal or similar medium, the oil being returned to the system.

Schwarz (766,289/1904). Pulverized ore mixed with water or saline solution is introduced gently onto the surface of oil floating on further saline solution in a tank. Gangue passes through the oil-solution interface and sulphide remains in the oil or at the interface.

Kendall (771,075/1904). Freely-flowing pulp is mixed with thin oil by causing the two to flow under pressure through perforated plates. The mixture is discharged as a thin sheet at considerable velocity beneath the surface of water in a spitzkasten. Oil with mineral overflows and gangue is discharged at the bottom.

Tunbridge (777,159/1904). Passage of aqueous pulp through a layer of oil and subsequently through a perforated septum which removes oil-mineral aggregates and passes unoiled gangue and water.

Orr and Finley (790,913/1905). Vertical passage of aqueous pulp, subdivided into drops by falling through a screen, through a horizontally-moving layer of oil floating on a body of pulp. Removal of mineral from the oil by filtration through a blanket and charcoal.

Finley (822,515/1906). Passage of aqueous pulp through a layer of oil floating on a body of pulp in a spitzkasten. Separation of concentrate from the oil by filtration.

Kirby (809,959/1906). Agitation of freely-flowing pulp with a solution of bitumen in a thin distillable hydrocarbon liquid such as kerosene, in such a way as to break the oil into small globules and bring them into contact with the mineral particles; followed by settlement, aided by gentle agitation with sub-surface injection of gas and fine streams of oil; skimming of oil with concentrate; finally, distillation of the oil from the solid. Gas undoubtedly aids levitation.

Elmore, A. S. (865,334/1907). Mixing aqueous pulp with oil in a centrifugal pump and circulation through the pump and a tank that is oil-covered to prevent oxidation of the metallic minerals.

Dunstone (956,800/1910). Aqueous pulp agitated violently with acid (about 1 per cent. on the solid) then with a light mineral oil (4 times as much in bulk as the solid) until an emulsion containing the metallic particles is formed. This is skimmed and settled to drop the metal.

Reed (1,262,984/1918). Aqueous pulp flowed against the under side of a stratum of oil held in place by baffles in a shallow trough.

Rideout (1,562,125/1925) describes the use of a kerosene emulsion made with water, sodium bi-carbonate and potassium carbonate for use in separating molybdenum.

Wet-oiling oil-flotation processes using thickened oils are described in the following patents.

Scammell (770,659/1904). Aqueous pulp agitated with oil (heavy petroleum, animal, vegetable or fish oil) that has been treated with chloride of sulphur. The extent of thickening should be increased with increase in mineral content of the ore.

Wolf (787,814/1905). Like the preceding with the addition that enrichment of oily concentrate is effected by passing the same through warm water. A method of recovering oil from waste pulps by blowing air through them is mentioned.

Dry-oiling oil-flotation processes with non-thickened oil, including those processes in which the ore is more or less moistened but not in the form of a freely-flowing pulp before oiling, are described in the following patents.

Robson (575,669/1897). Moistened ore in soft and plastic state, *i.e.*, with say, 25 to 35 per cent. water, is agitated with an oily liquid, the mixture is allowed to stratify in a separating vessel, the oily concentrate is drawn off and the solid separated from the oil.

Wolfe (725,609/1903). Dry ore mixed with oil is fed onto a layer of oil floating on brine thickened by clay or other earth. Metallic mineral adheres at the oil-brine interface in the separating vessel and gangue sinks. Clayey brine increases the buoyancy of the concentrate.

Darling (795,823/1905). Dry ore is mixed with oil (petroleum), the mixture is suspended in water by agitation and flowed to a screen, which separates the buttery mass of mineral and oil from non-agglomerated gangue and water.

Latimer (851,599 and 851,600/1907). Dry ore is mixed with oil, the mixture suspended in water by rotary agitation in a cylindrical vessel sufficient to cause centrifugal forces that will bring about some segregation of solid from liquid, and the suspended mixture is then subjected to hydraulic classification in the agitation vessel. The oiled mineral rises on the periphery while gangue sinks.

Seinsche (1,335,612/1920). Dry ore is fed onto a belt conveyor previously fed with oil. The oiled ore is discharged by the belt onto the surface of acidified water. Oiled mineral floats, gangue sinks. There is considerable skin flotation here.

Dry-oiling oil-flotation processes with thickened oil including those processes in which the ore is more or less moistened before oiling but not

brought to the state of a freely-flowing pulp, are described in the following patents.

Everson (348,157/1886). Ore is dry-mixed with a gelatinous, probably collodial, mixture of water with a sulphonated fatty oil. The mixture is subsequently worked, by slow churning or squeezing in acidified water. This causes the gangue to be dropped and leaves buttery masses of oily matter and mineral of specific gravity roughly between one and two. These may be separated from the pulp by any gravity method. A second method described utilizes untreated oil and considerable agitation. In the second method gas undoubtedly aids levitation.

Schwarz (771,277/1904; 807,501 to 807,506 incl./1905; 825,080/1906; 842,255/1907). A series of patents describing the mixing of oils, temporarily thin, such as melted hydrocarbons that are solid at normal temperatures, with moist or dry pulps by agitation; subsequently adding water, with further agitation and with or without the injection of air or steam; collecting a concentrate as a floating, more or less solidified and more or less gasified mass, and separating the same from the balance of the pulp by skimming.

FROTH FLOTATION

Froth flotation comprises two entirely different types of processes which resemble each other only in the fact that in both the concentrate is removed in the form of a froth or foam composed of gas, liquid, and solid matter which is preponderantly one of the minerals or classes of minerals. In the early days the mineral that was floated was mineral of metallic luster but greater knowledge of controlling conditions has now made it possible to float other kinds of mineral. The processes differ fundamentally both in the place in which concentration is done and in the mechanism of the selection of sulphide from gangue. On the basis of the first difference the processes may be classified as pulp-body processes and bubble-column processes.

PULP-BODY PROCESSES

These processes may be subdivided, on the basis of the method of introducing the bubble-making gas, into four types: (1) chemical-generation, (2) pressure-reduction, (3) boiling, and (4) agitation. All four types depend upon the fact that in a pulp, the liquid part of which is saturated with a gas, preferential precipitation of the gas onto particles of one particular class can be brought about by so changing the conditions that the liquid is supersaturated with respect to the surfaces of particles of this class. Preferential precipitation of gas from the supersaturated liquid is enhanced, if the mineral particles are coated with a film of some organic substance, and the presence of such a coating also makes the force of adherence between the precipitated bubbles and sulphide particles greater. As a result of preferential precipitation of gas on certain particles in the pulp, and its adhesion thereto, agglomerates consisting of one or more gas bubbles with mineral particles firmly attached to them are formed in the body of the pulp. These agglomerates later rise to the surface in the form of a froth which is separated as concentrate.

4. Chemical-generation process

This process depends upon chemical action of some kind to generate gas in the pulp. In some methods, as, for instance, the electrolytic, a part of the gas, at least, generates at the surface of the metallic minerals. In others, as the Froment, it generates at the surface of non-metallic minerals, goes into solution, and later precipitates preferentially at the surface of particles of sulphide mineral.

Potter-Delprat process (735,071/1903; 763,662/1904; 768,035/1904; to Delprat and 776,145/1904 to Potter) is the first commercially successful froth-flotation process applied to sulphide ores.

Dewatered pulp is fed into an apparatus of the type shown in Fig. 9. Hot sulphuric-acid solution of 1- to 10-per cent. strength or acid salt-cake solution of 1.3 to 1.4 density is introduced through the pipes (*a*) to the bottom of the vat. A layer of solids 2 ft. or more in height, depending upon the depth of the vat, is maintained in teeter above the spigot. Gas is precipitated as bubbles onto the sulphides and the bubbles rise to the surface with a load of sulphide, forming there a coherent froth, which overflows. The tailing is drawn off as a thickened product from the spigot at the bottom of the box. The compartment without a spigot is for the purpose of collecting any coarse particles that would tend to clog the spigot. With ores that contain carbonates, as do most of the ores at Broken Hill where this process was invented and practiced, it is probable that most of the effective gas is carbon dioxide. Air and water vapor will, however, precipitate in sufficient quantity, under the conditions of the practice of the process, to float the sulphide effectively in the form of a coherent froth, when treating ores containing no carbonates. No oil is added. On theoretical grounds it is questionable whether the process will work on an otherwise suitable ore if there is no organic material present, but there is no doubt that the lubricating oil introduced in ordinary mining operations, amounting in general to 0.05 to 0.1 lb. per ton of ore, is sufficient to cause successful practice of the process.

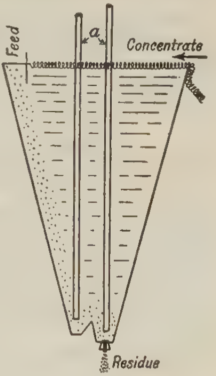

Fig. 9.—Delprat frothing box.

Performance of Potter-Delprat process (*Deposition of Leslie Bradford, M.S.N.A. Corp. and M.S., Ltd., vs. Magma Copper Co.*; *117 P 375*). The principal use of this process was at the Broken Hill Proprietary mine, N.S.W., from 1903 to 1917. The early work was in a shallow, sloping-bottom pan heated on the bottom by an open flame. About one long ton per hour was treated in a pan 3 × 6 ft. in area and about 2 ft. 6 in. deep. Feed was de-slimed tailing from the gravity-concentrating mill, practically all of which would pass a 40-mesh screen and from 20 to 25 per cent. remain on 60-mesh. The gangue was principally quartz, rhodonite and garnet with some gneiss from the walls and small amounts of rhodocrosite, siderite and calcite, totaling about 0.5 per cent. CO_2. Acid salt-cake ($NaHSO_4$) solution of about 1.3 specific gravity, heated to about 190° F. in stock-solution tanks by the use of superheated steam was mixed with the moist ore (6 to 9 per cent. H_2O) in the tank. Feed assayed about 17 per cent. Zn, 3 per cent. Pb and 4 oz. Ag per long ton; concentrate, 40 to 42 per cent. Zn, representing about 80 per cent. recovery. By 1904 apparatus similar to that shown in Fig. 9 was in use. The first boxes were 4 ft. × 4 ft. 6 in. in surface area and about 6 ft. deep, made of wood lined with sheet lead. Solution pipes were cast iron, tipped for 2 ft. 6 in. with 2-in. lead pipe drawn down at the end to ½-in. and perforated near the end with ¼-in. holes. Capacity was 10 long tons per hour. Other operating conditions and the results were approximately the same as above. The final installation used larger boxes of cast iron, 8 ft. × 9 ft. surface area, 2 ft. × 1 ft. at the bottom, and 15 ft. deep; 1-per cent. sulphuric-acid solution was substituted for the salt cake. The capacity of the larger boxes was 10 to 20 long tons per hour. Recovery occasionally got up to 90 per cent. but the general average was 80 per cent. Grade of concentrate was worked up to 48 to 49 per cent. Zn, 6 per cent. Pb and 10 to 12 oz. Ag. Concentrate was about 8 per cent. on 40-mesh and 17 per cent. −200-mesh. Tailing assayed 3 per cent. Zn, 2 per cent. Pb, 2 oz. Ag per long ton. Three to 3.5 tons of solution were added per ton of ore, entering under a pressure of approximately 15 lb. per sq. in.; acid consumption, including 1 to 2 lb. per ton of original feed discarded with the tailing, was 25 to 30 lb. per ton; strength of solution returning to stock tanks, 0.6 per cent. acid. Temperature of the incoming solution was 190° F., of solution in the frothing boxes, 165° F.; and of solution drained from concentrate and returned to the stock tanks, 145° F.

The purpose of de-sliming was to get high-grade zinc concentrate. Slimes assayed 17 per cent. Zn, 14 per cent. Pb and 14 oz. Ag as compared with the sand assay given above and concentrate from treatment of mixed sand and slime assayed 32 to 33 per cent. Zn, 22 to 23 per cent. Pb and about 30 oz. Ag. This concentrate could not be sold to advantage. Lead slimes were, therefore, dried in the open, heap-roasted, and smelted direct. Elimination of slimes made possible the high capacity of the frothing boxes, since slime treatment by this process requires long digestion of the pulp with hot acid solution in order to

float the slime mineral and, in fact, before high recoveries of the coarser material can be effected.

At this same plant slime-feed was concentrated with heated (140° F.) acid solution (0.3 per cent. H_2SO_4) without oil by sending the pulp through a series of four centrifugal pumps and separating boxes in alternate series. Concentrate assayed 34 per cent. Zn, 25 per cent. Pb and 40 oz. Ag; tailing, 4 per cent. Zn, 9 per cent. total Pb (8 per cent. oxide) and 4 oz. Ag. Plant capacity was 3000 tons per week.

Other apparatus designed for the practice of this process is described in patents 763,749/1904 and 784,999/1905, to **Goyder and Laughton**; and 778,747/1904, and 780,281/1905, to **Gillies.**

Froment process was patented in 1902 in Italy and Great Britain but was not patented in the United States.

Finely-pulverized ore with 1 to 2 per cent. of limestone is fed into a mixer in a pulp containing about 30 per cent. solids; animal or vegetable oil in an amount equivalent to from 1 to 1.5 per cent. on the ore is added and the mixture agitated at the rate of 1000 to 1500 ft. per min. peripheral speed. The agitated mixture is next run into a shallow vat provided with a slow-moving rake at the bottom. Sulphuric acid of about 30 per cent. strength in an amount sufficient to react with the limestone present is slowly added through a perforated coil suspended just above the rakes. Gas precipitates preferentially on the oiled-sulphide surfaces and forms aggregates of gas bubbles and mineral that rise to the surface and are removed in the form of a coherent froth. De-sliming of the feed aids in making clean concentrate, but is unnecessary with certain oils or if a small amount of acid is added in the mixing vat.

The Froment process never went into commercial operation. Results of tests in a laboratory apparatus are given in Table 6.

Table 6. Results of laboratory operation of Froment process

Sanders (805,382/1905 and 911,077/1908). Pulverized ore is agitated at a rate insufficient to beat in air in a non-acid solution, preferably heated, having a specific gravity of 1.15 to 1.25 and capable of reacting with the ore with evolution of gas. Aluminum sulphate and ferric sulphate are named for making the solution. In 988,737/1911, Sanders describes removal of calcite from calcitic ores prior to flotation with non-acid and with acid solutions.

Greenway (1,045,970/1912) describes a process that is essentially the Potter-Delprat except that dry or moist ore is oiled before addition to the flotation machine. This treatment stiffens the froth.

Leuschner process (*93 J 924*) as practiced at the Friedrichssegen and Ludwigseck mines in Germany was an operation of the Froment process in which oiled pulp containing carbonates was treated in a sulphuric-acid bath of 1 to 2° Bé. at 60 to 80° C. At Friedrichssegen the feed was – 1-mm. and contained 10 to 15 per cent. Zn. Concentrate contained 47 to 50 per cent. Zn and tailing 0.3 per cent. Oil consumption was 4 to 6 kg. per ton.

Electrolytic chemical-generation process was first described by **F. E. Elmore** in British patent 13,579/1904. In this process the water of a freely-flowing oiled pulp is decomposed by an electric current, gas precipitates preferentially on the sulphides and the mineral-coated bubbles rise and form the typical coherent froth.

Lockwood (1,329,127/1920). Ores whose metalliferous particles are capable of conducting electricity are passed through, over or between cathode and anode surfaces closely spaced so that the particles become temporarily anodes and cathodes on which hydrogen or oxygen or both from the decomposed water precipitate. Oxidized metallic particles are to be coated with oil containing ground conductors, such as sulphides, before treatment. Various forms of apparatus are illustrated.

Theory of the chemical-generation process. The actual phenomena involved may be seen clearly in the following experiment.

De-slime about 20 gm. of a silicious ore of fairly high mineral content (say 15 per cent. zinc ore) drain, mix in about 1 gm. of similarly sized limestone, add 1 or 2 drops of oleic acid and mix thoroughly. Make a small heap of the oiled ore in a shallow dish, cover with water, place a low-power microscope for observation from above, then add slowly, at a short distance from the ore, a few drops of concentrated sulphuric acid. As soon as the acid diffuses to the solid, gas bubbles may be seen to form and grow at the surfaces of both carbonate and sulphide particles. Those forming at carbonate surfaces detach and rise to the surface without any solid load. Those that form at carbonate surfaces down in the heap can be seen to push through slowly, throwing aside indiscriminately the gangue and sulphide particles with which they come in contact, and rising to the surface unloaded.

The phenomena producing the attachment of gas to sulphides are: (*a*) generation of gas at the carbonate surfaces; (*b*) solution of some of the gas in the water; (*c*) travel of this solution by diffusion and by reason of the stirring by rising bubbles until a sulphide surface is reached, and (*d*) precipitation there by reason of the fact that the solution is supersaturated with respect to such surfaces.

The same phenomena can be observed by placing individual pieces of, say, quartz, galena and calcite in a small cell under a projecting microscope magnifying 200 to 300 diameters, spacing the pieces at the points of a roughly equilateral triangle whose sides are several times the diameter of the pieces. Upon addition of acid, bubbles can be seen rising from the calcite, but none of these approach the other minerals. Shortly, however, numerous gas bubbles begin to grow on the galena while only rarely is a bubble to be seen on the quartz. In this experiment rapidity of precipitation and tenacity of adherence of bubbles are enhanced by previous oiling of the solids, but oiling is not ordinarily essential to the behavior described.

Formation of heavily-coated bubbles takes place by coalescence of lightly-loaded bubbles. Such coalescence results in reduction of bubble surface and consequent more complete covering of the surface of the resulting bubble by the double load.

5. Pressure-reduction process

Gas precipitation is brought about by reducing the external pressure upon a pulp that is saturated with gas. Processes utilizing this phenomenon are of two types, involving respectively pressures in excess of atmospheric (PLUS-PRESSURE) and less than atmospheric (VACUUM).

Plus-pressure process

Sulman, Picard and Ballot (835,479/1906). Pulp, oiled or otherwise, is pumped into a pressure tank and there subjected to a gas pressure of from 50 to 100 lb. per sq. in. for a sufficient time to allow saturation with gas. Pressure on the pulp is then released, when gas from the now supersaturated pulp precipitates preferentially on the metallic-mineral sur-

faces. The mineral-coated bubbles rise and form the characteristic coherent froth at the surface of the pulp. (See also 835,120/1906.)

Norris (864,856 and 873,586/1907; 1,167,835/1916). Water saturated with gas at a pressure well above atmospheric is discharged into an oiled pulp at atmospheric pressure. The result is the same as in the preceding process.

Vacuum process

F. E. Elmore (826,411/1906). Pulp, mixed with a small quantity of oil, and acid or alkali if necessary, is passed into a vacuum apparatus. Under the reduced pressure the water is supersaturated and gas precipitates preferentially on the oiled sulphide minerals and raises them to the surface as a coherent froth.

As practiced in the mills, the process was operated in a plant such as is shown in Fig. 10. Pulp ground to at least 0.5-mm. maximum size and containing about 50 per cent. solids was mixed in a tank (d) with oil in an amount generally less than 0.5 per cent. on the ore, with or without acid, and thence was discharged into the feed pipe (a) of the separating apparatus. Here water was added to bring the pulp to a consistency of 15 to 25 per cent. solids. The separating apparatus was a closed conical chamber fitted with a slowly revolving rake at the bottom, a tailing-discharge pipe (b) at the periphery and a concentrate-discharge pipe (c) from near the apex. The separating chamber was attached to a vacuum pump. The lower ends of pipes (b) and (c) were sealed by causing them to discharge below the surface of liquid in tanks as shown. The vertical lift in the pipe (a) was about 25 ft. and the vertical length of the pipes (b) and (c) was somewhat over 30 ft. A vacuum of 20 to 27 in. of mercury was maintained. Under the influence of this vacuum the pulp fed into pipe (a) passed up into the separating chamber. Here air was precipitated at the surfaces of the sulphides and the bubbles raised the particles through the liquid in the separator to the apex where they overflowed into an annular launder and passed down pipe (c). At the same time the tailing was slowly scraped to the periphery of the floor and passed down pipe (b). The rate of flow in pipes (a) and (b) was so regulated that the pulp level was maintained slightly below the overflow lip.

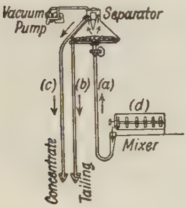

Fig. 10.—Elmore vacuum plant.

The capacity of a 5-ft. separator was from 25 to 50 tons of ore per day. Re-treatment of concentrate was not ordinarily necessary. Power consumption per pan was well under 5 hp. for mixer and vacuum pump together.

	H_2SO_4, 0.18 per cent. solution						

Development of the vacuum process was stopped by the introduction of the agitation-froth process but it is probable that if the same amount of work had been expended in attempts to make the vacuum process highly efficient, as was spent in bringing the agitation-froth process to its present degree of efficiency, the results wouldhave been equally favorable. Slimes are easily treated, if sufficient agitation with proper agents precedes the vacuum treatment, but granular sulphide is most easily treated out of the presence of slime. Table 7 presents results attained in the laboratory. The copper ore was of much lower sulphide content than the zinc, which to some extent explains the poorer recovery. Table 8 is a summary of parts of mill operations extending over several months. Mixing was performed in the apparatus shown in Fig. 10 at about 50 per cent. solids. Sizing-assay tests on composites of the feed and products of the run shown on the last line but one of Table 8 are given in Table 9. Improvement in metallurgical result should follow finer grinding, although the small amount of total copper present in the coarser sizes might not pay the increased grinding cost.

At Zinc Corporation (*88 J 205*) the feed to vacuum machines contained 20 per cent. Zn, 5.75 per cent. Pb and 8 oz. Ag per long ton. Concentrate assayed 43 per cent. Zn, 11 per cent. Pb and 17 oz. Ag.; tailing 3.5 per cent. Zn, 2.2 per cent. Pb, and 2.2 oz. Ag. Acid consumption varied from 10 to 20 lb. per long ton; Texas fuel oil, 6 to 8 lb. per ton. Cost of flotation alone (1909) was \$0.55 to \$0.60 per ton. Claudet (*103 J 786*) says that a standard unit will treat 35 tons of − 10- or − 20-mesh molybdenum ore per 24 hr., using a small quantity of coal oil (kerosene) and that molybdenite floats preferentially to pyrite and pyrrhotite. Slime is overflowed before flotation. At Kvina mines, Norway (*19 CMI 127*) feed assaying 0.8 to 1.0 per cent. MoS_2 produced concentrate containing 75 to 85 per cent. MoS_2, representing 80 per cent. recovery.

Schiechel (1,212,566/1917) recommends a number of vacuum machines in series, with vacuum increasing from first to last.

Callow (1,176,428/1916). Use

of a partial vacuum over a flotation pulp, but the flotation accomplished is not the work of the reduced pressure and the process is not pulp-body type.

Colburn and Colburn (1,226,062/1917; re-issue 14,497/1918; 1,226,063/1917; 1,415,314/1922). In an agitation-froth process, agitation of the pulp in a partial vacuum in the chamber of a centrifugal pump. This is nothing more than a statement of the known conditions existing in centrifugal pumps and is no departure in principle from other agitation-froth machines, as will be seen later.

Eldred and Graham (1,515,942/1924). A vacuum apparatus for use with unoiled carbonaceous pulps, especially graphite, so arranged that the floated particles, upon reaching the pulp surface and losing their bubbles sink again and are caught in a concentrate-receiving compartment that discharges through a barometric leg.

6. Boiling process

This process uses heat to cause supersaturation and selective precipitation of gas from the water of a pulp, with the usual coherent-froth formation. The phenomenon is effective both with and without added oil. Actual boiling is not essential.

Potter-Delprat process (Art. 4) is strictly a boiling process, although as operated in Australia it was a chemical-generation process.

Sulman (835,143/1906). Pulp, oiled by agitation, and with or without acid, is heated to a high temperature. The process works best with de-slimed, highly-mineralized ores. It is not economical and has not found commercial application.

7. Agitation-froth process

This process depends upon local supersaturation of the water of a pulp with air by the mechanical action of a swiftly revolving beater, and the simultaneous preferential precipitation of the air in the form of bubbles on the metalliferous particles. Agitation-froth machines consist essentially of an agitation chamber in which a stirrer mounted on a vertical spindle rotates

at high speed, and a froth-separating compartment in which the pulp is allowed to come to rest and the bubbles carrying the metalliferous mineral rise to the surface to form a froth which is skimmed off. The pulp in the agitating compartment, under the influence of the rotating agitator, is thrown from the center toward the side of the chamber. The result is that the surface of the pulp assumes the shape of an inverted cone. When the cone becomes so pronounced that the tip reaches down to the revolving beater arms, the tip is cut off and a large bubble of air is entrained. This bubble is immediately broken up into a large number of small bubbles by the direct impact of the impeller arms and by the violent swirling of the pulp. These bubbles, due to their minute size, are in the most favorable state to be taken into solution, and many of them are, at the time of their formation, subjected to considerably more than atmospheric pressure, due to the impact of the impeller blades. They have, also, on account of their small size, but slight vertical motion relative to the pulp mass, and are, therefore, kept for a comparatively long time in contact with the water and subject to the impact of the impeller blades. As a result, some of the air goes into solution in the water. At the same time there exists behind each impeller blade a volume of pulp on which the pressure is reduced by reason of the forward movement of the blade and the inertia of the pulp mass. Here air comes out of solution at the surfaces of the sulphide particles in the form of bubbles. The excess bubbles that never go through the solution stage, in this, as in the other pulp-body concentration processes, in part coalesce with the bubbles already formed on sulphide surfaces; in part pass with the pulp into the froth-separating chamber and there, rising, add buoyancy to the froth; in large part, however, they rise to the surface of the pulp in the agitating compartment and are lost to the process.

Theory of the agitation-froth process

Experiments illustrating the various steps in the preceding statement follow.

Gas precipitation by agitation. If a square-glass-jar agitating machine is provided with horizontal baffles fitting as closely as possible around the shaft and against the walls and placed just below the water level, when agitation is started no vortex forms and there is no introduction of air from the surface. If, however, the rate of revolution of the impeller is gradually increased, a speed is finally reached at which the liquid in the vessel becomes cloudy, showing the presence of finely-divided gas bubbles. When agitation ceases, air bubbles collect under the baffle plates. If these bubbles are released by tilting the plates and the impeller is again started, a higher speed must be reached before gas again precipitates, provided the temperature of the water has remained the same. Increase in temperature from 12° C. to 30° C., the heating being accomplished on a water bath without stirring, lowered the critical speed of gas precipitation with a 3-in. impeller from 1535 to 395 r.p.m. When heating to the same temperature was done by an electric heater, on which much gas precipitated during heating, the critical speed was 940 r.p.m. Adding pine oil to the water (0.006 per cent.) lowered the critical speed at 12° C. to 980 r.p.m.

Vacuum produced by agitation. In the apparatus described in the preceding paragraph an opening in the back of one of the beater blades, near the tip, was connected to a vacuum gage by a conduit within the blade and by a hollow shaft with a stuffing box at the top. Pressures were read at different speeds with the results given in Table 10. At the higher speeds the vacua recorded were well below those actually existing, because of the fact that air coming out of solution behind the blades broke the vacuum by passing into the hole in the beater arm.

Effect of agitation on froth formation is shown in Table 11. The critical speed for the laboratory Gabbett apparatus at ± 30° C. lies between 310 and 380 r.p.m., but at this speed the rate of precipitation of gas was so slow that 75 min. was required for frothing to start. At 380 to 420 r.p.m. fair concentration was attainable in 70 min., but at 40 min. it had not started. Compare these results with those in tests 10 to 13, representing the normal speed range for this machine. The speed at which froth production begins corresponds

with that at which gas precipitation begins in the square-glass-jar machine of corresponding size.

Attachment of air bubbles to mineral particles in a pulp. No appreciable part of the froth formed in the agitation-froth process is made by attachment of coursing air bubbles in the pulp to mineral particles therein, but substantially all air-mineral attachment is effected by precipitation of gas from solution onto sulphide surfaces.

Table 10. Suction behind blades of the impeller of an agitation-froth machine

Revolutions per minute of impeller	Vacuum measured, inches mercury	Revolutions per minute of impeller	Vacuum measured, inches mercury

1170	2.9	2610	10.9
1275	3.6		

* Calculated from observations on water gage. Temperature ±20° C.

To prove that lack of froth production in tests 1 to 3, Table 11, was not due to lack of air bubbles introduced at the lower speeds, these tests were repeated with air introduced in very fine bubbles at the bottom of the machine through a carborundum thimble, agitation proceeding as before. No difference in result was observable. Yet with no pulp present the water in the machine was clouded with a myriad of minute air bubbles.

The same failure of coursing bubbles in a pulp to adhere to sulphide particles is shown by another experiment. In a Gabbett mixer, the baffles were held in place by a metal ring fitting against the inside of the glass wall. At places there was sufficient space left for a bubble to catch between the ring and the wall. When this occurred large numbers of par-

Table 11. Effect of agitation on froth formation in agitation-froth process

Laboratory Gabbett-mixer (see Fig. 11). Zinc ore, 18.7 per cent. Zn. 18.8 per cent. solids. Oleic acid, 3.0 lb. per ton; H_2SO_4, 36.6 lb. per ton. (*a*) Degree indicated by change in color of settled solids from gray to white and actual appearance of agglomerates.

ticles of both gangue and sulphide could be seen to shower against the stationary bubble (this was particularly easy of observation with a de-slimed ore), but no particles adhered on a direct hit. Occasionally particles were caught in the solid angles formed between the bubble and the walls of the machine, and some of these eventually were pressed sufficiently hard against the bubble by the weight of the particles above, and held there for sufficient time, to effect attachment, so that when they eventually slid around the bubble they adhered to the bottom. But such particles formed an infinitesimal minority of the particles presented at the bubble surface by the swirl of the pulp.

The froths produced in pulp-body concentration processes are small-bubble, coherent and persistent, and characteristic. The volume of gas effectively utilized in floating the mineral is of the order of 20 to 50 cu. ft. per cu. ft. of solid floated. There is marked concentration of oil in the froth.

At Utah Copper Co. oil analyses of the feed and products of a Janney mechanical machine gave results shown in Table 12.

Table 12. Distribution of oil in products in agitation-froth process

Oil (*a*) added per ton, pounds	Oil analyses, pounds per ton			
	Feed (*b*)	Concentrate	Middling	Tailing
1.65	0.71	11.67	....	1.40

a 89 per cent. fuel oil, 10 per cent. coal-tar creosote, 1 per cent. pine oil. *b* Sampled ahead of point of oil addition. Contained oil is from circulation of middling.

8. Apparatus for agitation-froth process

The agitation-froth process was first introduced commercially in 1906, in Australia, but the results there obtained were little, if any, superior to those attained by the Potter-Delprat, DeBavay and Elmore vacuum processes, working on the same ores, and it was not until after the invention of the Hoover apparatus (953,746/1910) that the process became in any way dependable or generally useful. Patents have been issued covering a great variety of apparatus and reagents for the practice of the process. The principal apparatus are arranged below. For reagents recommended see Art. 16.

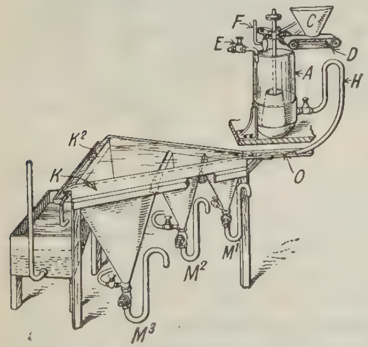

Fig. 11.—Apparatus for process of patent 835,120 (from patent drawing).

Sulman, Picard and Ballot (835,120/1906). Pulp with oil in an amount less than 1 per cent. on the ore, with or without acid and with or without added heat, is agitated with such intensity and for such a period of time as will result in passing through solution in the water and precipitating preferentially on the metalliferous mineral a sufficient volume of gas to float the major portion of the mineral. If the agitation is insufficient in intensity to cause gas precipitation, although sufficient to entrain air, no duration of agitation will be sufficient to cause flotation. The oil used must be to some extent soluble in the water of the pulp in order to spread at air-water interfaces and reduce surface tension. If it does not spread or reduce surface tension (the alternative expressions are equivalent in this connection) no frothing and hence no concentration result.

Apparatus described by the patent is shown in Fig. 11. Dry ore was fed into the agitat-

ing vessel (A) by belt (D) from hopper (C) together with oil from pipe (F) and water and acid from pipe (E). Following agitation, the aerated pulp was discharged through pipe (H) and passed in a thin sheet over apron (O) into spitzkasten (K) fitted for introduction of "hydraulic" water in the several compartments. (See Sec. 6, Art. 1.) Froth overflowed the lip (K^2) and tailing of increasing fineness was discharged from goose-necks (M^1), (M^2) and (M^3), in order. This apparatus is effective only on highly mineralized ores with oils that form heavily-loaded bubbles and the stiffest kind of coherent froth. It fails utterly to produce more than film flotation under other circumstances, because of the fact that the froth is broken up by surface tension at the large free-water surface on the apron and spitzkasten. For commercial apparatus see Fig. 14 and the descriptions therewith.

Hoover (953,746/1910). Fig. 12, taken from the patent, is sufficiently explanatory of the principle of the apparatus. (D) and (E) are oil and acid cans respectively. The stirrers operate at 1200 to 1800 ft. per min. peripheral speed. The close coupling of the agitation chamber with the spitzkasten and feeding of the agitated and aerated pulp below the surface of the pulp in the spitzkasten were the secrets of the success of this apparatus.

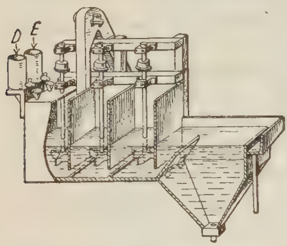

FIG. 12.—Hoover apparatus for agitation-froth process.

Hoover (979,857/1910) described an apparatus for the necessary re-treatment of tailing from the first flotation operation. This apparatus is shown in Fig. 13. Unfinished tailing or middling from the first spitzkasten (O') is pumped through pipe (Q') into agitating compartment (L^3) and, after agitation, passes through the slot shown into another agitating compartment (L^4) and thence into spitzkasten (O^2) for further froth separation. This retreatment is multiplied as many times as desired by multiplication of agitating compartments and spitzkasten. Pulp is maintained at a constant level in all the spitzkasten by the pipes (R), equalizing tank (S) and overflow pipe (S'). Any deficit of water is made up from faucet (T).

This patent has all of the essential elements of the present standard Minerals Separation machine except the mechanical froth skimmers which do away with the necessity for maintaining a pulp overflow from the spitzkasten. Many variations in the baffle over the inlet from agitation chambers to spitzkasten have been used and many forms of impeller. These are illustrated in part in the following figures.

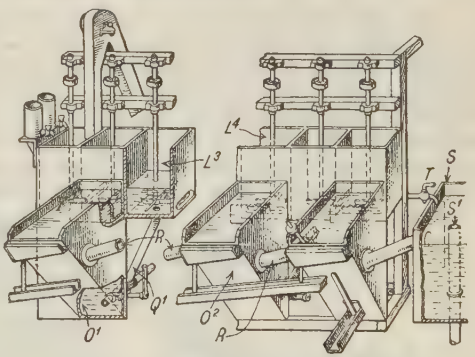

FIG. 13.—Hoover apparatus for repeated treatment.

Minerals Separation machine is shown in Fig. 14. The machine is installed as shown in the figure with agitators and froth-separating boxes on the same level. It consists essentially of the agitating compartment (a) and froth-separating compartment (b). The agitator, which is of the four-armed cross-type, with blades inclined 45 degrees, is placed close to the bottom of the agitating compartment and is carried on a vertical spindle (c), driven through enclosed bevel gears from a horizontal line shaft. End thrust is lessened by opposing the bevel gears on the shaft. Noise and power consumption are decreased by using bronze gears. Feed pulp is introduced into the first agitating compartment, or may be passed first through one or more agitating compartments, without froth-separating boxes, corresponding to the emulsifiers of the Janney machine. The pulp, after agitation and aeration, is thrown out through the

slot (*d*) into the froth-separating compartment, entering at a point about six inches below the pulp level. The tailing from the froth-separating compartment passes through pipe (*e*) into the bottom of the next agitating compartment, under the influence of the pumping effect of the agitator therein. The rate of flow is regulated by means of valve (*f*) actuated by hand wheel (*g*). Froth is removed by means of the revolving scraper (*j*). From 6 to 20 agitating compartments in series, each with one froth-separating compartment, comprise a unit.

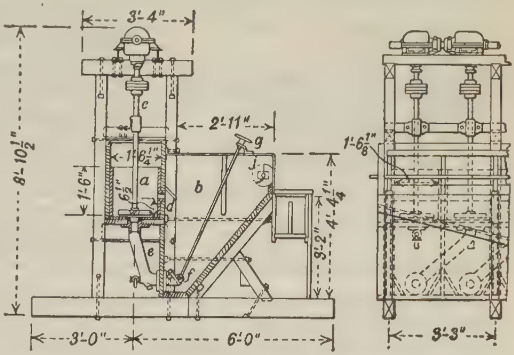

Fig. 14.—Minerals Separation 12-in. standard machine.

The size of a unit is indicated by the distance tip to tip of the impeller blades and the number of compartments in series. The usual impeller sizes are 12-in., 18-in., and 24-in. These machines have rated capacities of 50 tons, 300 tons and 600 tons respectively per 24 hours on silicious ores in pulps containing 25 per cent. solids. Average actual capacities are about 2, 12, and 25 tons per cell per 24 hours on such a pulp, with a diminution in capacity with decrease in percentage of solids about proportional to the increase in volume of pulp. The power consumption per agitator is 1.5 to 3 hp., 2.5 to 5 hp., and 3.5 to 10 hp., for the three sizes respectively, depending upon the speed of the impeller and the tonnage of pulp passed through. The usual peripheral speed is from 1500 to 1800 ft. per minute. The so-called low-level machines, which carry a relatively low pulp level, consume about 60 to 70 per cent. as much power as the standard machine.

Impellers are made of cast iron, cast steel, manganese steel or, in cases of acid copper pulps, of brass or bronze. Life ordinarily is from six months to two years. The agitating compartment is lined with hardwood or cast iron. Life of liners is usually between one and three years.

The minimum of attendance necessary is illustrated by practice at Anaconda and Inspiration. At the former mill four men handle eight M.S. standard machines treating 3000 tons copper ore per 24 hr. At Inspiration one man could handle two 800-ton sections containing two 10-compartment and four 6-compartment machines. (*56 A 677.*)

Performance. At Reocin mines, Spain (*115 J 398*) a 12-in. 12-compartment standard machine at 500 r.p.m. consumed 17 hp. when treating 200 tons per 24 hr. This is 11.8 tons per hp. or 1.52 kw.-hr. per ton. At St. Joseph Lead Co., Leadwood mill (*57 A 433*), one 23-cell 24-in. standard machine at 335 r.p.m. consumed 83 hp. and treated 540 tons per 24 hr., making 6.5 tons per hp. or 2.7 kw.-hr. per ton. At Federal Lead Co. (*57 A 374*) a local form of M.S. machine with 24-in. agitation compartment and 18-in. agitators consumed 4 to 4.5 hp. per spindle at 280 r.p.m. Increase in speed increased extraction somewhat but increased power consumption out of all economical proportion. Twelve to 24 compartments in series were used. At Mount Morgan, Australia (*102 J 755*) a 6-compartment 24-in. standard machine drew 55 to 60 hp. at 295 r.p.m. when treating 100 tons per 24 hr. of −48-mesh pyritic copper-gold ore or 10.8 kw.-hr. per ton. At Calumet and Hecla (*108 J 9*) a 16-cell 24-in. standard machine handles 400 tons of thickened mill slime per 24 hr. At Suan Concession, Korea (*119 P 843*) 250 tons per 24 hr. was sent through one 8-compartment 24-in. primary rougher, the first compartment having no spitzkasten. Stirrers were 21 in. tip-to-tip, driven at 285 r.p.m. by a 60-hp. motor, or 4.3 kw.-hr. per ton. A froth paddle of 6-in. radius made 24 r.p.m. It required 18 to 25 min. for pulp to pass through the machine. Crowding boards were used on the last three spitzkasten. Froth from the first six boxes went to an 8-compartment 18-in. cleaner with 12-in. stirrers driven at 390 r.p.m. and consuming 15.7 hp. The time required for pulp to pass this machine was 18 to 30 min. Total power consumption in flotation alone (1917) was 6.537 kw.-hr per ton. At Catemu (*123 P 928*) a 12-compartment 18-in. machine drew 30 hp. when treating 75

tons of slime per 24 hr. or 7.2 kw.-hr. per ton. At Swansea, Ariz., a 16-cell, 18-in. low-level machine required 3.4 hp. per spindle.

Smith (1,056,952/1913). Launder devices for regulating feed and discharge of spitzkasten.

Smith (1,058,111/1913). Agitator on horizontal shaft in enclosed chamber. See Fig. 15.

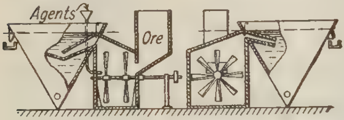

Fig. 15.—Horizontal-shaft agitation-froth machine (*Smith*, U. S. pat. 1,058,111, 1913).

Hebbard (1,064,209/1913). Multiple, staggered-spitzkasten, single-level, non-circulating, vertical-spindle machine.

Broadbridge and Howard (1,084,096/1914). Multiple agitators, two to a spitzkasten, single-level, non-circulating, vertical-spindle machine. Partitions between spitzkasten are submerged beneath the pulp surface allowing a continuous froth layer over all spitzkasten. Not used commercially.

Howard (1,084,210/1914). A variety of forms of vertical-spindle impellers and of methods of baffling in the agitation compartment to increase turbulence. No commercial forms.

Janney (1,167,076/1916). Multiple, pyramid, circulating, vertical-spindle machine. This is the best of the agitation-froth machines. Fig. 16 shows it in the form introduced in the mills. It consists essentially of an agitating compartment (*a*) with two froth-separating compartments (*b*). In the usual and best form the agitator shaft is an extension of the spindle of a 6-hp. vertical motor, 570 r.p.m. It carries two four-armed impellers with blades set at 45°. The agitating compartment is circular and contains four baffles extending slightly more than one-half the distance from the bottom toward the top. The arms of the lower impeller are shorter than those of the upper in order to clear these baffles. Feed is introduced through the side of the agitating compartment, near the bottom, by means of a pipe; is thrown out through the channels at the top on each side of the agitator compartment, and is introduced, by means of the submersion blades (*d*) slightly below the level of the pulp in the froth-separating compartments. In general, several machines are installed in series. Tailing leaving the first compartment passes through an opening (*e*), regulated by means of the valve rod (*f*), into the froth-separating compartment in the succeeding machine. The froth-separating compartments are divided to within about a foot of the overflow lip by means of a wall (*g*). From the bottom of the two compartments thus formed, pipes (*h*) lead back to the agitating compartment. Pulp, entering the first or upper of these two sub-divisions in a given froth-separating compartment, is drawn upward into the agitating compartment, thrown over the top into the froth-separating compartment and falls back, a part on each side of divider (*g*). Practically all of that which falls back on the upper side of the divider is again drawn up through the pipe from that compartment into the agitating compartment. A part of that which falls on the down-stream side of the divider (*g*) is also drawn back into the agitating compartment. Thus a part of the pulp is circulated in each machine and subjected to agita-

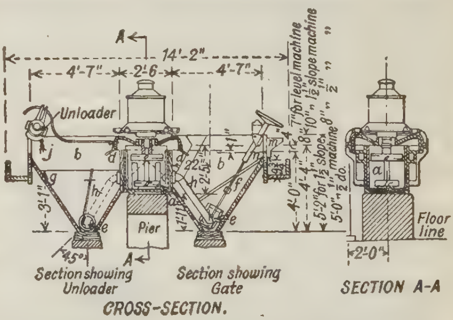

Fig. 16.—24-in. Janney mechanical machine.

tion and aeration more times than would be the case if the flow were alternately through successive agitating and froth-separating compartments. Froth is skimmed by means of the eccentrically driven unloader (*j*) which is operated by means of a small independent motor. The series of machines is sometimes preceded by one, two, or three agitating compartments built without froth-separating compartments, called EMULSIFIERS. Flotation agents are added to the pulp entering the emulsifiers. Additional flotation agents are added, if necessary, through the oil funnel (*m*) and pass through the oil pipe (*n*) into the circulating pipes (*h*). A multiple arrangement of feed, *i.e.*, with incoming pulp stream split between the first three or more cells is ordinarily used where it is desired to make a finished concentrate on the early cells and to circulate the froth from the later cells back to the head of the series. A series arrangement with all of the feed stream entering the first cell is used where the froth taken from the various froth-separating compartments is cleaned on other machines.

From five to fifteen agitators, each with two froth-separating boxes and preceded by one or two emulsifiers, comprise a unit. The size of a unit is indicated by the diameter of the agitation chamber and the number of single machines in series. A 24-inch, 16-compartment unit consists of one or two 24-in. emulsifiers followed by 16 agitating compartments with cross-armed impellers, the upper impeller 20 in. and the lower 14½ in. tip-to-tip, respectively, and 32 froth-separating boxes. The **capacity** of such a machine depends upon the percentage of solids in the pulp, the number and diameter of impellers, and the character of the ore.

On a silicious, sandy copper ore in pulps carrying from 10 to 28 per cent. solids, a 13-compartment, 24-in. machine at UTAH COPPER Co. had a capacity of from 150 to 550 tons per 24 hr., the relation between tonnage and percentage of solids being represented by a straight line.

Decrease in the number of cells in series will mean a corresponding and almost proportionate decrease in capacity, if the same grade of concentrate and percentage of recovery are to be maintained. There will also be a decrease in capacity if a slimy feed replaces a sandy feed. This is due principally to the fact that such a feed must be treated in a pulp containing a lower percentage of solids and that consequently the bulk to be passed through the machine for a given tonnage of solid is increased. The decrease in capacity is about in proportion to such increase in bulk.

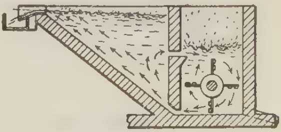

FIG. 17.—Horizontal-spindle agitation-froth machine.

On $-$80-mesh lead ore, an 8-cell 24-in. machine at FEDERAL LEAD Co. handled 500 tons per 24 hr. in a pulp containing 20 per cent. solids. At AMERICAN ZINC, LEAD AND SMELTING Co. mill at Mascot, Tenn., a 7-cell 24-in. machine treated 170 tons per day of $-$35-mesh zinc ore in a pulp containing 33 per cent. solids. The power consumption of a 24-in. machine is approximately 6 hp. per agitator. The machine is usually run at a peripheral speed of 3600 ft. per min.

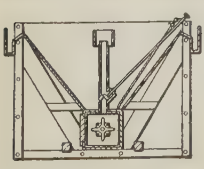

FIG. 18.—Mishler flotation machine.

Eberenz and Brown (1,187,822/1916). Horizontal-spindle, circulating machine. See Fig. 17. The impeller arms carry several spaced blades for the purpose of increasing agitation.

Mishler (1,197,843/1916). Several impellers on a horizontal shaft, each working in a closed agitation chamber at the apex of a spitzkasten. Compressed air supplied to pulp in the agitation compartments. Discharge into a spitzkasten by overflow of a standpipe above the agitation compartments. (Fig. 18.)

Janney (1,201,053/1916). Multiple, vertical-spindle, single-

level, circulating machine, differing from that described in patent 1,167,076, in that successive units are on the same level.

Brittain (1,224,066/1917). Multiple, vertical-spindle, single-level, non-circulating. Agitation and froth separation in the same chamber. Vertical disturbance of the surface is prevented by a feed conduit with bottom discharge placed directly above the impeller (see Fig. 19). Entering pulp flows successively through (8), (4), (10) and (11) to the impeller and, these passages being only partly filled, air likewise enters and is beaten in by the impeller in the usual fashion. Aerated pulp, discharged at the periphery of the impeller rises in (1), froth overflows lips (15) into concentrate and middling launders (19) and (20). Tailing discharges through openings (5) into ducts (8) leading to adjacent compartments for retreatment.

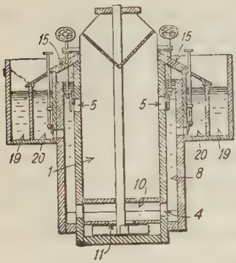

FIG. 19.—Brittain flotation machine.

Colburn and Colburn (1,226,062, 1,226,063/1917; re-issue 14,497/1918; 1,415,314/1922). Special centrifugal pump as agitator with regulated air inlet into a submerged feed pipe and discharge below the surface of pulp in a spitzkasten. Agitation in a vacuum is claimed, but the vacuum effect is probably no greater than in the usual open type of agitation-froth machine. See Fig. 20.

Norvell (1,243,093/1917). Vertical-spindle agitator. Agitation compartment suspended on the center line near the top of a V-box froth-separating compartment with discharge of pulp thereinto below the surface of pulp in the box.

Saffold (1,256,263/1918). Multiple, cross-bladed, vertical-spindle agitator mounted in a closed, compartmented vertical cylinder, the discharge ports for agitated pulp opening below the surface of the pulp in a conical or pyramidal spitzkasten. Also aeration through a perforated pipe at the bottom of a cylinder at the center of a spitzkasten with discharge of aerated pulp through ports in the side of the cylinder below the overflow level of the spitzkasten.

Pearce (1,277,750/1918). Multiple unit: vertical-spindle, cross-bladed agitator in square agitation compartment with a horizontal partition directly above the agitator blades and central opening around the shaft for pulp inlet. Direct centrifugal discharge from the agitating compartment into the apex of the spitzkasten with froth overflow at the side farthest from the pulp inlet and tailing discharge by overflow directly above the pulp inlet. (See Fig. 21.)

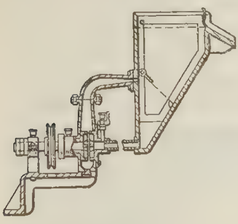

FIG. 20.—Colburn flotation machine.

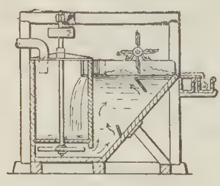

FIG. 21.—Pearce flotation machine.

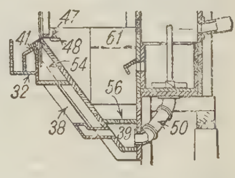

FIG. 22.—Lyons and Haff froth cutter.

De Mier (1,308,049/1919). Multiple unit: series flow. Vertical-spindle machine of substantially the standard Minerals Separation single-level type, but with two spitzkaste.. to each agitator. Cribbed agitating compartments are suggested.

Boggs (1,324,791/1919). Horizontal spindle with multiple, cross-bladed, 45-degr impellers mounted in the bottom of a long trough with feed at one end and tailing disch. at the other end of the trough.

Lyster (1,352,072/1920). In a series of centrifugal-pump agitators and spitzkasten, wi. air-valve control of the feed rate to the pump from the apex of the preceding spitzkaste a float in the spitzkasten automatically regulating the valve on the air-supply pipe.

Lyons and Haff (1,389,674/1921). In an agitation-froth machine of the Minerals Separation type, (Fig. 22), a floating froth cutter (47) regulated by float (48) to send the lower layer of overflowing froth to a middling launder (54) and thence by pipe (38) to chamber (39) under a false bottom in a preceding spitzkasten, there joining the tailing from this spitzkasten and thence by oblique pipe (50) to agitation chambers of the adjacent succeed-

ing spitzkasten. Any excess middling from chamber (54) flows through slot (41) to middling launder (32), there joining similar products from other spitzkasten and being returned by a bucket elevator or the like to the head of the machine. Coarse tailing from any spitzkasten discharges by sand-hole (56) into chamber (39); fine tailing overflows weir (51) at the tailing side of the spitzkasten into a channel leading to chamber (39).

Shimmin and Bushnell (1,402,099/1921). A modification of Janney (1,167,076/1916 and 1,312,115/1920), in which an open-ended prism is so supported in the agitation chamber as to form an annular space and the direction of rotation of the impeller is such as to force pulp down through the inner space and up through the annular space and thence into the froth-separating compartments.

Eberenz (1,505,324/1924) describes a type of horizontal-spindle machine, pictured with submerged blades, but, of course, not so operating. The agitating compartment is sealed against the atmosphere and injection of a gas such as hydrogen sulphide with an inert gas such as carbon dioxide, nitrogen, and the like is contemplated.

Kleinbentink (1,539,746, 1,557,369/1925) describes a circular machine in which a central agitating compartment in the shape of an inverted conical frustum, containing a pump-bladed impeller on a vertical axis, is surrounded by a flaring-sided froth-separating compartment with peripheral overflow, bottom-fed from the agitating compartment and feeding back thereinto through ports above the impeller and above the outlet ports. The apparatus is described principally for coal treatment but the claim names ores also.

Hydrotator flotation machine (Fig. 23) is essentially an agitation-froth machine using the centrifugal pump (*a*) with air inlet (*b*) and oil inlet (*c*) for agitation. Feed enters at (*d*), pulp is withdrawn through pipe (*e*), passes through the pump and thence into the rotating-sprinkler type of mechanism and, through jets (*g*), into the tank. Air-mineral agglomerates, formed in the pump, rise and overflow as froth.

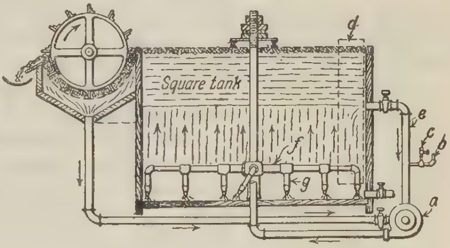

Fig. 23.—Hydrotator flotation machine.

Some tests on bituminous coal (− 20-mesh jig-overflow water) showed 60 to 70 per cent. ash reduction and 85 to 95 per cent. recovery of carbon content. In a test on −3/32-in. raw bituminous carrying 21.6 per cent. ash, the float analyzed 2.2 per cent. ash against 9.2 per cent. in jigged coal. Screenings (−3/32-in. rd. hole) from washery refuse assaying 50 per cent. ash yielded float containing 9.5 per cent. ash and representing 55 per cent. recovery. (*These data furnished by the Hydrotator Co.*)

9. Bubble-column process

General. In this process substantially all of the concentration is performed in a column of bubbles above and floating on the surface of the body of pulp. The volume of gas effectively used to produce concentration is 20 to 100 times greater than in pulp-body processes, being of the order of 1000 to 2000 cu. ft. per cu. ft. of solid floated. The result is that the froth is fragile and evanescent and strikingly different from that characteristic of the other class of froth processes. Further investigation of the process, by observation of the operation in glass-sided machines, shows that: (1) The bubbles are much larger than in pulp-body processes; (2) they are more numerous; (3) they rise through the pulp more rapidly; (4) they arrive at the surface of the pulp with a solid load composed of sulphide and gangue in substantially the same proportions that these exist in the pulp through which they have passed; (5) concentration begins at the bottom of the bubble column (*i.e.*, the upper surface of the pulp body) and progresses upward. The actual mechanism of concentration can be studied with a hand-glass. There is a differential draining of the gangue and sulphide particles in the bubble walls; the average downward velocity of the sulphide particles is less than the average upward velocity of the bubbles; the average downward

velocity of the gangue is greater than the average upward velocity of the bubbles; and as a result the sulphides are lifted up and away from the gangue. The sulphide particles in the bubble column are nowhere firmly adherent to bubbles as they are in the pulp-body processes. These various phenomena are generalized in Fig. 24. Segregation of sulphide from gangue in the water-filled space between the bubbles brings about a distribution of such particles as is idealized in the sketch. All particles are moving downward with respect to the bubbles, but there is a momentary retardation of sulphide particles at the bottom of the bubbles, indicated on the sketch by the crowding of particles at the bottom of the bubbles and the dependent tip. Bubbles near the top of the column carry more attached particles at any given instant than those lower down. The falling path of any given sulphide particle, following, as it does, the bubble surfaces, is longer than that of a given gangue particle, which falls as directly as possible through the liquid channels forming the bubble walls.

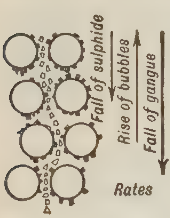

Fig. 24.—Action in bubble column.

Theory. Superficially bubble-column concentration is similar to hydraulic classification, with the essential differences, however, that a rising column of bubbles replaces the rising current of water, and that the buoyant effect of the rising current on the solid particles is modified and aided, in the case of the metallic minerals, by adhesion between the bubbles and these particles. But in both processes the essential feature is the presentation of a mass of grains of unequal settling power, under the conditions of treatment, to a rising current whose velocity lies between the average settling rates of the two classes of grains it is desired to separate. In the ordinary practice of bubble-column concentration the pulp is fed to the bottom of the bubble column, but it may be fed at the top, as in hydraulic classification. Selection of mineral particles by gas in the body of pulp, which is the essential basis of pulp-body processes, is not an element of bubble-column concentration, and consequently heat, chemical action, agitation, and external pressure change are unnecessary. All that is necessary in bubble-column concentration is to form and maintain a slowly-rising column of bubbles, and to present to it solid particles prepared by treatment with some selective agent, so that preferential adhesion of sulphide particles to the bubble walls will be more marked. Maintenance of a bubble column requires addition to the pulp of some substance that changes (usually lowers) the surface tension of the water. The selective agent is one that either from solution or from minute mechanical dispersion in the pulp, preferentially adheres to metallic-mineral surfaces. All successful mixtures of flotation agents must have both of these properties.

Quantitative experimental evidence of the difference between the bubble-column and agitation-froth processes is presented in Fig. 25. A pneumatic bubble-column machine and the spitzkasten of a Minerals Separation standard machine were fitted with ⅛-in. sample pipes projecting inward 6 in. from the inner surface of the walls, arranged in vertical rows running from bottom to top of the respective apparatus. Simultaneous samples from all pipes were drawn from each machine, assayed, and the assays plotted against position in the machine. Plot B shows that bubbles on emergence into the bubble column in the pneumatic cell are carrying a load of pulp; that no concentration at the bubble surface has taken place in the pulp body. Plot D shows that the solid load on the bubbles emerging from the pulp in the agitation-froth process is a concentrate of substantially the grade of the finished concentrate from the cell. The tests recorded in Fig. 25 were made in regular mill operation. Similar comparisons have been made in a 24-in. M.S. standard machine, a Janney mechan-

ical machine, a standard Callow machine, two special large-size Callow machines, an Inspiration-type pneumatic machine and a Cascade machine. These tests all show that plots *B* and *D*, Fig. 25, are typical of the behavior of bubble-column and agitation-froth machines respectively.

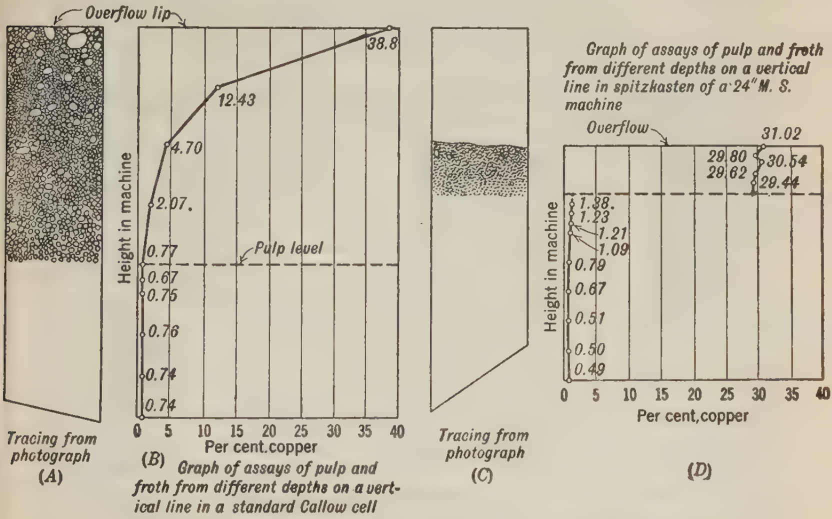

Fig. 25.—Charts showing place of concentration in standard Callow (bubble-column) and 24-in. M. S. (agitation-froth) machines.

It logically follows from the conclusions reached in the preceding paragraph that the body of pulp in the bubble-column type of machine can be eliminated without affecting the concentration.

A cell built to eliminate the pulp body, 10 ft. long, 14 in. wide inside and 12 in. from blanket to overflow lip, with bottom horizontal (see Fig. 26), was run side-by-side with a regular mill cell in the Miami Copper Co. plant. This shallow cell recovered the same weight of copper per square foot of blanket area that was recovered in the standard cells adjacent, and made the same grade of concentrate.

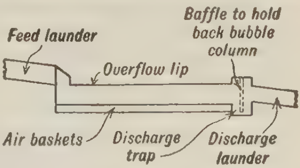

Fig. 26.—Shallow pneumatic cell.

Attachment of mineral particles to bubbles. Whether the actual method of adhesion of solid particles to bubbles is different in the bubble-column and pulp-body processes is not yet known definitely. It can be said without fear of contradiction that in pulp-body processes solid particles are held to bubbles in the same way that particles are held in film flotation (Fig. 3). There is, of course, a more or less complete film of the selective substance between the air in the bubble and the actual solid surface, but this is, in most cases, of monomolecular dimensions. That such is the mode of attachment follows from the way in which attachment is effected. The initial precipitation of gas is from solution in contact with the filmed particle and takes place at the interface between particle and solution, *i.e.*, in contact with the particle. Subsequent precipitation, causing growth of the bubble, may be at the liquid-solid interface or at the liquid-gas interface; probably it is at both. When the bubble is small with respect to the particle, particularly if it is growing on a substantially plane surface, the shape is that shown in Fig 27*a* and further growth causes it to take the shape shown in Fig. 27*b*. This non-spherical shape, indicative of definite contact angles, can only occur when there are three-phase contact points. Since the only visible phases present are gas, solid and pulp liquid, the relation must be that shown. This kind of attachment results in

substantially rigid systems of air, liquid and solid, evidenced generally by stiff, coherent froths and showing under the microscope little or no movement of solids in the bubble walls. The appearance of individual bubbles composing a pulp-body froth is of rough, solid-armored spheres packed together more or less closely in substantially quiescent water. This is entirely different from the unstable and temporary adhesion between bubbles and metalliferous particles in a bubble column and leads to the belief that in the bubble column another mode of attachment prevails.

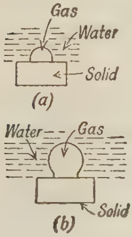

FIG. 27.—Relation of phases in pulp-body flotation.

Mode of attachment in bubble column. To a test tube two-thirds full of water add a few drops of an oil such as oleic acid or pine oil and a few hundred particles of finely-divided granular sulphide (about 0.1-mm. diam.) cork the test-tube and turn it end for end a few times, then examine with a low-power microscope. Aggregates of oil and mineral such as are illustrated in Fig. 28*a*, may be seen. Shake the tube gently so as to introduce some air, but do not shake enough to cause any substantial pressure differences. Aggregates such as are shown in Fig. 28*b*, may be observed. In both cases the rigidity of attachment of mineral particles to oil globules is slight. Continued shaking results in increase of air-oil-mineral aggregates with successive thinning of the oil film on the air bubbles, but with no change in the fragile nature of the bond between solid and oil. A limit is finally reached when, on many of the bubbles, the oil film is invisible, but one still exists and, barring such agitation as will produce gaseous supersaturation, the mode of attachment of solid particles thereto must be that shown in Fig. 28*c*, in which the thickness of the oil film is greatly exaggerated. The surface tension of an oil-water interface is from one-third to one-half that of the contaminated water-gas interface and the three-phase contact angle oil-water-solid is much smaller than the water-gas-solid angle, which would explain the more feeble adhesion observed in the bubble column as compared with the froth in pulp-body processes. The same conclusion as to necessary difference in character of attachment is reached by study of Tables 22 and 23.

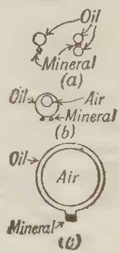

FIG. 28.—Probable method of adhesion of mineral particles to gas bubbles in bubble-column flotation.

The machines in which the bubble-column process is practiced may be classified, on the basis of the method of introducing air, as pneumatic machines, plunging-stream or cascade machines, and centrifugal machines.

10. Pneumatic machines

Pneumatic machines pump air directly into an oiled pulp through a pipe or pipes or the equivalent. In the best-known type the air for making the bubble column is introduced through a porous medium such as canvas, cotton twill, blanket, carborundum, or concrete. Machines described in the patents, as also some modifications introduced in the mills, are described below.

Sulman and Picard (793,808/1905) first described a bubble-column apparatus. In Fig. 29, (B) is a rectangular separating tank with sloping bottom, above which is suspended a perforated spiral coil (B'), revolved by gear (B^3). Air is supplied at (C) and oil from tank (C') may be atomized into the entering air or the pulp may be pre-mixed with oil. Feed enters through pipe (A') concentrate is overflowed into launder (B^4) and tailing discharged through valve (B^5). The utility of the process disclosed was not recognized by the inventors nor by the art, and the pneumatic process as at present practiced is not clearly claimed, if claimed at all, in the patent. The principle was not known to the patentees as late as 1907 as they say in a privately distributed publication of that date:

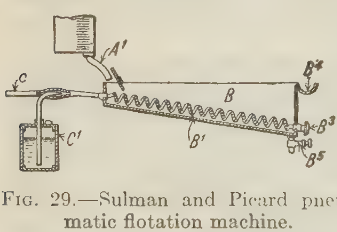

FIG. 29.—Sulman and Picard pneumatic flotation machine.

" . . . mineral flotation is difficult to achieve by simply passing a *current* of gas bubbles through a pulp. The explanation is that under such conditions supersaturation takes

long to establish. If on the other hand such a pulp be shaken vigorously with air, or air be whipped into it by mechanical agitation (*835,120*) flotation is just as readily ensured as if the gas were generated in the pulp itself by chemical means (*Froment*) ".

Towne and Flinn (1,295,817/1919) first recognized and described the action in the cell. Their apparatus (Fig. 30) shows a circular tank (1) which is fed with oiled pulp and supplied with low-pressure air through porous medium (5). The bubble column overflows into annular launder (22) and tailing discharges through pipe (12) and automatic valve (15). Other forms of apparatus by the same inventors are described in 1,317,244/1919; 1,367,322/1921; 1,378,920/1921; and 1,410,-781/1922. Flinn, 1,314,316/1919, describes a similar apparatus.

None of the forms of apparatus described by these inventors has had any commercial use. An installation of 24-in. cells was tried in the INSPIRATION TEST PLANT (*55 A 576*), but was rejected in favor of the Callow machine. The 24-in. cells were also tried at CANANEA and ARIZONA COPPER CO. but not adopted, although recoveries were good. One great fault was settlement of sand on the bottom and consequent boiling.

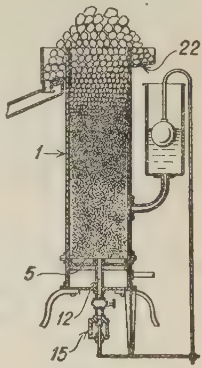

FIG. 30.—Towne and Flinn pneumatic flotation machine.

Callow pneumatic cell, as used in the mills, is shown in Fig. 31. It consists of a rectangular box with sloping porous bottom. The usual dimensions of the box are 8 to 9 ft. long, 2 ft. to 2 ft. 6 in. wide, about 18 in. deep at the feed end and 4 ft. deep at the tailing-discharge end. The porous bottom consists of three or four layers of medium-weight canvas or palma twill, supported on a screen or grid on top of an air box. The usual cell has the air box divided into eight compartments, each with an independent connection to a header, the purpose being to allow independent regulation of the air pressure on the under side of the blanket at different points in the length of the cell, in order to balance the different hydrostatic heads and prevent eddy currents due to unequal air distribution. Pulp is fed into the cell behind the baffle (*c*), froth overflows the sides, and tailing is discharged through the pipe (*d*). The rate of discharge is regulated by means of the adjustable float valve (*e*). The capacity of a single unit such as illustrated is from 35 to 80 tons per 24 hours, the lower figure corresponding to a slimy ore in a pulp containing a low percentage of solids, the higher figure corresponding to a silicious, rather sandy ore in a pulp containing in the neighborhood of 25 per cent. solids.

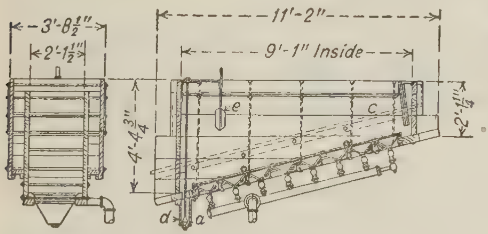

FIG. 31.—Standard Callow pneumatic cell.

In the MISSOURI lead mills, where pneumatic machines are used as scavengers, tonnages per machine run as high as 150 per 24 hr. At the Morenci mill of PHELPS DODGE (*69 A 180*) the feed rate to standard Callow cells was 2.5 tons per sq. ft. of bottom per 24 hr.

The air consumption is decidedly variable, ranging in different plants from about 6 to 12 cu. ft. of free air per min. per sq. ft. of porous bottom, at pressures of from 3 to 5 lb. per sq. in. on the supply side of the regulating valves. A good average figure is probably in the neighborhood of 9 cu. ft. per min. per sq. ft. of porous bottom. This air requirement corresponds to

a power consumption of between 3.5 and 4 hp. per cell. Large, shallow cells require about 0.3 hp. per sq. ft. of porous bottom.

The following detailed figures are given by Callow (*54 A 14*): NATIONAL COPPER CO., 500 tons per day treated in eight standard roughers and two cleaners; 950 cu. ft. of free air per min. at 4 lb. pressure required; blower power, 35 hp., 3.5 hp. per cell, 12.53 tons per hp. or 1.25 kw.-hr. per ton. At another plant treating 2400 tons per day in 48 roughers and 12 cleaners, 9600 cu. ft. of free air per min. at 5 lb. pressure was furnished with 210 hp., 3.5 hp. per cell, 11.45 tons per hp. or 1.56 kw.-hr. per ton. In the INSPIRATION experimental plant 200 tons per day was handled in 4 roughers and one half-size cleaner, requiring 950 cu. ft. of free air per min., at 5 lb.; blower power was 18 hp. making 4 hp. per cell, 10 tons per hp. or 1.79 kw.-hr. per ton. Laist (*113 P 634*) is quoted as giving comparative power consumptions for flotation alone as 0.15 hp. per ton of daily capacity for pneumatic at INSPIRATION against 0.25 hp. in M.S. machines at ANACONDA. Minimum attendance requirement is illustrated by INSPIRATION practice, where one man handles four 800-ton sections, and MIAMI, where two men handled 60 standard cells treating 3200 tons per 24 hr. (*56 A 577*).

Callow cells are usually run in parallel. General experience is to the effect that, whether run in parallel or in series, the capacity per sq. ft. of porous bottom, in machines producing concentrate of the same grade and recovering approximately the same amount of mineral, is the same irrespective of the method of operation.

A modified form of Callow cell designed to economize floor space is shown in Fig. 32. It consists of a rectangular box about 20 ft. long, 7 ft. wide and an average depth of 3 ft., set on a slope of about 2 in. per ft. The box is divided into eight compartments, 3 ft. 5 in. wide by 4 ft. 6 in. long, by means of a central longitudinal wall which extends to the bottom

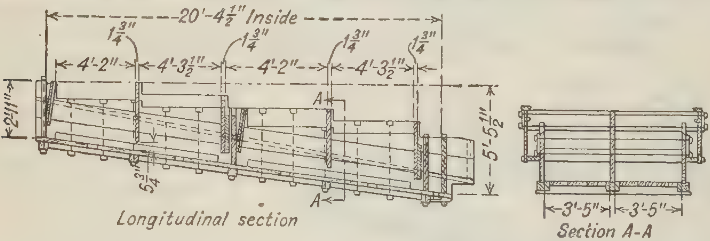

FIG. 32.—Miami-type pneumatic cell.

of the box, and three transverse walls. The first and third transverse walls extend to within 5 or 6 in. of the bottom of the box, the second or center wall is so arranged as to cause the pulp to overflow a weir in passing from the second to the third compartment on both sides of the cell. The purpose of this weir is to maintain the desired pulp level in the first two compartments on each side. Practically the partitions serve to divide the box into four cells. Air baskets consisting of shallow boxes with a porous top, of such size that they fit loosely into a compartment, are placed with the porous side up in the bottom of the compartment. The capacity of one of these machines is between 400 and 800 tons per 24 hr. treating a silicious ore in a pulp containing from 20 to 25 per cent solids.

Tests on air and power consumption of Miami-type pneumatic cells at MIAMI COPPER CO. showed that air consumption per square foot of porous bottom in the rougher cells ranged, during a period of 7⅓ days, from 8.1 to 12.1 cu. ft. of free air (12.82 lb. absolute pressure and 70° F.) per min.; average 9.6 cu. ft. Figures based on two- and three-day tests on individual bottoms showed a range from 7.4 to 14.5 cu. ft. per sq. ft. per min. for No. 1 bottom, average 9.5; 6.7 to 11.7 for No. 2, average 8.5; 8.7 to 13.0 for No. 3 average 10.4; and 7.2 to 10.6 for No. 4, average 9.3. The cleaner cells showed a range, on 4-day test, of 2.6 to 6.4 cu. ft. per sq. ft. per min., average 4.7. Power consumption per section containing 32 rougher and 8 cleaner bottoms, to which the average air supply based on the above figures was 4141 cu. ft. of free air per min. at 3.8 lb. per sq. in., ranged, on 15-day test, from 94.4 to 114.5 hp., average 106 hp. for the period. This is roughly 40 cu. ft. of free air per min. per hp. or 0.22 hp. per sq. ft. of blanket surface. One of these sections handles 1300 to 1500 tons per 24 hr., making power consumption 1.7 to 1.9 hp.-hr. per ton. Further test

showed that the power draft for the section with the cells empty was 39.3 hp. and the pressure 1.5 lb. per sq. in. With the cells full of water the power draft was 59 hp. and the pressure 2.5 lb. per sq. in. The increase above this latter figure with pulp in the cell was probably due largely to deposition of sand on the blankets, as the difference in density between pulp and water is insufficient to account for the increase in pressure and power consumption.

At the new mill of Morenci Branch of Phelps Dodge (*69 A 176*) a shallow cell, 4 × 40 ft., 15 in. deep at the feed end, bottom slope ⅛-in. per ft., stepped up to a depth of 15 in. at mid-length, was installed with an allowance of 1.25 sq. ft. of blanket area per ton treated per 24 hr. This figure was based on thorough experiment with the low-grade sulphide ore to be treated. Use of the shallow cell reduced the required air pressure from 4.75 to 3.5 lb. per sq. in. At Moctezuma Copper Co., Nacozari, Mex. (*118 J 446*) the blanket allowance was 1.5 sq. ft. per ton per 24 hr.

The principal advantage of the large cells lies in the compactness of the installation. A comparison of the standard cell with a large shallow cell at Morenci (*109 J 1352*) indicated little or no advantage in performance when the reduced feed rate in the large cells is considered.

Most of the recovery in a pneumatic machine is effected in the first few feet. Table 13 shows results of a test on a Miami-type cell. In one test on a

Table 13. Recoveries in successive compartments of a 4-compartment pneumatic cell at Miami Copper Co.

Patents issued to Callow covering various forms of porous-bottom bubble-column apparatus are: (1,104,755/1914). A circular flat-bottomed tank with slow-speed stirrer to keep coarse sand in suspension. (1,124,853/1915) The same with a high-speed stirrer, giving a combination of pneumatic bubble-column and agitation-froth flotation. (1,124,855 and 1,124,856/1915) A circular tank with slow-speed rotating porous arms. (1,141,377/1915) A circular tank with horizontal porous bottom, no stirrer, and perforated grids to lessen

pulp movement and disturbance of the bubble column. (1,176,428/1916) A rectangular tank with sloping compartmented bottom and a vacuum chamber above for removing and disintegrating froth. It is not likely that any substantial vacuum-type pulp-body concentration is effected in this cell, although it is not impossible. (1,182,748/1916) A rectangular box with horizontal porous bottom and a mechanical scraper for moving sands from feed to tailing ends. (1,201,934/1916) Substantially the modern form of cell as described above, but without the automatic tailing-discharge valve. (1,329,335/1920) Substantially the modern form with inclined bottom but with the tank compartmented with vertical transverse baffles extending from above the overflow lip downward to within a few inches of the bottom, in order to prevent sand deposition by creating a scouring action. (1,366,766/1921) A rectangular tank with horizontal porous bottom, adjustable transverse baffles to prevent sedimentation, and a weir overflow. (1,366,767/1921) In an apparatus similar to a Dorr thickener, a porous bottom, a peripheral feed into an annular space behind a cylindrical baffle extending nearly to the bottom, a float-controlled tailing-discharge valve, and revolving suction pipes for removing froth.

MacDonald (1,134,690/1915). In a circular tank, a plurality of air-lifts disposed near the periphery and discharging tangentially a short distance below the pulp surface, thus setting up a circular motion of the pulp; a skimmer or skimmers projecting from the side wall toward the center of the tank for leading froth to the periphery; a central cylinder extending above and below the pulp surface to confine the bubble column to an annular space; submerged feed of pulp; oil fed with compressed air in the air-lifts.

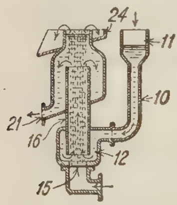

FIG. 33. — Wagner pneumatic machine.

Crerar (1,232,772/1917). An inclined porous bottom, the lower end only submerged. Pulp fed at the upper end, overflow of froth at the lower end. A porous surface similar to a 2-deck circular buddle with upper deck convex and lower concave is illustrated. The principle of this machine is correct in that no pulp body is necessary in a pneumatic machine and elimination of pulp body results in saving of power.

Wagner (1,235,083/1917, Fig. 33). A porous-bottom machine in which the flow of pulp in the separating chamber is upward with the rising air bubbes. This is interesting in that it recognizes the necessity of bringing all of the pulp into the bubble column, which is essential to recovery of mineral in bubble-column processes. In the figure, feed enters hopper (11) and passes through pipe (10) into chamber (12), thence upward through pipe (16) with air introduced through porous bottom (15). Tailing that falls out of the bubble column discharges through pipe (21). Concentrate overflows into launder (24).

Cole (1,243,814/1917; 1,375,211/1921, Fig. 34). The essential feature is the use of a grid of porous pipes (22) placed some distance above the bottom in the separating tanks (14), (15), (16) in order to prevent clogging of the air inlet passages by sedimentation of coarse sand. In operation feed enters at (19), meets the rising air bubbles and is lifted into the bubble column. Tailing from the bubble column passes downward through the grid of porous pipes, is roughly classified at (34), coarse sand being discharged from spigot (36) and fine sand and slime passing through pipe (23) to a second similar unit, etc. Hand wheels (28), controlling valves, regulate the flow and the pulp level. See also Flinn, (1,314,-316/1919.)

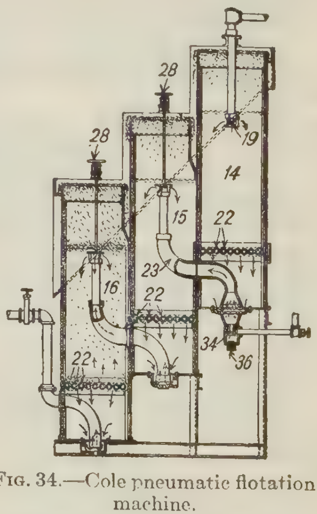

FIG. 34.—Cole pneumatic flotation machine.

At CANANEA CONSOLIDATED COPPER Co. four roughers and four cleaners treated 800 tons per 24 hr. of −28-mesh feed with a consumption of 132 hp. Air pressure was 5 lb. per sq. in. Tubes were covered with silencer cloth, which lasted 30 to 45 days. This apparatus has been tried out thoroughly at INSPIRATION (*55 A 576*) and ARIZONA COPPER Co. (*55 A 656*), but was not adopted at Inspiration and has been replaced by Callow cells at Arizona Copper Co. (*66 A 724*).

Peterson cell used at TIDEWATER COPPER Co. (*122 P 423*) is of this type. Five roughers and one cleaner required 2.8 hp.-hr. at the blower per ton of flotation feed.

Greenawalt (1,250,303/1917) similarly guards against interference with air introduction

due to clogging by the use of a grid of porous pipes above the bottom of the separating tank, but goes a step further in suspending the pipes and moving them slowly backward and forward by means of a suitable mechanism

Armstrong (1,269,150/1918). Restriction of froth overflow in pneumatic or other cells, for the purpose of deepening the layer of froth and thus obtaining cleaner concentrate, is described. The patent illustration shows a standard Callow cell with sides built up except for a short distance near the discharge end so that all froth must travel to this point to overflow. The effect is to increase the time for drainage of gangue from the concentrate in the column of bubbles. As this draining phenomenon does not occur, or occurs to but the slightest extent, in properly operating pulp-body machines, the method is applicable only to bubble-column processes. The method has been used in the mills. Overflow has been placed at the discharge end and counter flow of the bubble-column to side overflows arranged near the feed end, as well as to the tailing end, has been tried.

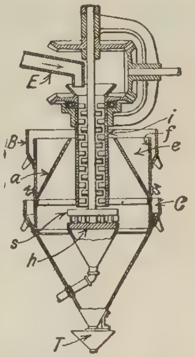

Fig. 35.—Rowand pneumatic flotation machine.

Rowand (1,312,754/1919, Fig. 35). Oiled feed pulp enters through pipe (*E*) and mixing chamber (*i*) directly onto the porous bottom (*h*) which is kept from sanding by scraper (*s*). A bubble column with constricted surface is formed in conical frustum (*a*) and overflows the upper rim of this frustum onto a body of water maintained in (*e*). Middling drains out as the bubbles pass over to the lip (*f*) and are discharged through suitable openings into launder (*C*). Concentrate overflows into launder (*B*); tailing is discharged at (*T*). The patent mentions the use of heat, which is both unusual and an unnecessary expense in bubble-column operation.

Wilson (1,341,770/1920, Fig. 36). Feed entering through pipe (27) is mixed with oil from tank (31) in the closed-top Pachuca tank (*F*), and passes into tank (*A*) where it is subjected to the action of air bubbles introduced through the porous medium (24) and rising in the tortuous passage (*B*). Material dropped in the passage of the mass of bubbles toward the overflow lip (9) returns by the passages (C) to be treated again. Concentrate overflows into launder (10) and tailing discharges through pipe (13). Enrichment of concentrate by draining during a passage over non-aerated pulp, as described in this and the preceding patent, is not so good as a second "cleaning" operation, in a bubble column maintained over aerated pulp, as is the usual practice.

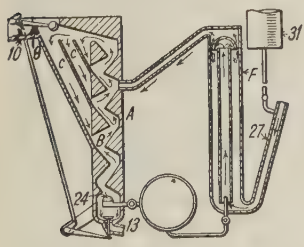

Fig. 36.—Wilson pneumatic machine.

Inspiration pneumatic cell is described in patents to Gahl (1,346,817 and 1,346,818/1920, and 1,401,598/1921).

One form used in the mills is shown in Fig. 37. It consists essentially of a launder about 3 ft. wide and 4 ft. 6 in. deep, with a slope of about ½ in. per ft. It is provided with a removable segmented porous bottom and is divided into compartments by partitions spaced about 3 ft. center to center along its length. The usual number of compartments in a roughing machine ranges from 15 to 20. The partitions have slots nearly 3 ft. wide and 6 to

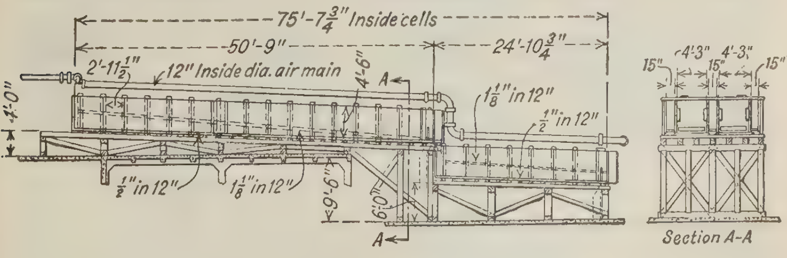

Fig. 37.—Inspiration pneumatic cell.

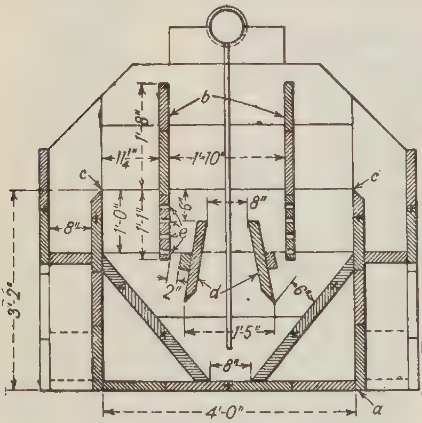
8 in. high, cut about 3 in. above the bottom of the launder. The size of the opening between compartments is regulated by gates operated by a threaded rod from a hand wheel and lug supported on timbers placed across the top of the launder. Air baskets, consisting of shallow boxes of such dimensions that they make a loose fit in a compartment and with the air-supply pipe coming down from the top, are placed in the bottom of the launder. In general, two such launders set side-by-side, with a common central froth launder, constitute a roughing unit. The rougher froth is cleaned in a similar smaller machine, fed by gravity from the roughing machine. The capacity of such a double unit with 16 roughing compartments each side and six cleaning compartments each side, is from 600 to 1200 tons per 24 hr., the lower figure on a slimy low-grade copper ore in a pulp containing 12 to 15 per cent. solids, the higher figure on a silicious, rather sandy low-grade copper ore in a pulp containing 20 to 25 per cent. solids. These figures reduce to 1.2 to 2.4 tons per 24 hr. per sq. ft. of blanket area.

At INSPIRATION, with 48-mesh pulp containing about 15 to 20 per cent. primary slime, 1.6 tons tons per sq. ft. is the regular feed rate and 3.2 tons has been treated. Power consumption in Aug., 1916 (*102 J 679*) was 2.8 kw.-hr. per ton. At AJO TEST MILL (*109 J 1314*) the feed rate was 1.88 tons per sq. ft. of rougher surface (2.07 tons per sq. ft. including cleaner tailing) and 0.85 ton per sq. ft. of cleaner. Air consumption was from 10 to 12 cu. ft. per sq. ft. of blanket surface, at from 4 to 5 lb. pressure on the supply side of the regulating valves. This means a power consumption of from 0.3 to 0.35 hp. per sq. ft. of blanket. At the GOLD HUNTER mill (*100 J 1044*; *102 J 16*) air was supplied at 8 lb. per sq. in. and the power requirement per cell was 9.6 hp. This is exceptionally high, due in part to the high pressure, but probably also to an inefficient blower installation. At INSPIRATION one operator and two Mexican helpers to wash bottoms take care of four roughers and four cleaners.



Cross-section of rougher

FIG. 37*a*.—Forrester flotation machine.

Forrester machine (Fig. 37*a*) consists of a hopper-bottomed trough (*a*), compartmented longitudinally by partitions (*b*), which are perforated below the pulp level. Length varies from 14 to 24 ft. Feed enters at one end above the pulp level, tailing discharges over a weir at the other end, and froth overflows lips (*c*). Air is introduced through ¾-in. pipes on 4-in. centers depending from a 6-in. header. Longitudinal partitions (*d*), arranged as shown or similarly, serve to form the foot-piece for an air-lift to raise pulp from the bottom of the hopper to a level between walls (*b*) higher than that of the pulp outside and to maintain the pulp therein in such a state of turbulence that a part of the air is broken up into sufficiently small bubbles to remain in the pulp in its passage through the perforations (*e*) and to form an effective bubble column in the quiet zones on the outside of walls (*b*).

Performance. This cell has been remarkably successful. The metallurgical results on porphyry copper ores have been about the same as in Callow cells while power and labor costs have been much lower. At one plant comparative performances of an 18-ft. Forrester and a 20-ft. Callow cell were as follows, the figures for the Forrester being given first: Daily tonnage, 350, 270; air pressure, lb. per sq. in., 1.6, 4.0; air consumption, cu. ft. per min., 702, 534; per ton of feed, 2888, 2848; power consumption, kw.-hr. per cell, 131, 224; per ton, 0.37, 0.83; cost, cents per ton: power, 0.448, 1.005; operating labor, 0.498, 0.783; repair labor, 0.095, 0.213. The reason for the great difference in the last item is the elimination of blanket scrubbing in the Forrester cell; this, with the almost universal use of lime with the chemical collecting agents is an important item in all plants.

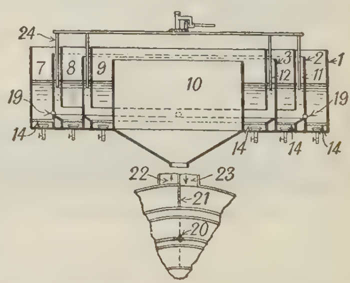


FIG. 38.—Myers pneumatic flotation machine.

Allingham (1,357,921/1920). A movable porous bottom suspended in a separating tank. See also Greenawalt (1,250,303/1917).

Myers (1,323,373/1919, Fig. 38). In a circular tank (1), a central cylindrical compartment (10) and a series of annular compartments (7), (8), (9), (11) and (12) formed by cylindrical walls of varying heights; and porous bottoms (14) arranged as shown. The outer annular compartment (7) is divided from top to bottom by partition (21). Oiled feed enters this compartment through inlet (23), is subjected to bubble-column action therein and divided into a rough concentrate that overflows the lip (2), and a tailing that is discharged at (22). The rough concentrate is re-treated in compartment (8) making a froth that overflows lip (3) and a middling that passes by check valves (19) back into compartment (7). The once-cleaned concentrate is re-treated in (9), overflowing finished froth into compartment (10) and discharging middling back into compartment (8) through check valves (20), spaced 90° to valves (19). Froth in the feed compartments of the various annular cells is broken down by revolving arms (24) or similarly driven sprays. Various types of porous media are described. One is a layer of fine lead shot, 0.5 to 2 in. deep, resting on canvas or muslin.

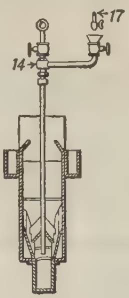

Fig. 39. — Waterhouse pneumatic flotation machine.

Waterhouse (1,346,286/1920). Fig. 39 is a cross-section of a sloping-bottom tank similar in shape to the standard Callow cell. (See Fig. 31.) Pulp is introduced into the tank at the shallow end and air is introduced with high-pressure water through pipes depending from injectors (14). Oil may be introduced at (17) and carried into the pulp with the aerated water. There is suggestion of both plus-pressure and cascade action in this description.

Terry (1,362,370/1920). A V-shaped tank with sides of a porous medium, feed troughs along the sides, concentrate overflow into a trough suspended along the center line, and tailing discharge at the bottom.

Riser (1,391,078/1921, Fig. 40). A covered rectangular tank (1) with sloping bottom (2), air mats (3) and sloping discharge end (4). Feed enters at (5), tailing discharges from the bottom by overflow of pipe (6). Froth formed by bubble-column action is forced to travel over unaerated pulp from a point over the lowest air basket to the end-discharge lip, thus allowing some drainage of gangue. (See remark on this practice under Wilson, 1,341,770.)

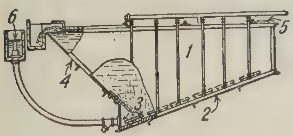

Fig. 40.—Riser pneumatic machine.

Borcherdt (1,440,129/1922). A long, flat-bottomed, compartmented pneumatic cell with weir overflow from compartment to compartment.

Conners (1,441,560/1923). A pneumatic cell with plunging feed behind a baffle and oil fed into the stream at the pulp level; also a horizontal screen just below the pulp surface, extending over the entire cell area.

Simpson (1,518,010/1924, Fig. 41). A spitzkasten with an air-lift to circulate pulp, a blanket placed above the cell bottom to prevent sanding, and a baffle to divide off a non-aerated pulp surface over which some draining of the bubble-column may be effected.

Dolbear (1,478,703/1923; 1,480,884/1924) describes a method and apparatus for feeding pulp on or into a bubble column, with the idea that selection will take place therein and the gangue will sink into the body of pulp beneath. The idea is attractive, but resolves itself into ordinary pneumatic operation for the reason that, while part of the mineral never reaches the pulp body, much does and is thereafter treated in the fashion usual in pneumatic machines. Failure to catch and hold the mineral is in part due to the fact that feeding tends to break down the bubble column at the feed point. The patent also describes methods for discharge from different depths in the bubble column by means of V-shaped troughs emerging through the sides of the cell, spaced so as to permit rise of bubbles between them, but designed to catch and discharge material dropped above them.

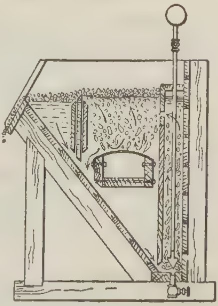

Fig. 41.—Simpson pneumatic cell.

Malmros (1,526,997/1925) describes a pneumatic cell with level bottom, flaring sides and longitudinal vertical baffle boards that register with the edges of the air basket but are so supported as to permit clearance to form pulp-circu-

lating passages between their lower edges and the cell bottom and of such height that the upper edge is below the bottom of the bubble column. In overflowing, the froth passes over a quiescent space between the upper edge of the baffles and the overflow lips and here additional draining takes place, which results in higher-grade concentrate.

Allen and Reid (1,547,548/1925) suggest a long, shallow, flat-bottom pneumatic cell with the side walls converging up to a height about three-quarters of the cell depth above the bottom, then flaring sharply to the overflow lips. The purpose is to provide an unaerated area over which accelerated draining of the bubble column may take place.

Mackintosh (1,608,896/1926) describes a slowly-rotating porous cylinder placed horizontally in the bottom of a V-shaped trough. Pulp is fed at one end of the trough, tailing discharges over a weir at the other and concentrate overflows the sides. The rotor has 2.3 sq. ft. of area per foot of length. At one plant eighteen 10-ft. (length) rougher cells and six 10-ft. cleaners (double cleaning) treat 3000 tons of copper ore per day. Air pressure varies from 1.5 to 3 lb. per sq. in. and quantity from 5 to 7 cu. ft. per min. per sq. ft. of porous bottom. Power-requirement is 0.6 to 0.8 kw.-hr. per ton. Blanket consumption is less than with standard pneumatic cells. Economies in power, blanket renewal and labor follow from the rotation of the porous medium which results in automatic removal of settled sand, thus decreasing air pressure and eliminating pounding of blankets. (*Data furnished by General Engineering Co.*)

Porous bottoms are usually made of three or four thicknesses of canvas or palma twill, stitched together with crossed seams spaced ½ to 2 in. Gahl (*55 A 576*) found that incrustation and loss of porosity were least near the center of the blankets where bellying and flexure were greatest and therefore concluded that rigid bottoms, such as carborundum stone, filtros, cement and the like would become clogged so quickly as to compare unfavorably with canvas. On the other hand the rigid bottoms are attractive in their promise of greater strength and longer life and much work has been done in attempting to develop them.

McCrae (*109 J 837*) describes the method used in making cement bottoms for Inspiration-type cells at Ray Consolidated Copper Co. In the early work the sides and bottom of the air basket were made of dense concrete poured in place in the cells and a porous top was then cast and cemented into place. Later practice was to make sides and bottom a sheet-iron pan, 7 in. deep, of such size as to fit readily into the 35½ × 51½-in. cell compartments. The pan was divided into three compartments and each of these into two sections. One-inch angle irons were riveted 3 in. from the top of the side walls and partitions, to serve as rests for the porous top blocks. These were made of sand-table tailing screened first through 18-mesh cloth held horizontally, then over the same screen at 45°. The concrete mixture was 5 parts sand to 1 part cement, mixed with only enough water to cause the cement to coat the sand and harden. The blocks were 3 × 10¼ × 22¾ in. reinforced with two ¼-in. rods 23 in. long and three 10½ in. long, wired securely at the crossings. The blocks were sprayed each day for 10 days, sparingly at first, to retard setting. These blocks were set into the pans with neat cement. Life at Ray was upward of 2½ years. The upper surface was scraped every 60 days. At Miami it was found that less scraping was necessary after the first time.

When canvas blankets are used it is necessary to tie them down at frequent intervals to prevent bellying, which would result in irregular distribution of air. Fig. 42 shows one method of reinforcing.

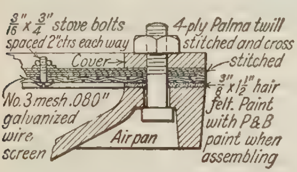

Fig. 42.—Air-basket joint and reinforcing.

Air pressure. The pressure required to force air through blankets is a function rather of incrustation and sand on the blanket than of the number of plies. In a test at Miami with 1-ply and 3-ply blankets working side-by-side it was found that as soon as the single blanket reached the normal incrusted and sanded condition (about seven days in the test quoted), the resistance to passage of air was substantially the same as that of the 3-ply blanket and that no power saving was, therefore, to be expected from the use of the thinner blanket. This reasoning is extensible to any porous medium. Multi-ply blankets have longer life in cells in which the bottoms must be pounded to prevent sanding, hence are generally used.

Useful life of canvas blankets is ordinarily between two and six months. It depends upon the amount of wear from scouring of the pulp and pounding to lessen clogging, upon the extent of chemical incrustation and upon how much dust is in the air furnished. Actual wear is normally not very great with find feed (65-mesh or smaller) and the life of blankets may be one or two years, but if there is considerable chemical incrustation which it is sought to relieve by pounding, or much coarse material, the blankets may last only a few weeks. Incrustation is usually removed at intervals by scrubbing with dilute hydrochloric acid. When lime is used to render pulp alkaline the blankets may need to be scrubbed every few days and wear will be high. Clogging by dust is lessened by filtering or even scrubbing the air entering the blower.

At Bunker Hill and Sullivan the use of quilted mats with rubber-impregnated canvas for the upper layer increased life from 3 months to 4 months. Increase was due to the fact that rusting (incrustation due to siderite) and felting with wood pulp were lessened (*106 J 257*). Life of cloth bottoms at Inspiration was about 6 months.

11. Cascade machines

Cascade machines effect aeration by causing a stream of water or pulp to plunge into a body of pulp. Air is entrained by pushing it into the body of pulp ahead of the masses or droplets into which the entering stream is broken. Any stream of pulp that falls through a distance greater than a few times its diameter breaks up into distinct masses, the breaking being greater the greater the velocity of the stream and the further its free fall. Each mass of entering pulp, if moving at sufficiently high velocity, pushes ahead of it a small volume of air in precisely the same way as an air bubble is pushed into water by a pebble thrown therein. The air thus introduced is broken up into smaller bubbles by reason of the swirl and movement caused by the entering stream and, rising to the surface of the pulp, forms thereon a column of bubbles, in which concentration takes place as previously described. The efficiency of the operation depends on the effectiveness of the apparatus in forming and maintaining an undisturbed, highly-aerated bubble column.

Ohrn (1,187,772/1916, Fig. 43). In a tank, a gas-and-pulp injector formed by hopper (*B*) and the steam or compressed-air pipe (*D*). Oil is fed with the air or steam through funnel (*F*). Gas introduced rises as bubbles (*L*) and forms at the surface a bubble column that overflows into launder (*J*) as concentrate. Tailing discharges at (*K*).

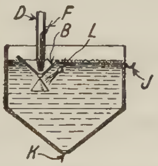

Fig. 43.—Ohrn pneumatic machine.

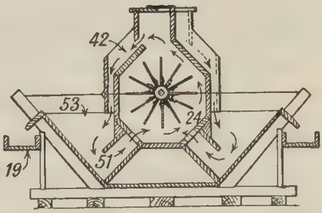

Fig. 44.—Rork cascade flotation machine.

Rork (1,136,485/1915, Fig. 44). Pulp with reagents is fed into chamber (24) and is lifted by the paddle wheel and thrown in the direction of the arrows through conduit (42) into spitzkasten (53), wherein a bubble column is formed that overflows into launder (19). Tailing follows the path of the arrows through conduit (51) back into the paddle-wheel chamber. Alternately pulp flows similarly through the spitzkasten on the other side. Feed enters at one end of chamber (24) and after passing through a plurality of spitzkasten is discharged from the last.

Arzinger (1,282,730/1918). A body of pulp in a trough is aerated by discharging water containing oil thereinto through small nozzles placed close to the pulp surface. High velocity of the jet is insured by high pressure in the water line. The patent reports 96 per cent. recovery on a graphite ore in the form of 80 to 88-per cent. graphite concentrate.

Blomfield (1,310,051/1919). By means of an air-lift placed in a tank containing oiled pulp, a part of the pulp is lifted above the general level and discharged against an umbrella which causes it to fall back into the body of pulp and thus entrain the air needed to set up bubble-column action therein.

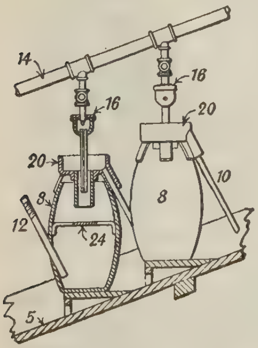

Fig. 45.—Emerson cascade flotation machine.

Emerson (1,311,882/1919, Fig. 45). A series of barrels (8) is set in an inclined trough (5) forming a concentrate launder. Oiled pulp enters the barrels by inclined pipes and (10) funnel-shaped feed boxes (20). Aeration is effected by means of water injectors (16) attached to a pressure pipe (14). Froth overflows the barrels and tailing passes

on through pipes (12) to succeeding barrels. Baffles (24) are placed in the barrels to prevent air from passing down into the tailing discharge.

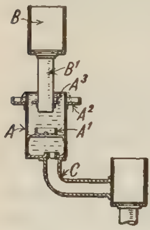

FIG. 46.—Seale and Shellshear cascade machine.

Seale and Shellshear (1,311,919 and 1,311,920/1919, Fig. 46). Oiled pulp falls from box (*B*) through pipe (*B*′) into a body of pulp maintained at the proper level in tank (*A*). Pipe (*B*′) is not filled with falling pulp, hence the stream breaks and the falling masses introduce air in the usual fashion. Baffle (*A*′) prevents passage of air into outlet pipe (*C*). Baffle (A^3) tends to prevent disturbance of the bubble column. Froth overflows into launder (A^2). Water is fed into (*B*) as necessary to maintain the proper pulp level in (*A*). The apparatus is operated with several pots in series with a pulp elevator in the flow where necessary. Another form is described in the second patent.

At JUNCTION NORTH MILL, Broken Hill, N.S.W. (*9 Min. & Eng. Rev. 296*) ten 16-in. (diam.) × 24-in. pots in series, five for lead flotation and five for zinc treated 22 tons per hr. Fairchild (*104 J 392*) reports failure of cascade machines on low-grade copper ore at RAY CONSOLIDATED, the apparent fault being lack of sufficient aeration.

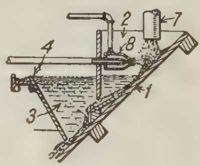

FIG. 47.—Ross cascade machine.

Ross (1,328,456/1920, Fig. 47). Oiled pulp is discharged through pipe (7) onto inclined apron (1) forming the back of feed-box (2). The falling stream is met by a stream of water from injector (8) and then passes through feed box (2) into spitzkasten (3), where a bubble column forms and overflows lip (4). Tailing is re-treated in subsequent similar boxes.

Appelquist and Tyden (1,367,223/1921). Oil, gasified or liquid, is fed with ore or pulp into a small hopper and there mixed and the mixture aerated by the cascade action of a jet of water. The oiled and partly aerated pulp discharges with more or less fall into a spitzkasten where flotation takes place by bubble-column action in the usual fashion.

Luckenback (1,397,815/1921) describes a machine similar to Seale and Shellshear (1,311,919; 1,311,920.)

Bonnell (1,399,539/1921, Fig. 48). Oiled feed pulp entering machine through pipe (17) is elevated by air-lift (24) to apron (21) and discharged onto the pulp in spitzkasten (12). Some mineral may float by skin flotation, the majority is raised and concentrated by bubble-

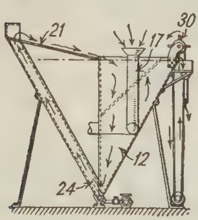

FIG. 48.—Bonnell cascade machine.

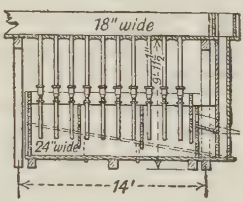

FIG. 49.—Donaldson cascade cell.

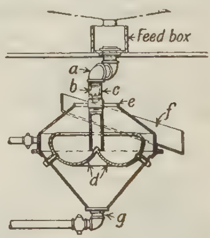

FIG. 50.—Court cascade machine.

column action in the spitzkasten and overflows or is scraped off by scraper (30). Tailing enters an adjoining spitzkasten for similar treatment. Some, but very little, of the air introduced in the air-lift remains in the pulp through its passage down the apron.

Donaldson cell (Fig. 49) was used for a time as a scavenger at the ARIZONA COPPER CO. mill (*103 J 665*). During 1915–1916 three boxes in series recovered about 1800 lb. of copper per 24 hr. in an 11 per cent. concentrate.

Court (1,470,350/1923) describes a cascade apparatus (Fig. 50) consisting of a double-conical shell containing a deflecting plate (*d*), fed by a nozzle (*b*) within an enclosing pipe,

the latter projecting below the pulp level in the machine. The bubble column is crowded by the upper walls of the cell and by a crowding plate and overflows into launder (*e*). An equalizing pipe permits regulation of pulp level by by-pass to the succeeding unit. Tailing discharges by gravity from the apex of the lower cone. The inventor recommends a number of units in series.

Experiments at MIAMI COPPER Co. showed that the pipe enclosing the nozzle had no other function than to prevent mechanical destruction of the bubble column by splash of the entering stream. This and similar devices have been tested at several mills, *e.g.*, OLD DOMINION, BRADEN, MIAMI, and have been found of no particular worth except to scavenge a minute amount of mineral from tailing.

Christensen (1,521,277/1924) describes a horizontal revolving cylinder whose lower surface just touches the upper surface of the pulp in a chamber that connects by suitable conduits with the bottom of two spitzkasten set back-to-back. Revolution of the cylinder throws pulp against a curved hood whence it falls into the spitzkasten. This is simple cascade action.

Hynes (1,394,306/1921, Fig. 51). A plurality of impellers (36) formed of perforated disks, set close together on a horizontal shaft and revolving somewhat less than half submerged. Discharge of agitated and aerated pulp through slot (19) into spitzkasten (17). The machines used at the ROSEBERRY MILL, Sandon, B. C. (*114 J 679*) had 35, 50 and 100 disks. The tank of the 50-disk machine was 6 ft. long, 5½ ft. wide and 4 ft. deep. Disks were 30 in. diameter, of 12-gage steel, with ½-in. holes on ⅞-in. centers and were placed 1¼ in. apart. Speed was 90 r.p.m. Performance at this mill was superior to that of the M.S. standard machine. There may be some agitation-froth action in this machine, in addition to the cascade action, but the speed is relatively slow and the appearance in the spitzkasten is distinctly that of a bubble-column machine.

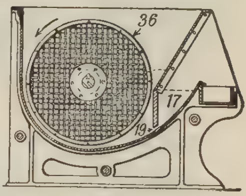

FIG. 51.—Hynes flotation machine.

12. Centrifugal bubble-column machines

These machines are sometimes known as SUB-AERATION MACHINES. They introduce air into the pulp by reason of the centrifugal force induced by a mechanism rapidly revolving in the pulp. Some of these machines have enjoyed considerable use in the mills, although such use has been small by comparison with the agitation-froth and pneumatic machines. Various forms of the apparatus are listed below.

Higgins and Stenning (1,155,815/1915, Fig. 52). Oiled pulp is fed through slot (*J*) into compartment (*A*) where it is aerated by air drawn in through pipe (*E*) by reason of the centrifugal pumping action of impeller (*B*). Aerated pulp passes up and under baffle (*L*) into the upper part of chamber (*A*) where typical bubble-column action is set up in and above a body of pulp protected by the inclined partition from the agitation caused by the impeller beneath. Froth overflows lip (*N*) while tailing passes on through a valve-controlled slot (*F*) for further similar treatment. The machine is inefficient on its face, by reason of the obstruction offered to the rise of air bubbles after introduction and has had little or no mill use. As in some of the other centrifugal machines later described, there is a small amount of pulp-body concentration (agitation-froth type) in this machine, the proportion with regard to the whole action increasing as the amount of air inflowing through pipe (*E*) is decreased.

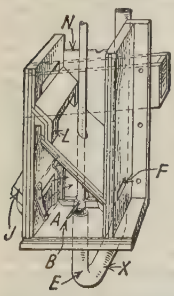

FIG. 52.—Higgins and Stenning sub-aeration machine.

Higgins (1,155,816/1915). Other forms of apparatus similar to that just described.

Owen (1,155,836/1915, Fig. 53) describes a practical form of apparatus consisting of a circular tank (*J*) with radial baffles (*E'*) to prevent vortical action of pulp therein, a pump impeller (*D*), feed inlet (*T*), tailing outlet (*M*), and constricted concentrate overflow rim (*P*). Air, pumped in through pipe (*N*) and regulating valve (*O*) by the action of impeller (*D*) is dispersed through the pulp by the action of the impeller and, rising through the pulp, forms a bubble column at the top, in which concentration takes place.

Fagergren and Green (1,195,453/1916, Fig. 54). A square pyramidal box (6) contains an inner box (17), perforated plates (30), (31) and (32) and a cross-shaped impeller (26) on a vertical spindle (29). Pulp enters through pipe (19). Air, introduced through pipe (20) with the feed pulp, is dispersed therethrough by the impeller and rises to form a bubble column at the top, causing concentrate to overflow into launder (9), as indicated by the arrows. Tailing, falling, is deflected over the lip (18) of box (17) and discharged through pipe (23). The perforated plates (30,) (31) and (32) prevent the turbulence set up by the impeller from reaching and disturbing the bubble column.

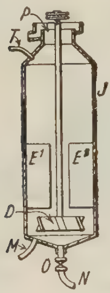

Fig. 53.—Owen sub-aeration machine.

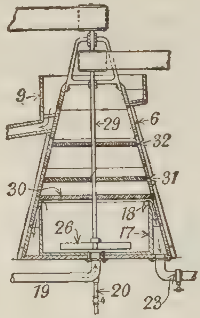

Fig. 54.—Fagergren and Green sub-aeration machine.

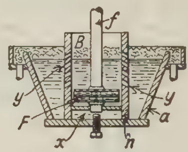

Fig. 55.—Groch sub-aeration machine.

Groch (1,276,753/1918 and 1,413,723/1922, Fig. 55). Air, drawn down the hollow impeller shaft (*f*) by reason of the rotation of the specially designed impeller (*F*) at the bottom, is dispersed through pulp in the box (*B*). Aerated pulp flows by gravity through the ports (*y*) into the spitzkasteñ (*a*), in which separation takes place by bubble-column action. Ports (*n*) allow circulation of pulp from the spitzkasten back, by means of the pumping action of the impeller, to the aerating chamber of the same compartment, and other ports (not shown) pass pulp from the spitzkasten into a chamber corresponding to (*X*) below the impeller in the following compartment.

Groch and Simpson (*21 CMI 145*) describe a commercial machine 14 ft. long × 5 ft. wide containing 6 impellers, having a capacity of 35 to 75 tons per day and consuming 7.5 hp. They state that at 200 r p.m. the vacuum in the hollow shaft becomes measurable, at 450 r.p.m. it is equivalent to 2.75 in. of mercury and at 750 r.p.m. to 6 in.

Ruth machine (1,445,042, 1,463,405 1923, Fig. 56) is similar to the Groch apparatus. It consists of a box (*a*) divided by partition (*b*) into an aerating compartment (*c*) and a spitzkasten (*d*). The aerating compartment is fitted with a grid (*g*) which prevents the creation of a vortex in the upper part of the chamber. A hollow vertical shaft (*e*), open at the upper end, extends into the aerating compartment and carries at its lower end a disk (*f*) for circulating pulp and introducing air. The revolution of the disk in the direction shown by the arrow produces a vacuum behind the shields (*Y*) over the air passages and air passes in through the hollow shaft to fill these spaces. The rotation of the disk also causes pulp to be drawn up through the passages (*X*) from the chamber (*h*) which opens into the lower part of the spitzkasten. Separation takes place in the bubble column above the compartments (*c*) and (*d*) and concentrate in the form of froth is overflowed at the lip (*i*).

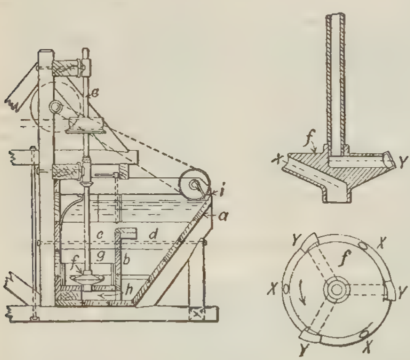

Fig. 56.—Ruth machine.

In the standard machine the disk is made 14 in. diameter and the hollow shaft is 1.1 in. inside diameter. The machine is driven at from 270 to 300 r.p.m. A capacity of 150 to

200 tons per day with a power input of about 1 hp. per spindle is claimed for an 8-cell machine. It is also claimed that 20-mesh material can be treated. These claims seem decidedly optimistic and probably a considerably lower tonnage of pulp ground to the usual flotation size (65-mesh) must be handled in order to get good results. At ZINC CORPORATION MINE, Broken Hill, Australia (*118 P 88*) impellers 10 in. diameter × 2 in. deep at 700 r.p.m. required 2.1 hp. per spindle.

Kraut (1,322,909/1919, Fig. 57). Pulp fed in at (*a*) is pumped by the revolving slotted cylinder (*b*) through the ports (*c*) into the shallow separating chamber (*d*) and there maintained in its flow toward the tailing-discharge box (*e*) by the rotating cylinder. The revolution of the cylinder also causes air to be drawn in at the ends thereof (*f*) and to pass through the ports (*g*) into the pulp and therewith into the separating chamber. Herein the air forms a bubble column with the oiled pulp causing flow of froth concentrate over the lips (*h*).

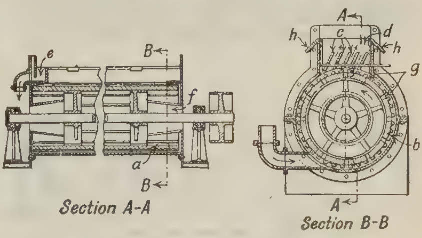

FIG. 57.—Kraut sub-aeration machine.

Hebbard sub-aeration machine is shown in Fig. 58. It consists of a trough (*A*) partially sub-divided into compartments by partitions (*t*), in which compartments are rotated vertical spindles (*a*) carrying at their lower ends disks (*b*) with radial arms on the lower face. The machine pictured is known as a 24-in. machine, so denominated by the diameter of the disks. The trough (*A*) is 3 ft. wide, 24 ft. long, and 5 ft. deep, allowing 3 × 3 ft. cross-sectional area for each 24-in. disk. Feed is introduced into the machine under the first disk, through a feed pipe (*e*) from a pressure box (*d*), or it may be introduced by means of an ordinary feed box through a slot in the end wall. Air under from 2 to 5 lb. pressure per sq. in. is supplied through the pipes (*g*) directly under each disk except the first. In machines fed through the end of the trough, air is also supplied under the first disk. Froth overflows the sides of the trough. Tailing is discharged through the slot (*l*) into the box (*m*). Pulp level is regulated by means of the valve in the discharge pipe (*o*).

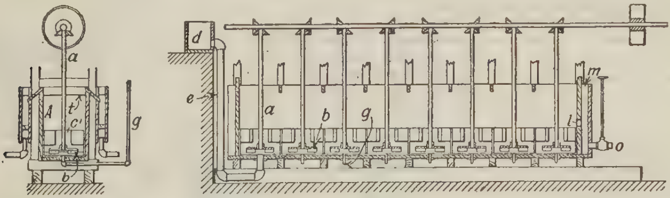

FIG. 58.—Hebbard machine.

The capacity of a 24-in. machine is about 80 tons of sandy feed per compartment per 24 hr. in a pulp containing 20 to 25 per cent. solids, with a power consumption of 10 hp. per spindle. An 18-in. machine treats about 40 tons per cell with a power consumption of 6.5 to 7 hp. per spindle. At INSPIRATION (*102 J 619*) the Hebbard machine drew 4.9 kw.-hr. per ton treated, including both spindles and compressed air furnished below the spindles. The air consumption is about 0.5 cu. ft. per min. per ton of daily capacity at a pressure of 5 lb. per sq. in. The machine has been almost uniformly unsuccessful in the mills.

13. Combination bubble-column machines

Many of the bubble-column flotation machines employ two or more of the methods listed for introducing the air necessary for bubble-column formation.

K. and K. machine (Kohlberg and Kraut, 1,174,737/1916, Fig. 59) utilizes the principles of both the centrifugal-type and the cascade-type bubble-column machines. The essential parts are an aerating compartment (*1*) and a froth-separating compartment (*3*). Aeration is accomplished by rapid revolution of the cylinder (*17*), which is about 30 in. diameter and 9 ft. long.

Pulp is introduced at one end of the aerating compartment at a point somewhat above the shaft (*16*) and discharges through a pipe at the other end of the settling compartment. The pulp level is maintained well below the center of the shaft in the aerating compartment. Circulation of pulp within the machine is accomplished through the ports (*11*). Aeration is accomplished differently according to which of the cylinder surfaces (*A*), (*B*), (*C*), (*D*) is used. When (*B*) or (*C*) is used, air is carried into the pulp on the down-coming side in the spaces between the cleats. This is essentially the action of the plunging stream in the cascade-type machine. When type (*D*) is used there is, in addition to air thus carried into the pulp, a creation of vacua in the ports (*21*) into which air passes from the center of the cylinder. A similar combination of phenomena occurs in the use of (*A*). The direction of rotation is as indicated by the arrow. Partially aerated pulp is thrown through the port (*7*) onto the body of pulp in (*3*) and flows under hood (*8*) and over the baffle (*9*) thus introducing air into the pulp in (*3*). Froth overflows the lip of compartment (*3*). Air is allowed to enter through pipes (*23*) and water can be added through pipes (*26*).

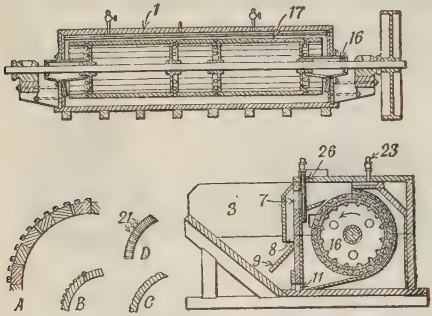

Fig. 59.—K. and K. machine.

The K. and K. machine is ordinarily driven at from 160 to 200 r.p.m. The capacity varies from 30 to 100 tons per 24 hr. with a power consumption of from 10 to 15 hp., according to the volume of pulp passed. Hardwood impeller slats last 6 weeks to 3 months. Watt (*57 A 376*) gives the following data concerning K. and K. machines in SOUTH-EAST MISSOURI. Cylinder housing, 30 in. diameter by 10 ft. long; cylinder shaft 3 7/16 in. diameter; drum lagged with 16 strips spaced 12 in. edge to edge, each strip carrying four hardwood riffles; minimum clearance between riffles and housing, 5/8 in.; speed, 180 to 200 r.p.m. Floor space required is 4 × 14 ft. and headroom 3 ft. Capacity, 50 to 80 tons per 24 hr. Power consumption, 10 to 15 hp. Weight, wood type, 2500 lb.; steel, 3500 lb.

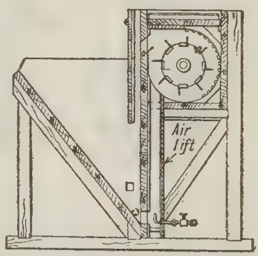

Fig. 60.—Ziegler machine.

Ziegler (1,324,139/1919). The usual form is shown in Fig. 60. It is similar to the K. and K. machine except that the rotating cylinder is placed higher with respect to the spitzkasten and air-lifts are used to aid pulp circulation. Cylinder speed is about 175 r.p.m. About 30 to 50 cu. ft. of air per min. is required for the air-lifts in a 5-cell machine and 5 to 6 hp. to drive the cylinder. Capacity on ordinary pulps is 75 to 100 tons per 24 hr. (*105 J 707*).

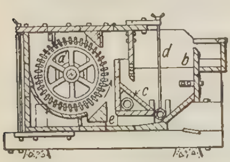

Fig. 61.—Rork and Sandberg machine.

Rork and Sandberg machine (1,454,656/1923, Fig. 61) is a combination of the pneumatic and cascade types. The essential parts are a long slatted cylinder (*a*), about 30 in. diameter by 9 ft. long, revolving in the direction indicated by the arrow, a transversely compartmented spitzkasten (*b*), provided with air baskets (*c*) and valves (*d*) for regulating circulation of pulp.

Feed is introduced at one end of chamber (*e*), lifted by the paddle wheel, and thrown into the first spitzkasten, thus aerating the pulp therein by cascade action. Further aeration is effected by air introduced through the porous medium (*c*) and a bubble column is built up and overflows. Tailing from the first spitzkasten passes back into chamber (*e*) and is thrown into the adjoining spitzkasten and thence in similar fashion until it discharges from the bottom of the last spitzkasten. Three to five is the usual number of compartments.

A modification of this type of machine has been used in various plants of the Phelps-Dodge Corp. At Morenci a single-cell machine treated 35 to 45 tons per day and a 3-cell machine 60 to 90 tons with a power consumption of 13.5 hp. for the single cell and 25 hp. for the 3-cell machine. The pulp contained 20 per cent. solids. Paddle speeds were 160 and 200 r.p.m. respectively. Tailing and concentrate on the same feed were substantially the same on both types of cell. At Burro Mountain the roughing cells were 3- and 5-compartment and the cleaners 2-compartment. The smaller roughers handled 85 tons per 24 hr. and the larger 130 tons, in pulps containing 18 to 20 per cent. solids. Power consumption averaged 27 hp. per cell at 200 r.p.m. Life of hardwood paddles was 60 to 100 days on feed containing 4 per cent. +48-mesh.

Parker (1,492,933/1924) describes a combination centrifugal and plunging-stream bubble-column machine, similar to the K. and K. except that the settling compartment is not divided off from the cylinder.

This machine was used at Bunker Hill and Sullivan. Three machines in series treated 75 tons per 24 hr. of 7.0 per cent. lead ore, 95 per cent. −200-mesh, in a pulp containing 33 per cent. solids. The oil mixture was 80 per cent. Barrett No. 4 and 20 per cent. steam-distilled pine oil; total added, 0.28-lb. per ton. Each machine drew 7 hp. at 78 r.p.m. Concentrate from the three machines, combined, assayed 60 per cent. Pb. Tailing went to a Callow cell which made a 1.5-per cent. tailing and 12-per cent. overflow, which was returned to the head of the Parker cells.

Dunn (1,219,089/1917, Fig. 62). Pneumatic and cascade. Pulp introduced into spitzkasten (*A*) is projected with gas (air) and oil into chamber (*B*) by means of injectors (17) until the pulp level in (*B*) builds up sufficiently to overflow (15) and fall back onto the surface of the pulp in the spitzkasten, when a bubble column builds up in (*A*) and overflows as concentrate at (*K*). Tailing discharge is at the opposite end of the spitzkasten from the feed inlet.

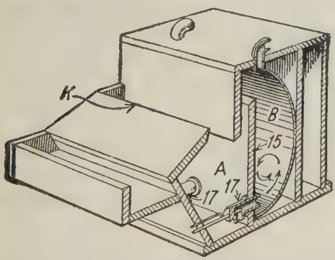

Fig. 62.—Dunn flotation machine.

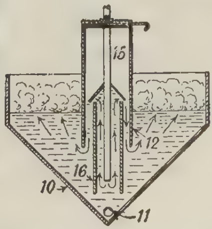

Fig. 63.—Welsch flotation machine.

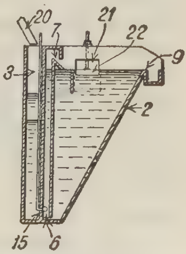

Fig. 64.—Brown flotation machine.

Welsch (1,253,653/1918, Fig. 63). In a spitzkasten (10) one or more air-lifts (16) discharging in a closed pulp-sealed chamber (15). Pulp in the spitzkasten is aerated by the escape of air under the walls (12) and also by the air introduced by the cascade action of the air-lift discharge, resulting in the formation of a bubble-column and an overflow of concentrate. Feed enters by a pipe (11) at one end of the spitzkasten and tailing discharges by a similarly placed pipe at the other end.

Terry (1,254,173/1918). This is a patent for differential flotation (see p. 877) but it incidentally discloses an operation in which the flotation reagents are mixed with pulp in closed agitation chambers so fed that no gas is present during the agitation, then discharged into an air-lift and thence with a free fall onto the surface of pulp in a spitzkasten.

Brown (1,351,155/1920, Fig. 64). In a spitzkasten (2) an air-lift (3), (15), (6), (7) discharging onto the surface of pulp in the spitzkasten. Pulp is fed through pipe (20) in the

down-going leg of the air-lift, aerated in the uprising leg (5) and further aerated in the fall into the spitzkasten. The bubble column overflows lip (9) and tailing goes over a weir (21), (22) into an adjoining feed compartment or to waste. There is also circulation of pulp within each compartment by a connection between the spitzkasten and corresponding air-lift.

Otsuka (1,393,821/1921). A modification of the K. and K. machine in which pre-mixing chambers are provided and air under positive blower pressure is introduced into the main aerating chamber.

Robbins (1,398,394/1921). In a Dorr thickener or similar apparatus, a grid of porous pipes suspended above the rakes for gas (air) introduction, and an air-lift or similar device centrally located for lifting settled solids to revolving distributing arms above the pulp surface. Aeration is both pneumatic and by cascade action of the circulating pulp. The bubble column overflows peripherally and tailing is disposed of by the central bottom discharge usual in Dorr thickeners.

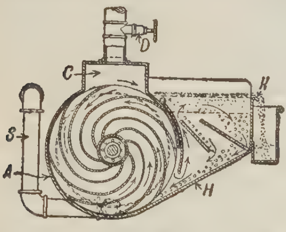

FIG. 65. — Gross, Akins and Bucher flotation machine.

Gross, Akins and Bucher (1,401,535/1921, Fig. 65). Pulp introduced through (*S*) into the bottom of chamber (*A*) is caught up by the spiral sand pump which, on further revolution, engulfs air from chamber (*C*). The mixture of air and pulp discharges from the spiral pump centrally and laterally into a squirrel cage surrounded by screen cloth, and thence is thrown out through the screen into the spitzkasten (*H*) and thus introduces more air by cascade action. There may be, also, some agitation-froth action by reason of the revolving parts in the body of pulp, but this is small on account of the relatively low speed. The bubble column formed in the spitzkasten overflows lip (*K*), middling is circulated, as indicated by the arrows in the spitzkasten, tailing discharges through a pipe at the opposite end from the pulp-entry. Some regulation of the extent of aeration is afforded by valve (*D*).

14. Atomizing

Atomizing processes differ from ordinary bubble-column operations only in that the oil is introduced in the form of a gas or vapor or a very fine spray with the air. The only essential difference between these processes and those in which liquid oil is added to the pulp is that, in atomizing, the oil, when introduced, is already finely divided, and dispersion throughout the pulp is, therefore, more rapid than in the case of liquid addition. Most of the patents state that this method of oiling lessens the amount of oil required, but this has not been the case in practice. All of the air introduced may be oiled, or only a part, in which latter case the oiled air is introduced first, as through the first compartments of the air basket in a pneumatic cell. Atomizing is first disclosed in patent 793,808 (see p. 808). Subsequent patents are described below.

Gröndal (1,202,512/1916) describes " . . . distributing the oil in a streaming elastic fluid under pressure such as steam or air and afterward mixing the steam or air under pressure with its contents of oil with a large quantity of an elastic fluid such as air or any other gas and then pressing the mixture into water holding the ore suspended."

Dunn (1,219,089/1917, see p. 823) describes also addition of oil by atomizing.

Schwarz (1,237,961/1917) describes the use for flotation in a bubble-column machine (since the use of an agitation-froth machine is practically debarred by the exigencies of the operation) of a gas other than air together with an oil; the whole apparatus being sealed from the atmosphere and the gas, with oil vapors contained, being re-used.

Scott (1,246,665/1917) describes " . . . using a volatile oil, impregnating the air with the gasified volatile oil, and introducing the gaseous mixture of air and oil into the pulp. . . ." In 1,508,478/1924 he describes the use of atomized oil in the agitation-froth process.

In 1,261,303/1918, Scott claims " . . . that it is not necessary to use any oils whatever in the [flotation] process, that is, it is not necessary to use any of the liquid substances heretofore employed in the flotation process, but that the concentration of the ore can be affected by the use of an admixture of air with a permanent gas . . . [*i.e.*], a substance that remains gaseous under ordinary conditions as opposed to vapors which condense at

ordinary temperatures . . . of the atmosphere and of the pulp. . . ." Acetylene is given as an example.

In 1,365,281/1921, Scott says: " . . . it has heretofore been proposed to dissolve a soap in the pulp and to decompose the soap by means of a mineral acid also mixed with the pulp, thus freeing the fatty acid contained in the soap. . . . I dissolve the soap in the pulp as formerly . . . but introduce the mineral acid in gaseous form in admixture with the air . . . the gaseous mineral acid within the bubble reacts with the soap in solution in the pulp . . . with the result that the fatty acid . . . is freed at the precise place where its properties are to be utilized, namely in the interfacial film." Any mineral acid that can be maintained in the gaseous condition while being introduced with the bubble-forming gas may be used, and under some conditions the mineral acid may be introduced in a finely-divided liquid or solid form with the gas. Any substance that is capable of reacting with a substance in the pulp to produce a third substance that will effect flotation, may be introduced with the gas.

In 1,369,045/1921, Scott describes the addition of acid with the bubble-forming gas to effect economy in acid consumption in the case of ores containing a constituent that reacts with and consumes acid.

Dosenbach (1,257,329/1918) states that "it is unnecessary that the modifying agent [oil] mixed with the air be in the gaseous or vaporized form, [referring to a preceding patent] but efficient results are obtained if the modifying agent in the liquid form is minutely subdivided, so . . . as to be carried with the stream of air in the form colloquially referred to as a 'fog' . . . the modifying agent is not injected into the pulp by means of an atomizer or injector, but a mixture of air with a modifying agent so finely divided as to remain suspended in the air is prepared in advance and a mixture of air and modifying agent so prepared is then . . . introduced into the ore pulp through a porous medium."

In patent 1,350,364/1920, Dosenbach describes the removal from an oil of the water-soluble and/or condensable portions and the introduction of the balance in gaseous form with air. In patent 1,354,031/1920, he describes apparatus for practicing atomizing and vaporizing methods in flotation operations.

Moffatt (1,400,308/1921) describes a method and illustrates apparatus for atomizing that was used on a large scale for treatment of porphyry copper ores. (Fig. 66.) The description applies to flotation in a pneumatic cell of the Inspiration type (see p. 813). The agent is any flotation oil such as oil, tar, creosote, etc. The porous mat or section of the cell floor through which the mixture of flotation agent and air is admitted is preferably at the feed end of the cell. Porous mats are preferably made of molded material such as porous cement made by bonding rock screenings with Portland cement, 6- to 8-mesh size being used for the more porous mats through which agent is to be introduced and 20-mesh size for the less porous mats for air alone. In the diagrammatic sketch *(28)* is a low-pressure blower, *(29)* an air heater, *(30)* a receiver with pipes *(32)* leading to the oiling compartments of the flotation cells. *(36)* is a tank containing flotation agent in liquid form, with oil-supply pipe *(45)*, and a pipe *(42)* for supplying high-pressure air from receiver *(41)* and compressor *(40)* for atomizing. *(38)* is an atomizer for dispersing the oil in the current of heated air in *(31')*. Condensed oil is drawn by pipe *(50)* into tank *(52)*. *(57)* is the unoiled-air main for supplying air to the later air baskets of the machine.

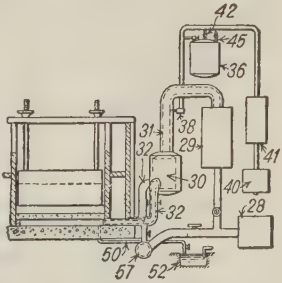

Fig. 66.—Moffatt apparatus for atomizing.

At Ray Consolidated Copper Co. 5000 to 6000 tons per day was treated in four 15-cell and ten 16-cell Inspiration-type rougher machines (3 × 4-ft. compartments) with oiled air introduced through the first six bottoms in each machine. The oil mixture consisted of one part of steam-distilled pine oil to 6 to 10 parts of coal-tar creosote, the total averaging 1.34 lb. per ton of ore. Rougher tailing was sent to waste. Rougher concentrate went to fourteen 9-compartment Inspiration-type cleaners, the last three compartments run counter-

current and discharging from cell No. 7. Cleaner concentrate was finished and cleaner tailing sent to waste. With a feed averaging 0.626 per cent. Cu, average tailing for one year's operation was 0.341 per cent., concentrate 16.93 per cent. and recovery 46.6 per cent. Oxidized copper in feed and tailing ranged from 0.25 to 0.40 per cent.

15. Combination pulp-body and bubble-column processes

A number of the processes described in flotation patents are combinations of one of the methods of pulp-body concentration, usually the agitation-froth, with one or more of the bubble-column methods. These combination processes sometimes give a better metallurgical result than can be achieved by either type of process alone, but the improvement is oftentimes made at an expense for additional power and equipment that results in a poorer commercial result.

Machines utilizing agitation-froth and pneumatic treatment are described in the following patents:

Callow (1,124,853/1915). See p. 811.

Clawson (1,240,824/1917). Pulp with reagents is fed into the feed hopper of a centrifugal pump which is fitted with an extension casing containing agitator blades mounted on an extension of the pump shaft. The pump discharges through an injector and thence through a zigzag pipe into a spitzkasten. Froth overflows and tailing discharges from the apex. The spitzkasten is closed over and the closed space connected by pipe with the injector, in order to re-use any gaseous frothing agent.

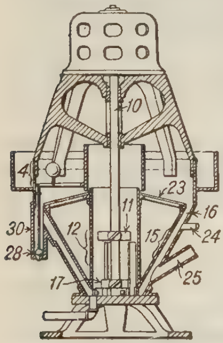

FIG. 67.—Jones-Belmont flotation machine.

Jones (1,326,453/1919, Fig. 67). Vertical spindle (10) carrying two cross-bladed, 45-degree impellers (11) and (17) is suspended in the cylindrical baffled agitating compartment (12), open at the top to the atmosphere and at bottom to the annular conical space (16). An annular sloping porous medium (23) on top of the air chamber formed by the walls (12) and (15) is supplied with air under pressure through pipe (24) and the air passes into the pulp through this medium. Feed enters by pipe (25) and passes into the agitation compartment. Agitated and aerated pulp is discharged from this compartment over the porous medium (23). Froth overflows rim (4). Tailing discharge through pipe (30) is controlled by the automatic ball valve (28). This is a combination of agitation-froth and bubble-column action similar to the Janney mechanical-air machine.

Janney mechanical-air machine (1,342,115/1920; 1,457,077/1923) utilizes pulp-body concentration by the agitation-froth method and bubble-column action by pneumatic and cascade means. The machine as installed in the mills is shown in Fig. 68. The combination of processes is effected by placing air baskets in the froth-separating compartments of a Janney mechanical cell and effecting therein further aeration of the pulp discharged from the agitating compartment, by reason of the cascade action of the incoming spitzkasten feed and by air introduced through the porous bottom. The agitating compartment is the same as that in the Janney mechanical machine, and has an individual vertical motor. The three-compartmented air baskets in each froth-separating compartment are supplied with air at from 4 to 5 lb. pressure on the supply side of the regulating valves. The machines are set up end-for-end as indicated in the drawing. The first machine in series is usually preceded by a Janney emulsifier Pulp passes from the emulsifier discharge box, which may be taken as represented by box (*a*) in the drawing, through a pipe by gravity into the agitator compartment of the machine and is thrown up over the top of the agitator compartment onto the air baskets. Froth overflows the lips of the air-basket compartments. The tailing is in part circulated

through the pipes (*b*) and finally passes through the adjustable overflow slots (*c*) into the tailing-discharge launders (*d*) and thence to the following machine. By thus utilizing both methods of froth concentration it is possible to make a good recovery in a relatively small number (5 or 6) of the machines in series.

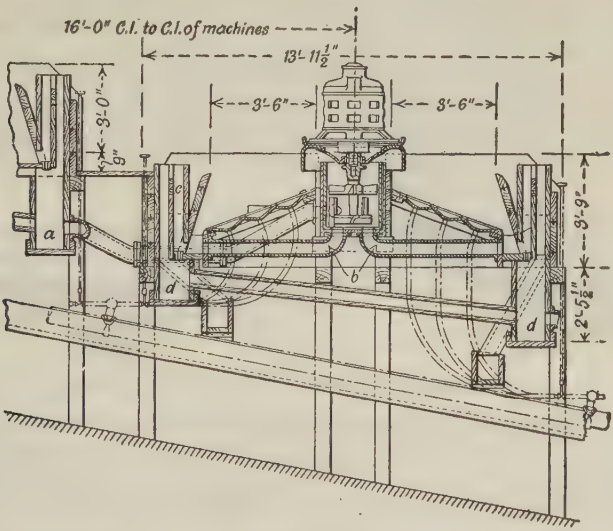

Fig. 68.—Janney mechanical-air machine.

The capacity of a 24-in., 5-compartment machine on silicious ore in a pulp containing 20 to 25 per cent. solids, is 150 to 200 tons per 24 hr. The power consumption per agitator is 6 to 7 hp. The air consumption per square foot of air-basket is from 5 to 10 cu. ft. of free air per min. at 4 to 5 lb. pressure, corresponding to an additional power of 5 to 8 hp. per machine.

The froth in this machine, as in others of its type, is not to be distinguished from a typical bubble-column froth from a cursory observation. It is probable that a large part of the increased metallurgical recovery is due to the fact that the buoyancy of the air-mineral agglomerates formed in the agitation chamber results in the presentation of a greater proportion of the mineral to the lower layer of the bubble column for treatment, but that the final effective concentration in the machine is due wholly to bubble-column action.

The flotation section of the Arthur plant of the Utah Copper Co. has 13 sections, each containing 55 of these machines, built, however, of concrete instead of wood and using vitrified tile instead of iron pipe for the pulp-circulating pipes.

Shimmin and Bushnell (1,402,099/1922). See p. 827.

Machines utililizing agitation-froth and cascade action are described in the following patents:

Janney (1,167,076/1916, see p. 802). In this machine, although the bulk of the flotation is of the agitation-froth type, nevertheless a considerable amount of air that is effective in making the froth buoyant is introduced by cascade action in the discharge of the pulp from the agitation chamber into the spitzkasten.

Piersol (1,335,600/1920, Fig. 69). Pulp with oil is introduced into chamber (5) and is agitated and aerated therein and then thrown through conduit (13) into the pulp in the spitzkasten. Pulp circulates from the spitzkasten back into the agitation compartment through conduit (18) and tailing discharges through pipe (32). The proportion of the recovery due to agitation-froth treatment will depend upon the speed of the impeller; if that is low, most of the recovery will be due to cascade action and *vice versa.*

Haley (1,357,556/1920). This is an apparatus consisting of a spitzkasten fed with oiled pulp pumped by means of a centrifugal pump with air admitted to the suction pipe through a nozzle discharging above the surface of the pulp in the spitzkasten.

Boggs (1,390,080/1921, Fig. 70). Ore is fed into chamber (A) with oil and is agitated by the slatted wheel carried on shaft (9) and thrown over into box (C) where it is further agitated by a similar wheel and finally thrown through slot (27) onto the surface of the pulp in spitzkasten (D). Concentrate froth overflows the spitzkasten; tailing discharges through pipe (32) into conduit (E), fitted with a spiral for elevation of sand tailing. Pulp may circulate through slot (F) back into the agitation chamber (A).

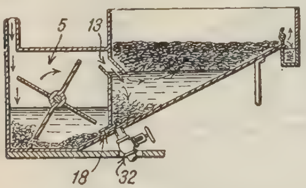

Fig. 69.—Piersol flotation machine.

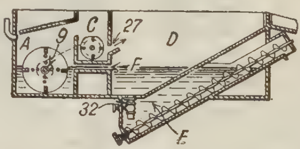

Fig. 70.—Boggs flotation machine.

Daman (1,556,083/1925) describes an apparatus in which the agitating compartment is placed so far below the spitzkasten that an air-lift must be used to return the agitated pulp to the spitzkasten. He thus obtains cascading of the return into the agitating compartment (which is wasted and useless) and also of agitated pulp into the spitzkasten, which is of some, though little effect. His apparatus also attempts, by suitable valve arrangement, to pass sandy tailing directly from compartment to compartment while slime is circulated several times in each compartment, without agitation, however. This lack largely vitiates any useful idea involved in slime circulation.

Machines utilizing agitation-froth and centrifugal or sub-aeration bubble-column action are described in the following patents:

Seale and Shellshear (1,341,024/1920, Fig. 71). Feed pulp admitted at (B) is pumped by impeller (F) through chamber (G) into separating compartment (A) and at the same time impregnated with air introduced through pipe (K'), which is curved and perforated at the lower end as shown at (K^2). In compartment (A) a bubble column forms on the surface of the pulp. Crowding boards (J) deflect the bubble column toward the overflow lips. Pulp from the first compartment flows toward the right where, in chamber (G^2) it meets two impellers, the first directing it back toward compartment (A'), the second pumping it onward toward compartment (A^2). Here it is further impregnated with air introduced through another pipe (K') and again passes into a separating chamber. Similarly in succeeding units. Tailing is discharged over a weir into box (C^3), thus maintaining the desired pulp level in the cell. Coarse sand is discharged at (C^2) as necessary.

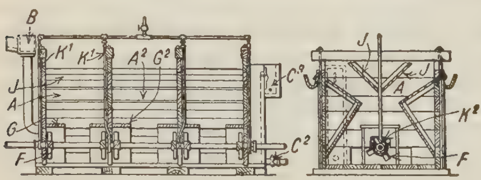

Fig. 71.—Seale and Shellshear flotation machine.

Kraut (1,549,492/1925). A downwardly-converging perforated conical rotor, closed except for a few holes at the top, revolving on a vertical spindle in a similarly-shaped chamber of slightly larger size which is, in turn, centrally mounted in fixed position in the center of a square pyramidal spitzkasten. The enclosing chamber is open at the bottom and has ports at about the pulp level. Revolution of the impeller causes aeration of the pulp both by agitation and by centrifugal action. Aerated pulp is discharged at the top of the fixed enclosing chamber and enters it at the bottom.

Lemmon-Hebbard machine (Fig. 72) was developed at Tul Mi Chung (*33 IMM 3*) to answer a demand for more vigorous frothing. It consists of a standard high-level M. S. machine with air introduced under the impeller, a grid baffle placed in the beater box just above the outlet to the spitzkasten and bubble-column overflow provided by cutting down the back of the beater box. The capacity of the machine was twice that of the standard machine and power consumption was reduced about 6.5 per cent. per spindle (to 7.1 hp.).

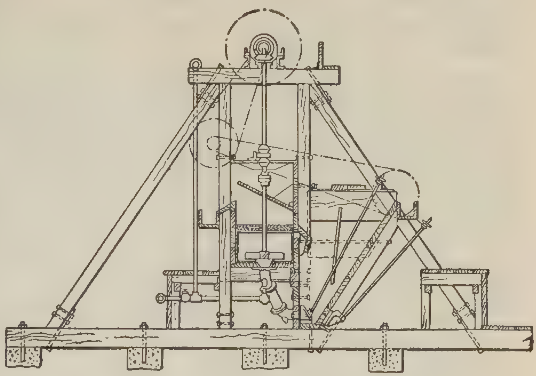

Fig. 72.—Lemmon-Hebbard machine.

Miscellaneous processes and apparatus, none of which has had any commercial application nor carries on its face any promise of success, are described in the following patents.

Nutter and Hoover (1,093,463/1914). This is an apparatus designed to cause "the froth as it is formed [by agitation-froth action] to fall over a trap baffle or wall below the level of the free air surface whereby the froth is collected and removed from the pulp before the bubbles can burst." The idea is impractical.

Wood (1,155,861/1915). This is a sub-aeration machine to be used without a frothing agent. It is expected that air bubbles attached to mineral particles will rise to the pulp surface and there break and drop their load onto a tray which discharges through the side of the box. The usual baffles are provided to prevent vortical action at the pulp surface. But this is a bubble-column machine; air bubbles do not arise carrying a load predominately mineral but pushing ahead of them a load of pulp. Concentration does not take place unless a bubble column is formed and an effective bubble column cannot be formed without a frothing agent, *i.e.*, an agent that modifies the surface tension of water.

Dolbear (1,343,313/1920) describes an apparatus that is essentially a pneumatic bubble-column machine in which the bubble column is supposed to be maintained below the general surface of the pulp underneath a transverse inclined baffle, and to discharge through valved openings in the side wall. The idea is ingenious but unworkable as the pressure of the head of pulp above the mass of bubbles would cause them to collapse, allowing the air to escape through the ports and the solid to drop back into the pulp.

Scott (1,375,233/1921). This is a porous-bottom tank arranged with a suction filter, such as the Oliver (see p. 1003), mounted above it in such a way that the filter drum dips below the surface of the liquid in the tank. It is stated that air bubbles carrying mineral will rise through the pulp and come into contact with the filtering surface, and that the air will be abstracted leaving the mineral adhering to the surface. As stated above (Wood, 1,155,861), the rising bubbles do not carry a mineral load, hence no such action can take place.

Dosenbach and Scott (1,401,055/1921). This is an apparatus built on the same theory as the preceding and failing for the same reason. It seeks to introduce air into an ore pulp through a porous medium and, by various means, to prevent the formation of a bubble column, by breaking the bubbles as they reach the pulp surface and collecting, as concentrate, the solid load that they drop. But, since the rising bubbles in the pulp do not carry concentrate, they cannot drop it

Ellis (1,488,745/1924) describes electrically grounding the flotation machine to prevent formation of static charges. Considering the substantially complete impossibility of obtaining or maintaining insulation of an operating flotation machine, grounding would seem to be superfluous.

Ellis (1,555,915/1925) recommends the use of oxygen or ozonised air as superior to atmospheric air for difficultly-floatable minerals, *e.g.*, sphalerite. He ascribes the improved results that he claims to electrical effects.

It is true that in the agitation-froth process, the more soluble the gas employed, the quicker the flotation effected. Thus carbon dioxide and nitrous oxide, with given flotation agents, yield considerably more rapid flotation than air. On the same basis oxygen should be somewhat more effective, but not sufficiently so to pay for its use.

16. Flotation agents

The term FLOTATION AGENT is used in this article to describe all substances added to an ore pulp for the purpose of aiding the separation therefrom, by flotation, of the valuable part.

Oil, according to dictionary and ordinary text-book definition, is an organic liquid having a greasy, slippery or unctuous feel, chemically neutral, inflammable, and immiscible in bulk with water. Oils are called animal, vegetable or mineral according to their source. Oil chemistry makes further subdivisions, only one of which is important here, *viz.:* the subdivision of vegetable oils into fixed oils and essential oils. FIXED OILS are those that cannot be distilled, either alone or with steam, without undergoing chemical decomposition; those that can be so distilled are called VOLATILE OR ESSENTIAL OILS. In flotation terminology the word oil has a much wider meaning than that above given. In its widest use it means any organic liquid added to the flotation pulp and common mill usage narrows this, if at all, only to the extent of requiring some oily feel or appearance. The word, therefore, includes substances such as oleic and other fatty acids which are not chemically neutral nor distinctly inflammable; kerosene and gasoline, which, while neutral, have not a distinctly oily feel; synthetic compounds such as the ester, amyl acetate; and many others. The purpose of addition of flotation agents is different in different processes, but in all processes one of the purposes is to effect, or aid in effecting, selection of valuable mineral from gangue. Other purposes are: (*a*) in film flotation, to accentuate the resistance to wetting offered by the mineral to be floated, and thus to aid in the support of this mineral at the air-pulp interface: (*b*) in oil flotation, to act directly as the buoyant medium; (*c*) in froth flotation, to make possible the formation of a froth, and thus, indirectly, to aid in buoying the mineral to be floated.

Alphabetical list of flotation agents described in U. S. patents up to Dec. 30, 1925, follows:

Acacia, 1,446,375, 1,446,376, 1,454,838.
Acetic acid, 348,157, 1,452,662, 1,457,680.
Acetic-phenyl-hydrazid, 1,364,306.
Acetone, 962,678, 1,425,327, 1,448,929.
Acetone phenyl hydrazone, 1,364,306.
Acetylene, 1,261,303, 1,541,292, 1,541,293, 1,548,351.
Acids (see also specific acids), 793,808, 807,501, 807,503, 807,504, 807,505, 807,506, 826,411, 835,120, 835,143, 842,255, 865,194, 865,260, 879,985, 938,732, 955,012, 956,773, 962,678, 1,045,970, 1,101,506, 1,104,755, 1,102,873, 1,126,965, 1,147,633, 1,156,041, 1,159,713, 1,176,441, 1,182,890, 1,228,183, 1,228,184, 1,236,933, 1,236,934, 1,240,591, 1,240,596, 1,240,824, 1,260,668, 1,269,157, 1,274,505, 1,286,922, 1,288,350, 1,302,966, 1,317,945, 1,322,816, 1,329,127, 1,329,493, 1,335,612, 1,369,054, 1,394,640, 1,394,958, 1,398,989, 1,398,990, 1,401,435, 1,417,261, 1,425,185, 1,425,186, 1,429,544, 1,438,435, 1,446,375, 1,448,929; 1,452,662, 1,457,680, 1,467,354, 1,469,042, 1,473,192, 1,490,736, 1,541,292, 1,548,351, 1,549,316, 1,560,170.
Acid sludge, 1,170,665, 1,452,662.
Acridine, 1,438,435.
Acridine derivatives, 1,438,435.
Acridine salts, 1,438,435
Agar agar, 1,499,872.
Albumen, 1,499,872.
Alcohol (see also specific alcohols), 955,012, 1,094,760, 1,170,637 (sulphonated), 1,246,665, 1,257,329, 1,364,304, 1,364,305, 1,364,308, 1,370,366, 1,386,716, 1,417,261, 1,417,262, 1,417,263, 1,425,327, 1,448,929, 1,452,662, 1,549,316, 1,552,197.
Aldehyde, aliphatic, 1,549,316.
Aldehyde condensation product, 1,378,562.
Aldehyde fatty acids, 1,549,316.
Aldol, 1,378,562, 1,478,697.
Aldol condensation products, 1,378,562.
Alkali, 521,899, 807,501, 807,505, 807,506, 826,411, 835,143, 865,194, 865,260, 870,985, 1,094,760, 1,176,441, 1,182,890, 1,203,341, 1,203,372, 1,203,373, 1,203,374, 1,203,375, 1,208,171, 1,208,334, 1,228,183, 1,228,184, 1,236,933, 1,236,934, 1,240,597, 1,240,598, 1,261,810, 1,301,551, 1,302,966, 1,317,945, 1,322,816, 1,329,127, 1,329,493, 1,364,304, 1,364,305, 1,364,306, 1,364,307, 1,364,308, 1,364,858, 1,364,859, 1,370,357, 1,370,366, 1,370,367, 1,370,843, 1,378,562, 1,394,640, 1,394,958, 1,401,435, 1,417,261, 1,417,262, 1,417,263, 1,421,585, 1,425,185, 1,425,186, 1,427,235, 1,429,544, 1,438,435, 1,446,314,

Classification of flotation agents may be made on several grounds. On the basis of chemical composition, they may be classified under the major

chemical subdivisions as organic or inorganic; on a physico-chemical basis, as soluble or insoluble in water; on the basis of their usual origin in the three great kingdoms of matter, as animal, vegetable, or mineral; on the basis of their supposed or apparent function in flotation, as collectors, frothers, depressants, etc. The difficulty is that no one of these classifications is rigid and consequently the assignment of certain agents to a given class or classes is a matter of individual opinion or experience. Chemistry ordinarily classes all substances containing the element carbon as organic and all other substances as inorganic, but in many text-books metal carbonates and the oxides of carbon are classed as inorganic. Solubility is a difficult ground because the concentrations in flotation practice are so small that published data are unreliable and original experimental determination difficult. Assignment to classes on the basis of origin causes similar, although not important, difficulty, because many flotation agents may be derived from substances originating in two or three of the kingdoms; thus phenol would be classed as mineral when derived from coal tar and as vegetable when derived from wood tar. Finally a substance that one flotation operator classes and uses as a frother may be used by another as a collector and by yet another as the sole agent, serving both ends.

Soluble and insoluble agents. This classification has had an artificial importance because of the legal effect of U. S. patent 962,678. Notwithstanding the claims of the patentees, no substance has ever been effective as a sole froth-flotation agent that was not to some extent soluble in the water of the pulp, and with the possible exception of a few petroleum products, no substantially insoluble flotation agent has ever been used in practice. It is not to be understood that there is not undissolved oil present in many flotation operations, but some soluble flotation agent must be present in every froth-flotation operation.

Solubility figures published in the chemical handbooks and elsewhere are useful with respect to the more soluble individual chemical compounds used in flotation, but are worthless in the case of very-slightly soluble substances, like the higher fatty acids. No figures are, of course, available for substances such as pine oil, tars, creosotes, and the like, which are not definite compounds but mixtures of a great many compounds of varying solubility. All of this class of substances are immiscible in bulk with water, but when mixed with water in the proportions usual in flotation operations, *viz.:* 1 : 4,000 to 1 : 80,000, all of them dissolve to a considerable extent. Table 15 gives the results of solubility determinations on a number of such agents.

Table 15. Solubilities of certain flotation agents in water when agitated therewith in the proportions 1 : 4000

Substance	Percentage dissolved
Kerosene	0.5
Olive oil	3.0
Fuel oil	4.0
Linseed oil	5.0
Oleic acid (crude)	5.5
Coal tar	6.5
Oleic acid (U. S. P.)	8.0
Coal-tar oil	12.5
Crude carbolic acid	15.0
Coal tar	29.0
Coal-tar oil	35.0
Blast-furnace oil	45.0
Eucalyptus oil	68.0
Pine oil	79.0
Oil of wintergreen	89.0
Cresol	92.0
X-cake	96.0
Phenol (U. S. P.)	100.0
Alkaline xanthates	100.0

Classification on the basis of duty in flotation. The phenomena that are vital in froth flotation and that, at the same time, are determined or fundamentally affected by the flotation agents, are: (*a*) the degree of water-wetting of the solid particles, and (*b*) the amount and character of the froth. The degree of water-wetting determines the possibility and ease of gas precipitation at particle surfaces or the behavior of particles at an oil-water interface or its equivalent. The amount and character of the froth determine its carrying and holding power and thus, to a considerable extent, the recovery and grade of concentrate, although both of these results are likewise dependent upon the degree of water wetting. It is necessary that the particles which it is desired to keep down in any froth-flotation operation be thoroughly and persistently wetted by water or aqueous solution, while those that it is desired to float shall be actually wetted (filmed) in whole or in part by an organic substance, substantially immiscible with the water in the state in which it is functioning, or shall tend strongly to become wetted with such a substance in the presence of water or aqueous solution.

The things that flotation agents do to affect and control these two fundamental phenomena may be grouped into five general classes; the groups of agents, named according to their function, are: (1) FROTHING AGENTS; (2) COLLECTING AGENTS; (3) DEPRESSING AGENTS; (4) DISPERSION AGENTS; (5) CONSERVING AGENTS.

A frothing agent is one that is primarily effective in froth formation. It may incidentally have more or less selective property. The froth formed should have sufficient stability and volume to maintain a regular and plentiful overflow when the machine is properly operated, but it should be sufficiently fragile to break down readily and the agent should not be so active that excessive frothing occurs in the ordinary movement of the pulp through the mill.

To effect frothing of an ore pulp a substance must affect the surface tension of water. Most frothing agents lower the surface tension. Change in surface tension requires solution, hence frothing agents must dissolve to some extent in the pulp water. The most effective agents are those whose effect on surface tension is greatest in solutions of a given strength. In any homologous series of substances the most effective are those of highest molecular weight and these are also the least soluble. Examples are: methyl and amyl alcohol; phenol and cresol; acetic and valerianic acid. In each case the second member is higher in an homologous series, *i.e.*, of higher molecular weight; it is the less soluble; the surface tension-concentration curve is the more concave; and the frothing effect is the greater.

Change in the surface tension of a liquid by a solute is the result of adsorption of the solute at the gas-liquid interface. In saturated solutions the concentration of a positively-adsorbed substance at the gas-liquid interface is that of a complete monomolecular film. The concentration of solute and the surface tension of the solution bear a linear relation in dilute solutions; they vary according to a logarithmic law in concentrated solutions; in solutions of intermediate concentration, the law of variation is variable and intermediate between the other two.

The rate of adsorption of solute increases with the concentration at a decreasing rate, and is greater the less the solubility of the solute. If a substance is insoluble in water and present alone therein, it will not adsorb at a water-air interface. This explains the non-effect of insoluble oils on surface tension. Distinct concentration of soluble oil takes place in the froth in a

flotation machine, with corresponding impoverishment of the water in the machine. The depression of surface tension due to the simultaneous addition of two or more solutes that are members of an homologous series is, in the main, the sum of the depressions caused by the individuals when present separately. This additive rule does not, necessarily, apply when the added substances are not chemical homologs. The simultaneous addition to water of a substance (*e.g.*, oil) insoluble therein and of another substance soluble in the water but not soluble in the first substance, produces only the effect on the surface tension of the water that would have been produced by the addition of the second substance alone. The simultaneous addition to water of a substance (*e.g.*, oil) insoluble therein and of another substance soluble both in the water and in the first substance, produces an effect on the surface tension of the water less than that which would have been produced by the addition of the second substance alone. Surface tension-concentration curves for this type of mixtures change with concentration from convex to concave, indicating progressive increase in extraction of solute by the water.

Oleic acid has but slight effect on the surface tension of water until the amount present is sufficient to and does form a mono-molecular film. Beyond this point, surface tension drops rapidly until an amount of acid equivalent to a film about one-and-a-half molecules deep is reached, when another change occurs and further addition produces again but slight effect. Oleic acid is a limiting case in the series of soluble substances affecting surface tension.

Maximum frothing occurs upon the addition of amounts of solute about one-half that required to saturate the solution. The point of maximum frothing is that at which the difference between the static and dynamic surface tensions of the solution is greatest. Emulsions in water, in which no water solute is present, do not froth. Emulsions of oil in water, consisting in part of mechanically dispersed oil and in part of dissolved oil, froth less than does a solution containing an equal amount of solute alone. The undissolved oil of an emulsion acts as a reservoir for soluble oil so that the frothing power of the emulsion is not diminished as greatly by dilution with water as would be expected were the solute present alone.

The larger the surface-tension depression at the beginning of a flotation operation, the greater the recovery and the poorer the grade of concentrate. The higher the recovery, the greater the possible change in surface-tension depression without resulting change in recovery. The finer the ore, the less the necessary depression in surface tension to effect a given recovery.

Experimental data underlying these statements are recorded in *68 A 479*.

The following list contains the best-known frothing agents:

Acid sludge (=kerosene acid sludge), aldol, coal-tar creosotes of high tar-acid content, cresols, essential oils (pine oil, eucalyptus oil, turpentine), terpineol, wood creosote, xylidin. In probably 90 per cent. of all flotation operations pine oil or a creosote is the frothing agent.

Collecting agents are organic substances that wet certain minerals, *e.g.*, sulphides, in the presence of water in preference to other minerals, *e.g.*, earthy or rocky gangues, and cause the wetted minerals to precipitate gas preferentially from supersaturated aqueous solutions of gas, or cause them to cling at the interface between an aqueous solution and a layer of frothing agent at a bubble surface.

The mechanism of the action is not the same in all cases. With oleic acid, definite preferential coating of the sulphide-mineral particles occurs, following contact of the particles with globules of the oil. Both sulphide-mineral and

gangue particles adsorb phenol molecules from solution, but the adsorption is greater at the mineral-particle surfaces. The same thing is true of xanthates, thiocarbanilid, and other non-frothing collecting agents; the differential adsorption is more marked the less the amount of reagent necessary to get the effect.

Collecting agents are frequently called COATING AGENTS, but since coatings of many different kinds function in flotation in many different ways and are markedly affected both by reagents in no way to be classed as collectors and by other conditions of the operation, the name is vague and misleading and should be dropped.

Collecting agents may be either solid or liquid. Most of them are more or less soluble in water but solubility is not so essential as it is in the case of frothing agents.

Oil-filming by incompletely-soluble liquid collecting agents is largely a mechanical process, effected by bringing the mineral particles into contact with the undissolved substance by stirring. With soluble agents the phenomenon is physico-chemical and the material is adsorbed from water solution. Typical examples of INCOMPLETELY-SOLUBLE COLLECTING AGENTS are: oleic and other higher fatty acids; animal and vegetable oils such as fish oil, castor oil, linseed oil, etc.; petroleum oils; the less-soluble parts of essential oils, creosotes, tars and the like. Typical ADSORBING COLLECTING AGENTS are alpha-naphthylamine, thiocarbanilid, various metal xanthates and a number of other soluble chemicals, such as pyridine, quinoline, etc. Some of the members of each class have frothing as well as collecting properties, *e.g.*, oleic acid and alpha-naphthylamine.

The action of incompletely-soluble collecting agents is pictured in Fig. 4 and described in the text therewith. Owing to the fact that the droplets of oil, after coming into contact with the mineral particles, do not spread to a mono-molecular film; that, in pulp-body processes at least, the film is effective only at its thinnest part; and that the degree of dispersion is relatively coarse, the amount of such agents necessary to effect good recovery is of the order of 1 or 2 pounds per ton of ore and upward.

The action of adsorbing collecting agents is preferential adsorption at certain of the solid surfaces in amounts of the order of mono-molecular films. The adsorption is, in general, greater by two to three times at sulphide surfaces than at gangue surfaces. This adsorption is an irreversible phenomenon in a given pulp, but a part of the adsorbed film can frequently be removed from the sulphide by aqueous solutions of smaller concentration of the adsorbed substance or by other solvents for the adsorbed substance. The amount of adsorption of different solutes at a given surface varies with the solute. The molecules in the adsorbed films are definitely oriented with respect to the adsorbing surface and the orientation in films that aid collection is such that the water-repelling end of the molecule is away from the solid. If the reagents also adsorb at air-water interfaces, the water-repelling end is likewise away from the water. The difference in behavior of filmed and non-filmed solid particles toward air takes place by reason of the orientation of the molecules in the adsorbed film. The difference in adsorbing power of sulphide and gangue minerals is one of degree only and varies with different solutes; hence by proper regulation of conditions, variation in difference of floatability can be controlled.

Owing to the fact that the film is mono-molecular and generally not complete and to the further fact that the degree of dispersion is substantially molecular, the amount of adsorbing collecting agent necessary to effect a

satisfactory recovery with most ores is of the general order of 0.1 to 0.3 lb. per ton of ore or about one-tenth that of the mechanically-applied collecting agents, provided the reagent is impervious to or is protected against the action of the gangue or of soluble salts in the pulp water.

Dispersion agents are substances added to an ore pulp which affect the state of dispersion of the gangue particles and at the same time change the extent to which these particles adsorb at sulphide-particle surfaces. When a finely-ground ore pulp is stirred with water of ordinary purity in the proportions usually employed in flotation there is invariably a certain amount of adsorption of fine non-metallic particles at the surface of the metallic particles; if the gangue is clean, unaltered silicate, the adsorption is usually slight and the essential nature of the sulphide surfaces is unchanged; on the other hand, if the gangue is decomposed and contains kaolin, sericite, iron oxides and like substances, adsorption at sulphide surfaces is immediate and so heavy that these surfaces are essentially changed. Sulphides thus coated differ little in floatability from the gangue minerals. The sulphide mineral in flotation froths has relatively little adsorbed gangue on its surface, less in rich concentrate than in low grade, and less the smaller the amounts of frothing and collecting agents used. On the other hand, the sulphide in the tailing from an unsuccessful float is usually heavily coated with gangue. It follows that successful flotation of a given sulphide mineral involves reduction of gangue adsorption to substantial nullity.

Solid-solid adsorption is in part, at least, an electrical phenomenon dependent upon the electrical charges carried by the adsorbing surface and the dispersed particles. In this respect it is, therefore, dependent upon the same properties as those that control dispersion of the slime (see Sec. 16, Art. 3) and any change in the pulp that affects the dispersion of the gangue is likely also to affect gangue adsorption. Ordinarily gangue adsorption is greatest when gangue dispersion is maximum and any treatment of the pulp such as heating, agitation, or the addition of a colloid or electrolyte that produces flocculation will decrease adsorption, but there are cases where the reverse situation holds and increase in the degree of dispersion accompanies decrease in gangue adsorption.

Thus the slime from Anaconda and from Utah ores in pulps made with ordinary potable water are highly dispersed and adsorb heavily at the surfaces of sulphide minerals in the ore while a slime, almost equally fine and highly dispersed, made by grinding a certain sample of barren quartz, adsorbs practically not at all on the same sulphide minerals immersed therein. Addition of one part of pine oil in 50,000 parts of water had no apparent effect on the dispersion of Anaconda slime and made no change in the gangue adsorption. Larger amounts of pine oil (1 in 16,000 and 1 in 4000) together with agitation produced incipien flocculation and materially decreased gangue adsorption. With Utah slime the addition of pine oil in the proportions of 1 in 50,000, 1 in 16,000, 1 in 4000 and 1 in 2000 of water had little or no effect on flocculation and correspondingly small effect on gangue adsorption. With Anaconda slime, pine oil (1 in 50,000) and lime (1 in 2000), the slime is distinctly flocculated and gangue adsorption is markedly less than with no reagents; Utah slime with the same reagents is slightly flocculated but gangue deposition is greater than with no reagent. On the other hand, the dispersion of Anaconda slime is increased when pine oil (1 in 8000) and sulphuric acid (1 in 800) are added, and gangue adsorption is increased, while with Utah slime similar dispersion produced by sulphuric acid and pine oil is accompanied by decrease in gangue adsorption. Increased recovery in flotation follows decreas in gangue adsorption in every case.

Common dispersion agents are sulphuric acid, lime, copper sulphate soda ash, caustic soda and sodium silicate. Certain organic agents of this class, *e.g.*, argol, glue, albumen, etc., have been proposed but have had littl or no commercial use.

The usual apparent physical effect of successful dispersion agents is to cause flocculatic of the ore pulp. Moses states (*104 J 749*) that the use of copper sulphate with zinc ore w. accompanied in one case by flocculation of both gangue and sulphide slimes, and in anothe case by flocculation of the sulphide slimes alone.

Flocculation of very fine oil-filmed sulphide particles is a great aid to gas precipitation thereon, if it is not a necessary condition precedent thereto. This may be proved readily by filming, say, 0.1-mm. and 0.01-mm. particles of galena with oleic acid (by immersing them in a dilute benzol solution and allowing them to dry), then placing them in water and heating. If the finer particles remain as individuals, gas precipitates on them reluctantly, if at all, although it precipitates freely on the larger particles. If now the small particles are caused to flocculate, as may be done by adding sulphuric acid and stirring, gas precipitates readily on the floccules when heating is continued.

Borcherdt (U. S. patents 1,445,989, 1,446,375 to 1,446,378 incl., 1,448,514, 1,448,515, 1,454,838), sets forth the hypothesis that the dispersion agents produce de-flocculation of gangue-slime particles in the pulp, thus opening previously-locked sulphides to the action of gas and lessening mechanical entanglement of flocculated gangue slimes in the froth.

Some oils have marked effect on dispersion, making the use of inorganic agents unnecessary; some ores show no need for dispersion agents by reason of the small amount of primary slime present.

Loth (*108 J 950*) states that the wood creosote used for collective flotation of lead and zinc at Picher, Okla., is added in the froth-overflow launder as the concentrate goes to a shaking table for separation. The table slime and tailing return to the feed-thickening tank and the overflow contains much semi-colloidal injurious slime that will not similarly overflow when oil is not entering.

Until within the last few years a majority of flotation operations were performed in acid pulps. At present, however, nearly all flotation is carried on in slightly alkaline pulps, as these are best for the chemical collecting agents. The change has effected large operating economies, since acid pulps, with copper ores particularly, were destructive of all iron with which they come into contact.

Depressing agents is the name given to substances that are used to lessen the floatability of one or more of the minerals of the ordinarily-floatable class in a mixture of such minerals, *e.g.*, to depress sphalerite when it occurs with galena, or pyrite when associated with chalcopyrite, and thus make it possible to float the galena and chalcopyrite respectively in concentrates relatively free of sphalerite and pyrite. The art of differential flotation is built on the judicious use of depressing agents.

The agents of this class do not all act in the same way. Most of them fall also in the dispersion-agent class; a few react chemically with some sulphides and not with others; and there is some evidence of a third type of action involving preferential deposition of a compound formed by the added agent and some constituent of the ore pulp other than the mineral upon which the salt deposits.

Depressing agents that are also dispersion agents include lime, sulphuric acid, sodium carbonate, sodium bicarbonate, sodium silicate, alkaline cyanides, zinc sulphate, copper sulphate, alum (potassium), and like inorganic substances. Their action is to effect differential adsorption of gangue at the sulphide surfaces.

With a certain lead-zinc ore having a clean quartzitic gangue both lead and zinc floated in neutral (salt-free) solution and the sulphide-particle surfaces were substantially gangue-free. Addition of 1 lb. LIME per ton of ore caused differential gangue adsorption, heavier on the galena, after which, by intensifying the flotation effect, differential flotation of sphalerite could be effected. Another lead-zinc ore having a slimy gangue showed heavy gangue adsorption with pine oil alone; the addition of 4 lb. LIME per ton of ore produced marked lessening of the adsorption at the sphalerite surface, although the differential effect persisted for only a short time (less than 5 min.). It was, therefore, possible to float blende preferentially for a short time after the addition of the lime, but thereafter both blende and galena were depressed so vigorously that flotation was impossible. POTASSIUM CYANIDE and ZINC SULPHATE used together in combining proportions in the presence of SODIUM CARBONATE or SODIUM BICARBONATE and Barrett No. 4 creosote substantially prevent gangue deposition on galena in some pulps while blende and pyrite in the same pulps are heavily slime-coated, hence galena floats while blende and pyrite remain submerged. COPPER SULPHATE added to some pulps after flotation of the lead as above removes the coating

from the sphalerite while causing an intense coating on the galena and intensifying the coating on the pyrite, hence blende may be floated subsequently substantially free of the other minerals. ALUM in the presence of lime and pine oil may prevent gangue deposition on galena while that on sphalerite is relatively heavy, hence the galena can be floated preferentially.

Not all of the effects above noted are equally strong and persistent; the cyanide-zinc sulphate and the copper-sulphate actions are the most distinct.

Depressing agents that react chemically with one of the sulphides and thus alter its surface are typified by the alkaline dichromates.

With PINE OIL (1 in 8000), SODIUM CARBONATE (1 in 4000) and SODIUM BICHROMATE (1 in 1000) in water alone, at 140° F., galena is markedly attacked and covered with a yellowish deposit that completely obscures the characteristic luster. Sphalerite is unaffected in the same solution. The same reagents in the same quantities in a non-slimy pulp produce the same effect and differential flotation of blende can be effected. In a slimy pulp, on the other hand, both galena and sphalerite are coated with adsorbed gangue and the galena surface is not attacked. Similarly the addition of 1 part in 20,000 of ALBUMEN to the water mixture first described inhibits attack on the galena. But the same amount of albumen added to the slime-pulp along with the other reagents prevents gangue adsorption and permits attack of the chromate, with the result that the galena surface is dulled and preferential flotation of blende made possible. POTASSIUM PERMANGANATE is said to act like the dichromate (Australian patent No. 9508 of 1913). GLUE acts like albumen and both are dispersion agents rather than depressing agents, used merely to prevent gangue adsorption from interfering with the dichromate (or permanganate) attack.

TANNIC and PYROGALLIC ACIDS are similar to the dichromates in that they apparently react chemically with galena in slime-free water and do not attack blende. In the presence of one slime tested there was such heavy gangue deposition with both reagents on both minerals that no flotation was possible. Addition of ferrous sulphate with both reagents with this slime markedly decreased slime deposition, permitting attack on the galena and rendering it unfloatable while the blende surface remained bright. There was, of course, distinct reaction between the tannic acid and ferrous sulphate, resulting in a fine black precipitate, so that the action of the two cannot be segregated.

Preferential agents that deposit salts formed by reaction of the agent with some constituent of the pulp are indicated by the work of Gates and Jacobsen (*Bul. 16 UU No. 4*) but their work could not be duplicated at Columbia University. They show photomicrographs of coatings produced on galena, sphalerite and pyrite in solutions containing 0.0375 per cent. of lime; the coating was least on the lime and greatest on the pyrite. Their description indicates identification of the coating as calcium carbonate. In light of the fact, however, that the weights of coating pictured are not in agreement with the relative floatabilities under similar conditions presented elsewhere in the paper and of the further fact that surface effects are distinctly different in fine pulps and in water, it is doubtful whether action of this sort plays any part in flotation.

Conserving agents are substances added to ore pulps to protect the other flotation agents from attack by substances present in the ore pulp. They are of no particular chemical character and may, in other pulps, play some other part in the flotation operation.

In one pulp in which alpha-naphthylamine was used as the frothing and collecting agent there was large consumption of the reagent by ferric iron. Sodium hydroxide added in an amount sufficient to precipitate the iron as insoluble ferric hydroxide reduced the consumption of naphthylamine markedly. Lime used with ores containing free acid, when an alkaline xanthate is used as a collecting agent, is, in part at least, acting as a conserving agent.

Trade names of flotation reagents are almost invariably used around the mills and frequently used without explanation in flotation literature. Table 16 names a number of the commoner oils and gives many physical properties useful for identification and specification. X-cake is alpha-naphthylamine; X-Y reagent is, ordinarily, 4 parts of X-cake dissolved in 6 parts of xylidin. T-T is a solution of thiocarbanilid in orthotoluidin, ordinarily 10 parts of the former to 90 of the latter.

Reconstruction of oils by distilling them with a small amount of sulphur in a reflux condenser causes a chemical change that results in solution of the sulphur, probably in the form of a $C = S$ compound with one of the constituents of the oil. With some oils and ores reconstruction consistently causes improved flotation results, both more active frothing and sharper selection accompanied by higher grade of concentrate and better recovery. With other oils frothing is d creased somewhat, although selection may be bettered.

Patent 1,593,232/1926, to Whitworth describes reconstruction with phosphorus and sulphur or with a phosphorus-sulphur compound, *e.g.*, P_2S_5. Whitworth claims that more sulphur combines than when sulphur is used alone thus forming more $H - S$ compounds. He claims best results by treating cresol with phosphorus pentasulphide but states that almost any substance containing a hydroxyl (OH) group is suitable; substances containing carboxyl (COOH), aldehyde (CHO), or ketone (CO) groups may also be used. The patent recites results with untreated cresylic acid, cresylic acid reconstructed with sulphur and reconstructed with phosphorus penta-sulphide. These results show progressive lowering of tailing by the reagents in the order named.

Kind of flotation agents used depends primarily upon the kind of ore and water, the result sought, the price, and the dependability of the supply. It is possible to compensate for certain variations in grinding and in pulp consistency by corresponding changes of agents, but it is better to eliminate the variations than to attempt compensation.

Character of ore to be treated is to be considered from the point of view of both the sulphide and gangue minerals. Certain agents appear to film certain sulphides more quickly or more completely than they do others, *e.g.*, pine oil and eucalyptus oil will produce good concentrate with most lead and zinc ores but do not ordinarily effect clean concentration of copper ores; coal tar and X-cake are usually highly selective with chalcocite and bornite but not so effective with galena and sphalerite. No general rule can be set down to the effect that for certain sulphides certain reagents are to be used and for certain other sulphides certain other agents. Thiocarbanilid and the alkaline xanthates come as near being universal agents as can be expected and pine oil, in the minute quantities necessary with these powerful collectors, is an almost universal frother. Coal- and wood-tar creosote are useful in conjunction with the chemical collectors in the case of most ores, and are also extremely effective with many when used without the chemical agents. Table 17, compiled by J. M. Callow, gives data concerning agents used and results obtained at many of the principal U. S. plants as of Jan., 1925. The following examples from practice at different mills, culled at random from periodical literature, show older practice and are useful in indicating reagents alternative or supplementary to the chemical reagents.

Copper ores

INSPIRATION (*54 A 11*): chalcocite and chalcopyrite in schist; 80 parts crude coal tar and 20 parts coal-tar creosote in neutral pulp. CONSOLIDATED ARIZONA SMELTING CO. (*104 J 72*): chalcopyrite and pyrite in quartzitic gangue; 70 parts stove oil, 25 parts wood creosote, 5 parts acid sludge, total, 1.31 lb. per ton. OLD DOMINION (*102 J 754*): chalcocite, chalcopyrite and pyrite in quartzitic gangue; 85 parts coal tar, 8 parts coal-tar creosote, 4 turpentine and 3 of pine oil in neutral pulp. This mixture produced concentrate containing only 8 per cent. Cu with 31 per cent. Fe and 21 per cent. insoluble. UTAH LEASING CO. (*105 J 535*), 85 parts coal tar and 15 parts coal-tar creosote with crude soda ash. NEW CORNELIA COPPER CO., Ajo test mill (*109 J 1314*): chalcopyrite in monzonite porphyry; 70 parts coal tar and 30 parts crude pine-wood oil (destructively-distilled). Fuel oil in the mixture brought up too much gangue. ARIZONA COPPER CO. (*109 J 1350*) used coal-tar, coal-tar creosote and pine oil in many of the experimental flow-sheets but found X-cake and xylidin with lime superior. SWANSEA LEASE (*109 J 845*): chalcopyrite with hematite in gneiss; petroleum oil, pine oil, pine-tar oil and coal-tar creosote. ARIZONA HERCULES (*109 J 1115*): coal-tar creosote and pine oil reconstructed with sulphur for an ore containing sulphides, oxides and metallic copper. MOUNTAIN COPPER (*119 P 333*): acid sludge, crude turpentine, tar oil and light fuel oil. MIDDLEMARCH (*118 P 182*): coal tar, pine oil, coal-tar creosote. MT. LYELL (*123 P 90*): eucalyptus oil and coal tar. ENGELS

JM Janney mechanical. *JMA* Janney mechanical-air. *MS* Minerals separation. *P* Pneumatic. *KK* Kraut and Kohlberg.

Copper Co. (*123 P 190*): crude turpentine and petroleum oils. Nevada Consolidated Copper Co. (*123 P 328*): X-cake and xylidin with lime. Consolidated Coppermines (*64 A 823*): coal tar and coal-tar creosote with pine oil; later X-cake and xylidin with lime. Catemu (*123 P 921*): chalcocite and oxidized copper minerals in a clayey gangue; blast-furnace oil and Mexican fuel oil. Sodium polysulphide was used to de-flocculate the gangue and frothing was kept down in order to keep from carrying over the de-flocculated clay mechanically. It was found here that pine oil, pine tar and wood oils generally floated calcite and clay and thus lowered the grade of concentrate. Calumet and Hecla (*117 J 284*): native copper; coal-tar products were most effective, *e.g.*, a mixture of coal tar, two coal-tar creosotes, wood creosote and a little pine oil as needed, in a neutral pulp.

Lead ores

Missouri (*57 A 337*): wood creosote in all lead plants. Bunker Hill and Sullivan (*102 J 36*): pine oil. Silver King Coalition (*116 J 372*): pine oil. Shattuck Arizona (*110 J 761*): oxidized ore; coal-tar creosote, hardwood creosote, oil tar, pine oil.

Zinc ores

Butte and Superior: pine oil. Timber Butte: pine oil. Anaconda: pine oil. The latter two plants are now practicing differential flotation of lead and zinc. Butte and Superior has also used coal-tar creosote, various petroleum products, and wood creosotes, both with and without pine oil, but the latter alone is most satisfactory. Copper sulphate is necessary for best results with all these ores. Thornberry (*113 J 54*) found X-cake and orthotoluidin with copper sulphate best for Tri-state zinc ores.

Lead-zinc ores

Joplin (*105 J 733*): hardwood creosote, coal tar and pine oil in acid pulps. Picher, Okla. (*108 J 950*): hardwood creosote with copper sulphate. Reocin (*115 J 397*): pine oil, coal-tar creosote and copper sulphate. If cresol is used to replace pine oil, more copper sulphate is necessary. Daly-Judge (*54 A 11*): 40 parts crude coal tar, 40 parts creosote and 20 pine oil. See also "Differential Flotation."

Precious-metal ores

Gold King (*100 J 634*): pyritic gold ore; coal-tar creosote and pine oil in acid circuit. Belmont Shawmut (*121 P 661*): pyritic gold ore; 3 parts wood creosote and 4 parts California fuel oil with sodium sulphide. The latter is essential to flotation of the gold; it causes a reduction in tailing with a 3-oz. ore from 0.045 oz. to 0.01 oz. California Rand (*124 P 15*): pyritic gold ore; 10 parts water-gas tar, 7 parts stove oil, 2 parts hardwood creosote and 1 part pine oil with sodium sulphide or sodium carbonate. Suan concession (*119 P 844*): complex gold-silver-copper ore; eucalyptus oil, brown camphor oil and thin coal tar with lime. Campbell (*103 J 920*) reports the successful use of a mixture of pine oil and wood creosote with or without small quantities of gas- or coal-tar oil for treating a complex gold-silver ore containing chalcopyrite, pyrite, antimonides of silver and tellurides; also small amounts of sericite, kaolin and calcite. Acid was necessary to clean the froth. Parsons and Gilmore (*20 CMI 73*) report conclusions from an extensive series of tests on Canadian silver ores to the effect that crude hardwood creosotes or pine oils were satisfactory frothers; coal-tar creosote was indispensable as a collector, and that sodium hydroxide "gave an almost incredible improvement in extraction and grade of concentrate." Cobalt (*105 J 785*): native silver and arsenic and antimony compounds of silver in quartzitic gangue; coal tar (10), coal-tar creosote (75) and pine oil (15) or a similar mixture was used in most plants.

Oils vs. chemicals for flotation agents. Chemical agents are preferable on operating grounds. Their outstanding advantages are: (1) they can be more accurately specified for purchase and the seller can more closely approach specifications; (2) they are, in general, more readily dispersed in the pulp; (3) the concentrate made with them is usually of higher grade and more readily broken down in the concentrate thickeners than that made with oil; (4) the concentrate formed with chemicals filters more rapidly and completely.

At Consolidated Copper Mines (*64 A 825*) substitution of X-cake for creosote oils gave a higher-grade concentrate and made it possible to filter one day's concentrate in one shift with one or two filters while three shifts with three filters had been required with oil.

The cake was drier, also, with the X-cake. The DISADVANTAGES of the chemical reagents are: higher cost, the fact that they are rarely locally available, but must be shipped long distances, and an unsettled patent situation (Mar. 1927).

Inorganic agents. The practice in the addition of inorganic flotation agents is no more subject to generalization with regard to different types of ores than is the question of organic agents. The only general statement that seems to be founded in experience is that a small amount of copper sulphate solution, say such an amount as will introduce into the pulp between 0.1 and 0.3 lb. of copper per ton of solids, usually improves results with sphalerite ores. Results at SLOCAN, B. C., showed that addition of copper sulphate had no effect on grade of tailing nor did it have any differential action with respect to pyrite, but the grade of concentrate was raised 10 points by exclusion of gangue slime (*114 J 680*). Freeman (*120 P 833*) says that at BROKEN HILL addition of 0.5 lb. $CuSO_4 \cdot 5H_2O$ per ton of ore reduced the acid required in floating blende from 60 or 70 lb. per ton to 25 lb. Sulphuric acid has been widely employed with blende ores, when oils were used as collectors, but with the chemical collecting agents alkalis have been substituted in many plants. Sodium silicate is sometimes used where preferential separation of galena from sphalerite is practiced. A majority of the tonnage of low-grade chalcocite ores is probably being treated in neutral or slightly alkaline circuit. This is almost invariably the case when thiocarbanalid or xanthate is used. Acid salt cake was used in place of sulphuric acid in some instances, notably where it was cheaper or where there was a considerable amount of carbonate in the ore and treatment in an acid pulp seemed necessary.

The most extensive work reported on the effect of inorganic agents is that of Thornberry and Mann (*Effect of addition agents on flotation, Bulletins Missouri School of Mines, Vol. 4, No. 2 and Vol. 5, No. 2*). The work comprised several hundred tests on Missouri lead ores with various addition agents including sulphates, hydroxides, nitrates, chlorides, bromides, acetates, oxalates, chromates, carbonates, tartrates, phosphates, nitrites and permanganates and a number of miscellaneous substances as follows: sodium sulphite, tannic acid, dextrose, lactose, gum arabic, gum tragacanth, boric acid, carbolic acid (phenol), picric acid, and potassium chlorate. The tests with the inorganic agents were of distinctly negative character except on two or three points. None of the reagents produced any distinct improvement on the results of the standard tests with creosote or pine-tar oil. Chromates were distinctly harmful, lowering the grade of concentrate to between 20 and 30 per cent. Pb and the recovery to generally less than 20 per cent. Salts of certain metals, notably tin, uranium and cadmium were markedly harmful, especially in the higher concentrations. The higher concentrations of tartaric acid, potassium tartrate, phosphoric acid, ammonium phosphate, sodium sulphite, tannic acid, gum arabic, gum tragacanth, and phenol substantially destroyed flotation.

Unfortunately this elaborate record omits all of the essential observations required for interpretation. Chemical attack of the galena is, of course, indicated in the case of the chromates, and heavy gangue adsorption with colloids such as tannic acid and the gums, but further than this no generalization is warranted other than that this particular ore could be floated as well or better with certain oils alone than with certain specific organic and inorganic agents present in addition.

Ralston and Yundt (*104 J 749*) state that sulphuric acid was harmful with INSPIRATION ore and ascribe the bad effect to copper sulphate formed by reaction with the oxidized copper mineral, but this cannot be taken as a safe generalization, since UTAH COPPER Co. used sulphuric acid successfully for several years with an ore that contained sufficient oxidized copper to cause rapid replacement of all iron with which the pulp came in contact.

An anonymous writer (*117 P 931*) records the results of an investigation of the effect of the soluble components of a silicious silver ore. This showed that ferrous, magnesium, manganese and alkaline sulphates were present; that the ferrous sulphate was the only harmful solute, and that its bad effect could be overcome by the use of sodium hydroxide, sodium carbonate or lime (which, of course, precipitated the iron salts). In laboratory experiments it was found that the effect of the soluble salts was cumulative with re-use of water and that even when neutralizing reagents were used it was necessary to add considerable fresh water.

At the Mountain Top Mining Co. (*107 J 1130*) it was found that a small amount of spent calcium carbide would cause froth to form when frothing had failed with the usual oils.

Fineness of the ore has some effect on the kind and amount of frothing oil required. The froth must be sufficiently stable to permit removal from the machine. The more closely particles of solid are packed together in the bubble walls and the thinner the layer of liquid between adjacent pieces of solid, the stronger the bubble film, and with finely-ground ore little or no aid in stabilizing is needed from the oil. If the ore is coarse a froth-stiffening agent must be used. Tars, wood creosotes and some petroleum oils add stiffness or toughness.

Percentage of solids. When the percentage of solids is low, bubbles arrive at the surface less heavily loaded than in a thick pulp and are, therefore, less stable. If more stability is desired, an agent that stiffens or toughens the froth must be used.

If a given tonnage of solid matter is to be passed through a given machine in a given interval of time, say 24 hours, a greater volume must pass through in each unit of time with a thin than with a thick pulp and less time is afforded for dispersion of the agent through each unit of volume of thin pulp. With the degree of agitation and the rate of solid feed fixed, it follows that a more mobile or more easily soluble agent, or both, is necessary with a thin than with a thick pulp.

Kind of froth formed by various agents. Essential oils produce small-bubble, effervescent and brittle froths that drop mineral freely unless a large amount of oil is used. Excess oil makes the froth dirty and very liquid, but does not cause noticeable increase in size of bubble. Wood-creosote froth is distinctly irregular in size of bubbles, very tough, hard to break down and hard to clean. An excess causes the froth to carry much gangue, which is practically impossible to remove in cleaning. Coal-tar creosote forms a froth similar in texture to that formed by wood creosote, but the small bubbles are not generally so small and the large are more frequent and not so large. Neither is the froth so tough as that made with wood creosote nor so hard to clean when excess oil has been added. Coal-tar creosote and pine oil may form a very tough froth. Aldol, terpineol, turpentine, and cresol are intense frothers. They produce small-bubble, rather fragile froths, with the exception of turpentine which produces a tough froth in which the bubbles are initially small, but quickly grow by coalescence to considerable size. None of these substances has any useful selective qualities. Sodium oleate and kerosene sludge acid produce froths with relatively large bubbles, lightly loaded and glassy in appearance, and tending to carry considerable fine gangue. Xylidin froths are reasonably uniform in texture, with medium-sized bubbles. They break down readily, but are not so effervescent as the froths formed with essential oils. Alpha-naphthylamine is not ordinarily used as a frothing agent, but in a few mills where it has been used alone it forms fragile, rather coarse, irregular froth with strong carrying power, yet breaking down readily in the cleaner cells and thickening tanks. Petroleum products and tars are not frothing agents, but they add considerable toughness and stability. Tars are likely to bring in considerable silica; froths produced with petroleum products present are frequently of higher grade than when the petroleum is absent.

The best kind of froth, from the point of view of mill operation, is one that is fairly tough, with medium-sized bubbles and not too voluminous. Such a froth requires little attention to maintain steady overflow from the flotation machines, it does not carry coarse gangue mechanically, and breaks down readily in the cleaner machine and in the thickening tanks. These conditions

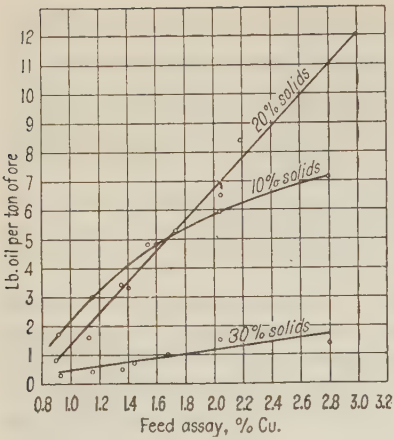

FIG. 73.—Relation between grade of feed, pulp consistency and quantity of oil.

are ideally satisfied when chemical agents are used as collectors and a mimimum of pine oil as a frother. This mixture eliminates the relatively insoluble, so-called neutral oil, which causes stiff, dirty froths.

Quantity of flotation agent necessary depends upon (*a*) the kind; (*b*) the recoverable mineral content; (*c*) the percentage of solids; (*d*) fineness of grinding and, less directly, on (*e*) the treatment of pulp subsequent to oil addition; and (*f*) the mineralogical composition of the ore.

Mobile and highly soluble agents can be employed in minimum quantities because of ready dispersion and the minute state of subdivision.

In the agitation-froth process, the recoverable mineral content of an ore, the amount of given frothing and collecting agents necessary, the percentage of solids in the pulp treated, the grade of concentrate and the recovery attained are distinctly related.

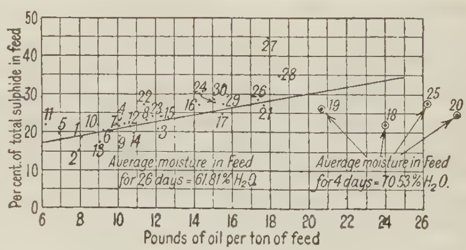

FIG. 74.—Chino Copper Co. Relation between total sulphide in feed and quantity of oil required.

In order to recover a given percentage of the recoverable mineral in an ore in the form of a concentrate of given grade, if the percentage of solids is fixed, the amount of a given collecting agent necessary is in direct proportion to the amount of recoverable mineral in the feed.

In order to recover a given percentage of the recoverable mineral in a concentrate of given grade, if the grade of the feed is kept constant, the amount of reagent necessary is in almost direct proportion to the percentage of moisture in the pulp.

The results of laboratory data leading to this conclusion are shown in Table 18, presented graphically in Fig. 73. The ore tested was a porphyry-copper ore assaying about 0.9 per cent. copper and 1.5 per cent. iron, enriched, in order to get the higher-grade feeds, by gravity concentrate made from the same ore. Flotation tests to the number of about two hundred, made by the same operator, identical as to speed, temperature, reagent, and manipulation of solids and quantity of agent, are the basis of the curves. The reason for the departure, with the richer feeds, of the curve for "10 per cent. solids," from the law indicated by the tests of low-grade feeds, is not apparent.

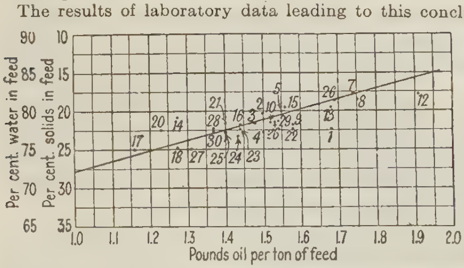

FIG. 75.—Butte and Superior Mining Co. Relation between pulp dilution and quantity of oil required.

Figs. 74 and 75 show these relationships in operating plants. Payne (*116 J 1106*) states that at Magistral-Ameca the quantity of flotation agent was increased as the feed increased in richness. Barcena y Diaz (*115 J 396*) says that at Reocin, Spain, the amount of oil needed when the feed ran 10 per cent. Zn was 2.2 lb. per ton while 4.4 lb. was necessary for a feed assaying 20 per cent. Zn.

2.09	3.55	1.0	85	34.0
2.80	4.85	1.4	60	33.3

Excess of oil generally results in a tough, low-grade concentrate that is hard to clean; usually, also in high tailing content; a deficiency produces a tender froth and high tailing.

When water is reclaimed the frothing element comes back in considerable quantities and the amount of new frothing agent can be cut down, at times to the vanishing point.

Quantity of flotation agent that can be used was of artificially great importance for several years prior to November, 1923, because of the limitation of the basic agitation-froth patent (835,120) to an amount of oil less than 1 per cent. on the weight of the ore. The experience of the patentees had led them to conclude that their process was dependent upon such restricted use of oil and they had so limited themselves in their claims. On account of the exorbitance of the early royalty demands, it was in many cases cheaper to use more than 20 lb. of cheap oil per ton than to meet the license contract offered, and the result was that methods of operation with more than 1 per cent. of oil were quickly devised. The patentees

then clamorously denied that the part of the oil in excess of 1 per cent. was active in the process, and claimed infringement. The fact is that no critical point in oil quantity exists at 1 per cent., and that the large quantity of oil plays precisely the same role in agitation-froth flotation as the small quantity. When the oil quantity is increased beyond a certain maximum, continued agitation may cause the oil-sulphide sheaths of the air bubbles to become dislodged and roll up into shot-like granules as described in the Cattermole patents (Sec. 14, Art. 4). The change from flotation to granulation takes place, however, over a wide range of oil quantity, dependent upon other factors of the operation. It may be accomplished with less than 1 per cent. of certain oils, and it may be deferred until the amount of oil is upwards of 25 or 50 per cent. Table 19 presents the results of a series of tests run in a

Janney laboratory machine on regular flotation pulp at the Utah Copper Co. mill. Tests in the operating mill confirmed these. Mill operation is easier with a smaller amount of oil, on account of the difficulty of cleaning and dewatering high-oil froths; and the use of large quantities of oil would have been uneconomical except under the peculiar conditions that existed entirely unconnected with the technology of the process. It is also true that with certain oils, notably oleic acid, it is difficult to produce froth with large quantities of oil, but there is substantially no oil mixture that cannot be used in excessive proportions, if other elements of operation are regulated to correspond.

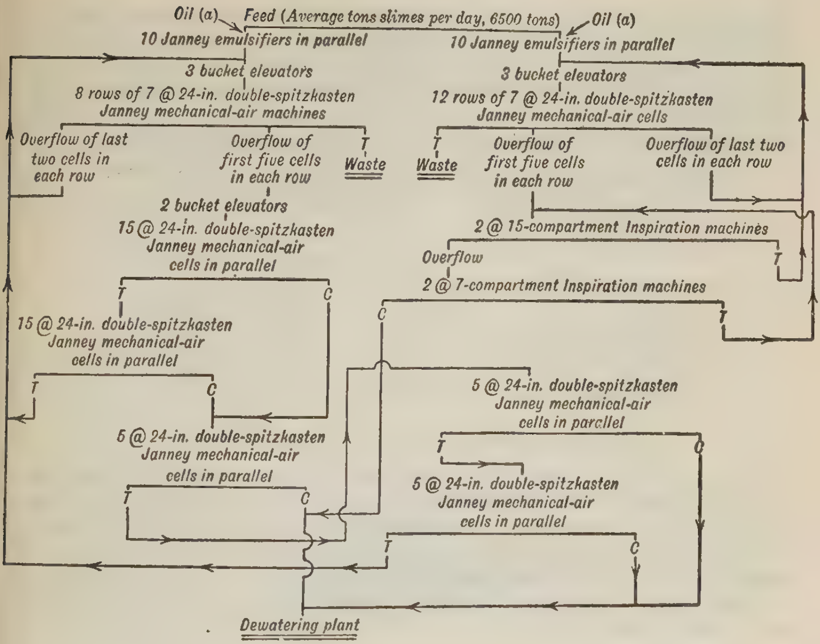

Fig. 76.—Flow-sheet for operations with more than 20 lb. of oil per ton at Ray Consolidated Copper Co.

At Ray Consolidated Copper Co. slimes were treated at the rate of 6500 tons per day according to the flow-sheet shown in Fig. 76. Average results are shown in Table 20. Comparative results at the same mill with a flow-sheet in which the oil was thoroughly emulsified in water with a Penberthy steam injector, then mixed with the slime feed in a Pachuca tank and treated in one 16-compartment Inspiration rougher (3 × 4-ft. compartments) and one 6-cell cleaner of the same type are given in Table 21. In another arrangement of the same machine, adding fuel oil to the boot of a bucket elevator returning cleaner tailing, and wood creosote and coal-tar creosote to a distributing box ahead of the rougher cells, 13.8 per cent. concentrate and 0.372 per cent. tailing were made from 0.705 per cent. feed when adding 20.2 lb. oil per ton; a recovery of 48.6 per cent. Table 21 also shows the marked improvement in grade of concentrate that is typical of the use of chemical agents with certain ores.

Pounds of oil per ton.....	1.4	20.8

Cost and availability of reagents. Price of oils ranges from a few cents per gallon for petroleum fuel oils to about 50 cents per gallon for the best grade of steam-distilled pine oil (1926). The organic-chemical reagents ordinarily cost more than oils per unit of weight, but, on account of the smaller consumption

and greater ease of operation, as well as greater recovery and higher grade of concentrate they frequently show sufficient economy to stand the greater price and the royalty payment. When considerable quantities of inorganic agents are necessary, these will ordinarily constitute the greatest item of cost, notwithstanding the usually lower unit price. Market prices of reagents are quoted at short intervals in Eng. and Min. Jour. and Chem. and Metl. Eng.

a Coal tar, coal-tar creosote, fuel oil in various mixtures.

It is rarely that an ore will respond to one reagent or reagent mixture only and the difference in cost of reagents per ton treated is ordinarily small. Such being the case, the question of dependability of supply is much more important than the price per pound. Other things being equal, locally-produced reagents are superior to those manufactured at a distance, but it is rarely that a suitable local supply can be found. Irregularity in transportation can be taken care of readily by generous provision for storage at the plant.

17. Operation

General. Operation of froth-flotation processes requires a higher class of labor and more careful and intelligent supervision than does any other operation in a concentrating mill. This is due to the fact that successful operation involves harmonizing many different elements and it is substantially impossible to formulate simple rules that set forth the proper things to do under the multifarious conditions that arise. Even in the laboratory where conditions are under the best possible control, skilled and unskilled operators working from the same set of instructions and with the same materials will obtain results differing as much as 30 or 40 per cent. in recovery and proportionately as much in concentrate assay, and yet the differences in the things they do are very slight and are differences of degree rather than of kind. The early results obtained in any plant are almost invariably poorer than those attained at a later date, notwithstanding that the elements of the operation have not, in so far as they are capable of definition, substantially changed. It is not, of course, to be understood that any mystery is involved, but rather that control of the magnitude or intensity of essential operating factors and judgment of results are matters that must be gained by intelligent observation and experience. All of which may be summarized in the statement that in the present state of knowledge froth flotation is an art rather than a science, to perhaps a greater extent than any other operation in concentrating practice.

The definable elements of operation are: (1) size of feed, (2) character of feed, (3) kind of machine, (4) kind and quantity of flotation agent, (5) pulp density, (6) feed rate, (7) intensity and duration of agitation and aeration, (8) temperature, (9) character of water supply.

Size of feed. Apart from the fact that low-grade tailing and high-grade concentrate are not to be expected until grinding has freed substantially all of the valuable mineral, froth flotation will not, in general, recover mineral grains larger than 0.25-mm. and will not make a high recovery of grains coarser than 0.15- to 0.175-mm. Maximum recovery is made of grains between 0.03- or 0.04- and 0.10- or 0.12-mm.; there is a considerable drop in recovery of the finest sizes. The agitation-froth process will save coarser mineral than the bubble-column process and the latter is more efficient in saving very fine material. (See Tables 22 and 23.)

Fig. 77 (*55 A 576*) shows the relation at Inspiration between fineness of grinding and grade of flotation tailing.

There has been a gradual decrease in size of flotation feed ever since flotation was first introduced into the mills, so that while in early practice 28- or 35-mesh (0.59- or 0.42-mm.) was the limiting size, the present average maximum lies between 65- and 80-mesh (0.21- and 0.18-mm.). This trend is in part due to study of losses in tailing and in part to the steadily increasing adoption of pneumatic machines.

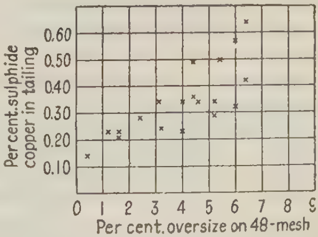

Fig. 77.—Relation between size of feed and assay of tailing (pneumatic machine)

The reasons for the failure to recover large and small particles are different. Large particles are lost because of the inability of the bubbles to carry them. In the agitation-froth process many of the bubbles carrying large particles do not have sufficient buoyancy to lift them to the top of the pulp in the spitzkasten, as may be seen by removing some of the pulp from the spitzkasten in a test-tube and examining it before a microscope. Also in many cases the large particles are jarred loose from the bubbles that precipitated upon them, because of the relatively great inertia of these large particles. In pneumatic machines, it is difficult to lift the large particles into the bubble column, on account of their greater settling velocities, and it is, of course, more difficult to lift them in the bubble column, for the same reason. As between the two types of processes, the agitation-froth process is the better fitted to hold large particles in the froth, once they have been raised to that point, both because of the firmer bond between the particles and the bubble walls and because the fine-textured froth acts mechanically as a screen and prevents large particles from falling back, even though they become detached from the bubbles.

The reason for loss of small particles is not definitely known. It is not improbable, however, that it is in part due to the locking of these particles in slime floccules and in part to the lack of flocculation of the sulphide particles themselves. Both of these hypotheses accord with the observed facts that the losses in the finest sizes are greatest in the agitation-froth type of machine, since the agitation of this machine in itself tends to produce flocculation (see Sec. 16, Art. 4), and flocculation of the slime-sulphide particles is essential to gas precipitation, which is no part of the pneumatic process.

Coghill (*119 P 404*) states that at the PRIMOS CHEMICAL Co. molybdenum plant recovery was raised from 60 to 83 per cent. by floating coarse pulp and then re-grinding and re-floating the tailing and ascribes the improvement to the fact that first grinding all of the pulp to ultimate flotation size overground some of the mineral.

Character of feed. High-grade feed makes for easy operation on account of the heavy loading of the bubbles and the consequent great stability of the froth. It is easier to make high-grade concentrate with high-grade feed, probably on account of the tendency of the mineral to crowd gangue from the bubble surfaces mechanically. On the other hand, the tailing from the treatment of high-grade feed will almost invariably be higher than that obtained from a low-grade feed of equal general floatability. It may happen, however, as is the case with free-milling non-sulphide gold ores, that the amount of metal present is insufficient to stabilize a selective froth, in which case, of course, flotation is inapplicable.

There is no great difference in floatability of the sulphides of different metals. The principal differences of importance are in the gangue minerals. An ore containing a large amount of clayey material, *i.e.*, a large amount of primary slime, will invariably be more difficult to float than an ore with a clean silicious gangue, and different methods of treatment may have to be employed. (See pages 844–858.)

Attempts have been made in some mills to solve the problem of primary slimes by separating them from the granular material by classification and treating the granular and slime materials separately, but these attempts have not been successful. In several instances it has been found, particularly in pneumatic machines, that the recovery from the granular material was not so high when it was treated alone as it was when treated in the presence of the slime, and that the recovery of the slime was not improved sufficiently to make up for this loss or to pay for the more complicated treatment.

Gahl (*55 A 576*) found at INSPIRATION that the granular material could be treated with ease but that the slime portion would not respond to flotation at all. He found, however, that if the percentage of primary slime in the flotation feed was kept below 20, Inspiration ore could be treated without greater tailing loss than was experienced when treating the granular material alone, although the grade of concentrate went down as the percentage of slime in the feed increased.

Control of the feed to keep the primary-slime content within proper limits is now the practice at all mills where such control is possible, and fairly elaborate methods of mixing in the mill bins is practiced to attain this end.

Kind of machine is not an operating variable, but is, of course, within control of an experimenter in preliminary testing. What has been said under "Size of feed" indicates that the pneumatic machine is preferable to the agitation-froth type for the reason that it is better fitted to save slime mineral, while its lesser ability to save coarse mineral can be taken care of by finer grinding. The pneumatic machine is easier to operate and control, once its operation is learned, than the mechanical machine, takes less power, and is cheaper to install and maintain.

Kind and quantity of flotation agent. Over-oiling is a frequent cause of poor operation. It is usually indicated by decrease in grade and increased mobility and overflow of froth. Aggravated over-oiling may kill frothing completely unless other conditions are adjusted to this condition. Excess of inorganic agents usually lowers both grade of concentrate and recovery. Where large amounts of inorganic salts are present in the mill water, however, it is usually possible to change other operating conditions, so as to overcome the bad effect.

Ralston (*105 J 735*) relates that at OHIO COPPER CO. the bad effect of the presence of copper and iron sulphates in the mine water used for flotation was rectified by addition of potassium cyanide.

Small-bubble froths frequently carry considerable coarse gangue. This condition can usually be rectified by changing oils in such a way as to produce coarser froth. The effect is to increase the inter-bubble space in the froth and allow the coarse material to drain back. The effect is particularly noticeable in machines of the combination agitation-froth and bubble-column types.

Place that agents are added makes considerable difference in their performance. Viscous oils and slow-dissolving chemicals should be added at the intake of the grinding mills. On the other hand, chemicals that alter quickly and, when altered, lose their effect, should be added directly to the flotation machine. Reagents that depend for their effect on chemical reaction with a constituent of the ore should be added far enough ahead of the cells to allow time for the reaction, *e.g.*, sodium sulphide with mixed sulphide-oxide ores.

Benitez (*123 P 922*) records that at CATEMU sodium sulphide added to the ball mills upset classifier performance and also lost its effectiveness by the time the pulp reached the flotation cells and that addition of freshly formed saturated solution near the tail end of the machine, where it would not interfere with sulphide flotation, gave the best results. Ralston and Yundt (*115 P 547*) state that at MIAMI lime added to the grinding mills increased recovery, but if added at the head of the flotation cells, was harmful.

Methods of adding reagents. The fundamental requirement is that the addition shall be regular and proportioned to the quantity of feed. No satisfactory method of automatically changing the addition rate with change in pulp-feed rate has been perfected. Solutions and mobile oils are readily

fed through needle valves, but it is essential, if the feed rate is to remain constant, that the head on the discharge shall not vary.

Rice (*106 J 1022*) describes a can feeder in which the oil is displaced upward and overflowed by means of water dripped into a pipe that feeds into the bottom of the oil container. This method is, of course, applicable only with oils and mixtures that are lighter than water and substantially immiscible therewith in bulk and has the disadvantage that the water abstracts a part of the water-soluble portion of the oil. With heavy oils a salt solution may be used to float the oil.

For viscous liquids various mechanical methods have been perfected, such as a small piston pump whose stroke length can be varied as desired: a miniature bucket elevator, of which either the speed; pitch, size, number or inclination of buckets; or the height of liquid in the boot can be varied at will: or a mechanism in which a revolving pulley dips into a tank of oil and the oil is removed from the face of the pulley by a scraper, the width of the scraper cut determining the amount removed (Braun oil feeder). Solid reagents are best added in solution, where possible. Failing this, the best method of addition is to pulverize them and then feed over a miniature of one of the various types of ore feeder, such as a traveling belt or chain, roller, vibrating or shaking plate or the like.

Ordinarily the reagents are dropped onto the surface of the pulp, but Barker (1,447,006/1923) describes an apparatus consisting of a horizontal perforated pipe surrounded loosely by a screen (about 18-mesh), attached by a tee to the lower end of a feed standpipe. Screen and perforated pipe are submerged in a moving stream of pulp and the screen acts as a permeable cylinder, emitting the reagent in minute droplets and films into the passing pulp, This apparatus, while not so successful in effecting dispersion as grinding the agent with the pulp, is nevertheless remarkably effective with mobile oils. At RAY CONSOLIDATED COPPER Co., using the same flow sheet as in atomizing (see Fig. 76) but adding a mixture of one part wood creosote to three or four parts of coal-tar creosote at the rate of 1.0 lb. per ton through a perforated pipe, the average tailing was 0.435 per cent. Cu and concentrate 16.03 per cent. Cu from feed averaging 0.682 per cent. Cu. This is a recovery of 37.2 per cent. Oxide-copper assays in feed and tailing respectively were 0.25 and 0.40 per cent.

In the modern use of chemical reagents such as alpha-naphthylamine, thiocarbanilid, xanthates and the like with slightly alkaline pulps, regulation of the degree of alkalinity in the pulp is an important factor. It is usual to effect this by frequent titration.

McLeod (*114 J 991*) describes an apparatus that indicates continuously the condition of the pulp as regards alkalinity. It consists of a filter that is placed in the pulp near the head of the cell, connecting by means of a flexible tube and a glass tube coated on the inside with fused phenolphthalein, with a vacuum bottle. The redness of the liquid dropping into the bottle is an indication of the degree of alkalinity of the pulp. Arrangement is made for periodical flushing of the system with water or compressed air.

Pulp density. Apart from the effect on the kind and quantity of flotation agents necessary and on the capacity of the machine (see descriptions of various machines), pulp density has a marked effect on recovery and grade of concentrate. The usual range is between 18 and 25 per cent. solids in rougher machines for pulps with average slime content. Density of slimy pulps ranges between 10 and 15 per cent. solids, in general. High pulp density, compared to the above figures, ordinarily causes low recovery and low-grade concentrate, with a sluggish, gangue-colored small-bubble froth similar to that produced by over-oiling, although this is not necessarily the case with sandy pulps. Low density causes production of a lightly-loaded, watery froth, a decrease in recovery and, usually, a drop in the grade of concentrate in the rougher-cell. This is because of the more intense aeration required with dilute pulps to maintain froth overflow, and the consequent overflow of gangue.

Low density is the usual condition in a cleaner cell, but here, although the recovery is generally low as compared with the rougher, the grade of feed is so high that overflow can be maintained with moderate to slight aeration and gangue is not, therefore, carried over mechanically.

Nevett (*121 P 349*) cites experiments at the JUNCTION NORTH mine, Broken Hill, to the effect that with 56 per cent. solids in the feed the machines treated 8 tons per hr. with poor results, while with 35 per cent. solids the same plant treated 24 tons per hr. with much improved results. The lower figure is much higher than is usual in the United States.

Maintenance of constant pulp density is just as important as determination of the right density. Ordinarily other conditions can be so adjusted that any pulp density within a considerable range will yield the same results, but once adjusted, results will fall off, if density varies. When mechanical classifiers prepare flotation feed, pulp density can be readily watched either by a hydrometer or by noting the height to which water rises in a small glass tube (about ⅛-in. bore) supported near the overflow end so as to project about 6 in. below the overflow lip. At the SULLIVAN MILL (*119 J 170*) flotation pulp is run through a small spitzkasten (18 in. square by 30 to 36 in. deep) suitably baffled to give uniform flow; a ¾-in. pipe with a bell fitting on the bottom carrying an 8-oz. canvas diaphragm is supported with the diaphragm 7 in. from the bottom of the spitzkasten; the upper end of the pipe is connected with an inclined glass tube against a calibrated scale and the whole is filled with colored water. At several mills hydrometer-controlled valves are installed on the line supplying water to the classifier and pulp density is kept substantially constant. This also keeps the size of flotation feed substantially constant. Where automatic or hydrometer control is not practiced, the usual procedure is to weigh samples of known volume and read density corresponding to the result from a chart or table.

Feed rate. There is a maximum feed rate for any cell under given conditions, but there is no minimum rate other than that imposed by economic considerations in design. That is to say, recovery in a given cell under given conditions is a maximum at the minimum feed rate, but the fall in recovery with increasing feed rate is very slow until the overload point is reached, when recovery falls rapidly with further increase. Many cells are fed far below the maximum rate.

Gahl says that at INSPIRATION doubling the section feed caused only a slight diminution in flotation recovery.

This condition of underload is more evident in series installations, such as the standard multi-compartment agitation machines and pneumatic machines of the Inspiration type, than with single-cell machines of the standard Callow type. In the multi-compartment machines the later compartments are acting as scavengers only, under normal operating conditions, and the recovery that they effect is small. When the feed rate is increased, more work is put on these later, normally underloaded, compartments. On the other hand, in the parallel-type installation, the machines are usually worked much more nearly to ultimate capacity, and when increased load comes on, some of the additional mineral goes into the tailing.

The ultimate capacity per cell is the same in both series and parallel installations. This was conclusively proved by careful experiment, both with standard Minerals Separation machines and with Callow machines, at the MIAMI COPPER CO.

Constant feed rate is important, for the reason that other variables, particularly agent addition, are based on a given rate, and change in rate changes the proportions and usually results in poorer performance.

Agitation. Intensity of agitation is not an operating variable, but recovery can frequently be increased, at the expense of increase in power consumption, by increasing the speed of impellers in agitation machines. This is particularly necessary when changing over from oils to chemical collecting agents. Agitation is not a function of pneumatic machines.

Attempts have been made to utilize the first cell as an agitator to mix flotation agents with the pulp, but they have been almost uniformly unsuccessful.

Duration of agitation may be increased by adding more compartments to a series machine, or decreasing the rate of feed. The effects of both of these changes are discussed above.

Aeration can be varied in agitation machines only by varying the intensity of agitation. In pneumatic machines variation in intensity of aeration is one of the principal operating variables. If there is too little aeration, the bubble column may break down at the surface nearly as fast as it is added to at the bottom, and recovery will suffer although grade of concentrate will increase. If there is too much aeration, boiling of the pulp may be sufficient to prevent a bubble column from forming, when, of course, there will be no concentration. If a bubble column forms under conditions of too much aeration, the froth will be low-grade on account of excessive return of gangue to the bubble column.

Temperature of the pulp has great effect in pulp-body flotation processes on account of its effect on the solubility of air in the water. The intensity of effect of all other flotation conditions is increased by increase in temperature of the pulp, minerals that are difficult to float in cold pulps are readily floated in hot pulps, and readily-floated minerals may be floated with less agitation or with less oil. Rise in temperature has a certain beneficial effect in pneumatic flotation with oil, but the effect is apparently only that it aids dispersion of the oil, since the same effect is not found when soluble, readily-dispersed frothing and collecting agents are used.

At Mt. Lyell (*123 P 90*) the winter temperature of the pulp is 47° F. and summer, 74°. Results in agitation-froth machines consistently improve in summer. Nevett (*121 P 349*) says that in the differential plant at Junction North mine, Broken Hill, a rise in temperature of even 1° F. above 90°, which was the desired temperature for lead flotation, caused zinc to commence to float, and that in the zinc-flotation machines, which were operated at 135° F., drop to 130° caused increased zinc losses. Ralston and Cameron (*99 J 937*) state that on practically any flotation pulp heating aids selective action and betters grade of concentrate.

Water supply is not normally an operating variable, except in those cases where reclaimed and fresh water are at the disposal of the operator for alternative use.

In the early work at Broken Hill it was found that when the amount of inorganic salts in solution in the flotation-pulp water exceeded a certain amount, flotation was harmed, hence sufficient fresh water was added to the circuit to keep the supply below this harmful concentration. As late as 1920, Nevett stated (*121 P 349*) that at the Junction North mine results fell off, if the concentration of salts in the mill water fell below 1400 or rose above 2600 grains per gal. In Arizona, where much of the mill water may be reclaimed from a tailing dam, the water frequently becomes so concentrated in certain soluble substances, due to evaporation, as to have a harmful effect on performance; on the other hand, a heavy rain which dilutes the water in the tailing pond may also have a harmful effect, particularly where the return water is depended upon for some of the flotation agents. In other words, the situation is that after the mill operation has been adjusted to a certain amount of contamination in the water as a regular operating condition anything that disturbs the regular condition is harmful. At Tul Mi Chung the spring floods bring large quantities of clay-like solid into the water supply and so long as this material is present flotation is uncertain and unsatisfactory. Bates (*109 J 552*) notes similar interference with flotation in a Mexican mill. Water from bogs and swamps usually contains tannin and vegetable acids which are ordinarily deleterious.

Stage flotation. One form is described by Gayford and Crerar (1,176,441/1916), consisting in grinding in two or more stages with intermediate flotation to remove concentrate.

At MIAMI COPPER Co. recent practice is to grind to 3 to 5 per cent. +48-mesh (instead of 65-mesh, as formerly), float, classify primary flotation tailing, sending slime to secondary flotation and sand to re-grinding mills and thence back to the primary flotation machines. This practice has greatly increased capacity, although it involves 33 per cent. additional grinding equipment.

Typical flotation flow-sheets may be classified into two general types on the basis of the part that flotation plays in the mill-treatment scheme and each of these classes may be again subdivided on the basis of the method of routing the pulp through the flotation machines. On the first basis, a flow-sheet is of the PRIMARY type when flotation is the primary or principal means of concentration employed and the bulk of the concentrate is recovered thereby; it is SECONDARY type when flotation is an accessory or subordinate process and some other means of concentration, usually gravity concentration, is the principal method of treatment. On the basis of pulp routing, a flow-sheet is of the CONCENTRATE-MIDDLING type when the flotation feed pulp passes through a set of machines in series, and these machines deliver finished froth concentrate off the early cells, a clean tailing as the underflow or spigot product of the last cell; and a low-grade froth or middling as the overflow of the later cells; this middling being returned to the head of the machine. A flow-sheet is of the ROUGHER-CLEANER type when two machines, not in series, comprise the flotation installation; the first (ROUGHER) makes a finished tailing and low-grade concentrate, which is sent to a second machine for cleaning; the second (CLEANER) makes finished high-grade concentrate and an underflow or spigot product constituting a middling, which is returned to the rougher cell. Combinations of these two methods of routing are also met with and may be classed as COMBINATION methods. Many combination routings are possible.

The bases for the differences in methods of flotation treatment are (1) the differences in the mode of occurrence of the valuable minerals in an ore and (2) the inability inherent in flotation processes to make a finished concentrate and a finished tailing with no material of intermediate value, in one treatment on one and the same machine. If the sulphide mineral in an ore occurs in coarse aggregates, a considerable proportion can be saved by gravity concentration at a less cost than by flotation, and ordinarily in the form of a concentrate that is more valuable than the concentrate made by flotation; assuming, of course, that the specific gravity of the gangue is sufficiently different from that of the sulphide to make gravity concentration efficient. In such case, flotation will probably form a subordinate part of the flow-sheet. On the other hand, if the sulphide mineral is disseminated through the ore in fine grains and the difference in specific gravity between the sulphide mineral and the gangue is not great, gravity concentration can recover only a small part of the valuable mineral and flotation should form the principal part of the treatment scheme. The choice as to the method of routing depends, to a large extent, on the percentage of floatable minerals present in the ore and on the grade of concentrate desired. A rougher-cleaner routing is usually used where the percentage of mineral in the flotation feed is low, and the concentrate-middling routing or combination routing is used when the percentage of mineral is high. The rougher-cleaner routing is best adapted to making a high-grade concentrate.

Cost. The approximate cost of pneumatic flotation (1926) as estimated by J. M. Callow (*PC*), follows:

		Cents per ton	
		Simple, one-metal ores (Cu)	Complex, two-metal ores (Pb-Zn)
1. Power @ 1¢ per kw.-hr.		3.0– 4.0	6.0– 8.0
2. Repairs and renewals		1.5– 2.0	3.0– 4.0
3. Reagents		4.5– 9.0	20.0–30.0
Total		9.0–15.0	29.0–42.0
4. Labor	100-ton scale	12–15	15–20
	500-ton scale	6–7	7–9
	1000-ton scale	4–5	5–6
Total costs, items 1, 2, 3, 4	100-ton scale	21–30	44–62
	500-ton scale	15–22	36–51
	1000-ton scale	13–20	34–48

(The above estimate includes only those items directly chargeable to flotation.)

For agitation-froth flotation add 1¢ to 2¢ per ton for additional power. The following actual costs at Utah Apex, grinding to 60-mesh and making a lead-zinc separation verify the estimate: Power, 6.2¢; repairs, 1.8¢; reagents, 21.9¢; labor, 4.0¢; total, 33.9¢ per ton of flotation feed. Total cost was \$1.60 per ton of crude ore, hence flotation was 21 per cent. of the total.

Total milling costs in a number of flotation plants follow (*J. M. Callow*):

Plant	Year	Tons per 24 hr.	Cost, dollars per ton
Utah Copper Co.(*b*)	1920	30,000	0.61
Inspiration(*b*)	1916	15,000	0.53
Nevada Cons. Cop. Co.(*b*)	1918	12,000	0.93
Miami(*b*)	1923	6,000	0.64
Porphyry Copper (*a*),(*b*)	1926	4,200	0.60
Porphyry Copper(*a*).(*b*)	1926	3,500	0.55
Utah Cons. Copper Co.(*c*)	1920	1,000	1.10
Magma Copper Co.(*b*)	1916	400	1.04
Bluestone(*b*)	1918	500	1.23
Utah Apex(*d*)	1924	400	1.36
Silver Dyke(*e*)	1923	400	1.36
Eustis Copper Co.(*c*)	1925	175	1.54

18. Flotation of gold and silver ores

When precious metals are intimately associated with base-metal sulphides, or the precious-metal value is a sulphide, or in the metallic form and sufficiently finely divided and present in sufficient quantity or with a sufficient quantity of base-metal sulphides to stabilize a froth, flotation may be employed and good recovery made. Low-grade non-sulphide precious-metal ores cannot be treated by flotation because there is not enough metallic substance present to stabilize froth.

Kaanta (1,539,120/1925) describes a process for treating precious-metal ores mixed with sulphides, consisting of pre-treatment by grinding and agitation in a dilute solution of alkaline cyanide (about 3 lb. per ton) and a collecting agent, *e.g.*, coal tar, in order to brighten and coat the precious metals, followed by agitation with a precipitant such as aluminum or

zinc dust, sodium sulphide or charcoal, for any dissolved precious metals, after which a frothing agent is to be added and flotation carried forward in the usual fashion. He states that the process is also applicable to oxidized ores.

At Vindicator Consolidated Gold Mining Co. mill (*114 P 202*) results on a 300-ton basis showed $40.25 concentrate and $0.375 tailing from $5.40 feed, which is a recovery of 93 per cent. Del Mar (*123 P 497*) states that at a mill treating a silver ore containing native silver and polybasite a K. and K. machine with crude petroleum and steam-distilled pine oil averaged 1189-oz. concentrate and 1.5-oz. tailing from feed containing 11.3 oz. silver. At a gold mill treating oxidized ore containing lead carbonate, the same type of machine with the same oil mixture made 22.2-oz. concentrate and 0.14-oz. tailing from a feed assaying 0.87-oz. gold.

Flotation *vs.* amalgamation and cyanidation. The following summary accords generally with experience: (1) If amalgamation will recover any considerable portion of the precious-metal values, this part will be recovered more cheaply than by either cyanidation or flotation; the amalgamation treatment will not interfere with subsequent practice of either of the other processes, and should be installed. (2) Cyanidation requires a more expensive plant than flotation. (See Sec. 23.) (3) Operation of the cyanide process is, in general, more expensive than operation of the flotation process. (4) Clean-up and refining of cyanide precipitate is cheaper, per ounce of metal in the original ore, than the recovery of metal from flotation concentrate. (5) If the gold remaining after amalgamation is free, *i.e.*, not associated with or included in sulphides, cyanidation will almost surely make a considerably lower-grade tailing than flotation; if the precious metals are associated with sulphides, flotation will probably make the better recovery and will probably, also, not require the pulp to be ground so fine as for cyanidation. This is because it is not necessary for the gold and silver in a sulphide particle to be exposed to the pulp liquid in order that they may pass into flotation concentrate, but it is necessary that they be exposed, if they are to be dissolved in cyanide solution. (6) The base-metal sulphides may be extremely deleterious in cyanidation, and will certainly be largely wasted in a cyanide mill, while in a flotation mill they may add value to the concentrate.

Rickard (*115 P 265*) has analyzed comparisons at several plants. At North Star, 80 @ 1050-lb. stamps crushed 110,000 tons per year to pass 20-mesh. The product was amalgamated, tabled, classified, and sand and slime cyanided separately. Table concentrate was re-ground to 200-mesh and cyanided. Amalgamation recovered $8 per ton, cyanidation $2. Tailing assayed $0.25 to $0.35 per ton; recovery was 97 per cent. The cost, including tailing loss, was $1.14 per ton in 1915, which could be reduced to $0.98 per ton. To treat the residue from amalgamation by flotation required re-grinding to pass 80-mesh; flotation tailing assayed $0.25 to $0.30 per ton. Ratio of concentration was 30 : 1 and concentrate assayed $70 to $90 per ton. Concentrate handling and smelting cost $17 per ton of concentrate or, roughly, $0.50 per ton of ore. Cyanidation of flotation concentrate required re-grinding to 200-mesh, consumed 6 lb. of cyanide per ton of concentrate, and the tailing assayed $6 per ton. Assuming $0.25 per ton for re-grinding, $0.30 per lb. for cyanide, and $2 per ton of concentrate for precipitating and refining of bullion makes the cost per ton of concentrate, including losses, substantially $10. Flotation operation and concentrate treatment (excluding loss) were estimated at $0.63 per ton, tailing loss was taken at $0.25 per ton and concentrate-treatment loss would amount to $0.20 per ton; total, $1.08 per ton. At a Mexican mill cyanidation recovered 77 per cent. of the gold-silver content and gravity concentration 14 per cent., milling cost was $1.55 per ton and tailing loss $1 per ton. Flotation tests indicated recoveries between 70 and 83 per cent. on $10.50 ore at a cost about as much below that of tabling and cyanidation as is equivalent to the decreased recovery. Flotation concentrate required to be shipped to a United States smelter which cost more per ton of original feed than treatment of cyanide-plant product. At Melones Mining Co., pyritic-quartz gold ore assaying $3.65 per ton was treated by amalgamation, tabling, classification and cyanidation at a cost of $0.50 per ton, recovery 86 per cent. Re-grinding and flotation of amalgamation tailing was estimated at $0.47 per ton and recovery at 90 per cent. The total estimated difference in return on this basis was $0.146 per ton, assuming similar cyanide treatment of gravity and of flotation concentrate.

At Dutch-App, stamping, amalgamation and gravity concentration cost $0.38 per ton, concentrate handling, treatment and loss cost $0.36 per ton of mill feed and tailing loss was $0.90 per ton, total $1.64 per ton. Flotation treatment in the remodeled mill cost $0.35 per ton for stamp crushing and ball milling, $0.15 for flotation, $0.38 for concentrate handling, treatment and loss, and $0.35 tailing loss; total $1.23 per ton. At the Argo custom mill, the usual ore contains gold and silver associated with pyrite, chalcopyrite and tetrahedrite. The first step is table treatment to remove coarse gold. Flotation made slightly better recovery on table tailing than cyanidation and cost less; it was sufficiently flexible to handle ores ranging from $1.25 to $80 per ton and copper was not a hindrance but rather an advantage in that it added value to the concentrate. At Portland, a reverse result was shown, resulting in change from flotation back to cyanidation. Treating $2.25 dump material, flotation cost $0.10 per ton more than cyanidation for grinding, as flotation required 48-mesh grinding against 20-mesh for cyanidation for substantially equal recoveries. Flotation had to bear also a royalty charge. Flotation concentrate was highly silicious and more expensive to treat than cyanide precipitate and high-grade table concentrate. The smelters paid $20 per oz. for gold in concentrate and nothing for silver; the mint paid $20.67 for gold and 95 per cent. of New York quotation for silver. Wartenweiler (*17 JCM 87*) reports a comparative test on a Transvaal gold ore containing considerable arsenopyrite. The feed contained 0.7 oz. Au per ton. Recovery by amalgamation was negligible. Grinding through 150-mesh and cyaniding gave a recovery of 45 per cent. Flotation of −90-mesh pulp gave a concentrate assaying 3.35 oz. Au and representing 71 per cent. recovery. Tailing and middling, assaying 0.20 and 0.435 oz. respectively, yielded a final tailing of 0.089 oz. after cyanidation, the interfering substances having been thrown into the concentrate by the flotation operation.

DIFFERENTIAL FLOTATION

19. Introduction

The term differential flotation is used in contradistinction to the phrase collective flotation. The latter indicates an operation in which all of the minerals of one general class, *e.g.*, sulphides, are separated by flotation from all minerals of the non-sulphide class; the first term describes separation effected between two or more minerals of the same class, *e.g.*, lead sulphide from zinc sulphide, or one non-metallic mineral from another. Typical cases are: galena from blende, pyrite from blende, chalcopyrite from pyrite or pyrrhotite, chalcopyrite from blende; carbonates of copper from rock-forming silicates, mica from rock-forming silicates, and coking from non-coking bituminous coal. Fluorspar may be separated from quartz, apatite and tri-calcium phosphate from rock-forming silicates, cassiterite from quartz, cerussite from cassiterite, etc. Separation is never sharp. Differential galena concentrate, for example, will contain some gangue and considerable zinc, the blende concentrate will contain considerable gangue and considerable lead, and the tailing will contain more or less of both sulphides.

It is possible, by proper choice of the method of treatment, to float the whole of the solid matter of a given pulp and leave behind clear water; at the other extreme a frothing operation can be conducted on the same pulp to yield nothing but watery bubbles. In the first case all of the factors tending toward the formation of solid-carrying froths have been over-emphasized, in the latter, these factors are missing or weakened to such a degree as to have become ineffective. Differential flotation is performed by careful control of flotation conditions so that a particular degree of flotation between these extremes is effected.

The factors whose control is most important are: (*a*) intensity of frothing, (*b*) sulphide filming, (*c*) adsorption of gangue at sulphide surfaces.

Intensity of frothing is controlled by varying the kind and quantity of frothing agent and the intensity of gasification.

Frothing agents that make fragile, effervescent froths yet which, when present in extremely minute quantities, have considerable frothing effect, are

most desirable for differential flotation. The best known of these are pine oil, eucalyptus oil, cresylic acid and certain coal-tar and wood-tar creosotes of high phenol content. These agents are all relatively soluble in water, small quantities have large effect on the liquid-gas surface tension, they are readily dispersed with a minimum of agitation, and the amount of frothing is substantially proportional to the amount of agent added.

Gasification comprises introduction of gas into the pulp and, in pulp-body processes, precipitation onto the desired mineral particles. Intensity of gasification involves volume alone in bubble-column processes; in the agitation-froth process, additionally violence of agitation and heat. If the intensity of gasification is low, *e.g.*, if the volume of gas is small, in a bubble-column machine, only the most easily floated mineral is raised to the surface of the bubble column.

Shellshear points out (*115 P 613*) that the upper part of the bubble column in a subaeration machine in lead-zinc flotation is much richer in lead than the lower part, while the lower part is richer in blende.

The mineral raised may be the most easily floated because it has been previously preferentially filmed with collecting agent; or because, though equally filmed, it is inherently easier to float; or, what is usually the case, because the other sulphide is more heavily coated with adsorbed gangue (see page 844). In any case, intense gasification may be sufficient to float the less-floatable mineral, when, of course, the more-floatable is raised also and no differential action occurs.

Agitation. In the agitation-froth machine volume of gas and passage through solution in the water of the pulp both increase with increasing violence of agitation, hence differential work requires reduced speed for the first flotation.

Del Mar (*117 P 691*) says that galena floats under given conditions in a Minerals Separation machine at 200 r.p.m. while blende requires 600 r.p.m. under similarly favorable conditions.

Heat decreases the solubility of gas in the liquids of the pulp and hence increases the rate at which it precipitates, all other things being equal. Hence heating a pulp increases intensity of gasification. It also affects gangue coating.

Machines. It is an extension of the same reasoning that explains the fact that bubble-column and agitation-froth machines are unequally applicable to differential processes. Gasification is so intense in agitation machines that they are unsuitable for delicate differential work and can be used for the first frothing only in those cases where the differentiating effect due to the reagents is great.

Shellshear (*115 P 616*) notes this and says that the agitation-froth machine may be used in the Bradford salt process because of the intense differentiating effect of the solution but that the Lyster process, with only slight differentiation effected by the chemical character of the solution, works best in a bubble-column machine. On the other hand, the agitation-froth machine may give much the better recovery of the second sulphide, which, having been intentionally deadened before the first flotation operation, may be difficult to raise in the second.

Size of particles is of greater importance in differential flotation than in collective because of the fact that the first float is made with feeble flotation conditions, *i.e.*, the buoyant effect of the gas is lessened as much as is possible, consistent with any flotation at all, and as a consequence any desired particle that is unduly heavy is likely to go into the tailing. When galena is floated

from blende it is frequently the finest of the galena only that floats. For this reason the tailing from gravity concentration is particularly suitable for lead-zinc differential flotation since the coarse lead has already been removed and hence is not lost in the lead-flotation tailing.

Pulp density is usually above normal, *e.g.*, 25 to 50 per cent. solids during lead flotation and drops to 20 to 25 per cent. solids in zinc flotation. Maintenance of constant conditions is particularly important in the first flotation.

Filming is of paramount importance. Within certain limits, the mineral or minerals that will be filmed by a given collecting agent in a given mixture of minerals is dependent on the quantity of agent present; *i.e.*, if too little reagent is present for filming all of the sulphide minerals in the pulp, one of the sulphides may be filmed in preference to the others; if, on the other hand, the quantity of reagent is in excess of that required to float the sulphides, gangue minerals will usually begin to float. Thus one method of producing differential flotation is to add such a small quantity of filming agent that it will all be appropriated by one mineral. This method is known as the STARVATION METHOD.

The same filming agents that are used in collective flotation of a given mineral are frequently effective in differential flotation.

Gangue adsorption on sulphide surfaces prevents filming by collecting agents and thus prevents flotation. Control of gangue adsorption is the most important operation in differential flotation. Control is effected by the use of agents, mostly inorganic, of which the principal ones are lime, sodium carbonate, sodium cyanide, sodium hydroxide, sodium silicate, sodium sulphide, copper sulphate, sulphur dioxide and zinc sulphate. The active phenomena are described at page 845.

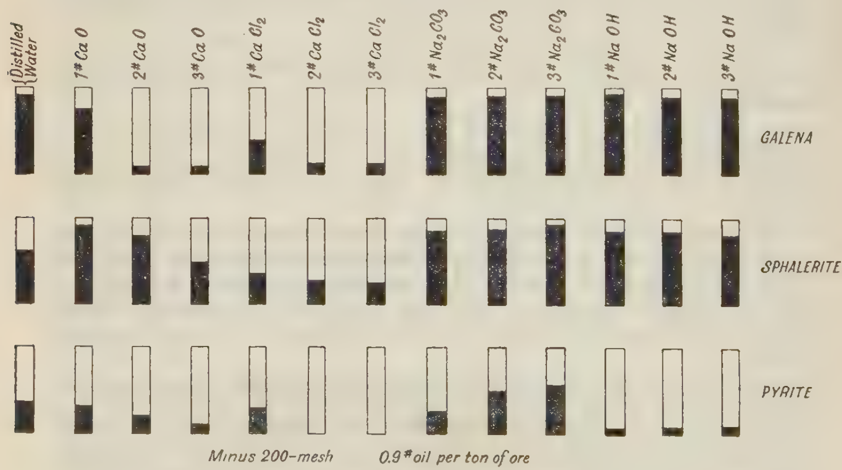

FIG. 78.—Relative floatabilities.

Soda ash aids in producing a high-grade lead concentrate with "starvation" quantities of oil on some lead-zinc ores and shows differential effect in certain copper-iron separations (*205 Bul. USBM 23, 53; 36 Aa 98*). Sodium silicate and sodium carbonate have been used to aid lead flotation with coal-tar creosotes (*120 P 459*). Sodium sulphide is used to keep down blende in the presence both of galena and chalcopyrite (*114 J 629*) but Fahrenwald (*4 UId 16*) says that blende tends to float in preference to galena if the solution is

alkaline with sodium hydroxide or sodium sulphide. Kirtley says (*104 J 64*) that when more than 5 lb. per ton of sodium sulphide is used it raises iron but keeps down zinc, while with less than 1 lb. per ton the zinc is lifted; an excess lifts gangue to the exclusion of sulphides and forms a watery froth. Sodium sulphide may be used to keep down both chalcopyrite and blende in the presence of molybdenite or to keep down chalcopyrite in the presence of galena (*114 J 629*). Gates and Jacobsen (*16 UU 38*) investigated the effect of various agents on the floatability of galena, sphalerite and pyrite. Their results are summarized in Fig. 78. See also p. 846.

Tucker and Head (*73 A 354*) made an ingenious investigation of the effects of cyanide, zinc sulphate and lime. A summary of the results of their tests is presented in Table 24. The tests show that cyanide plus zinc sulphate lessen the floatability of zinc

Table 24. Effect of cyanide on floatability of lead, zinc and iron sulphides. (*After Tucker and Head*)

and iron markedly but do not substantially affect the floatability of lead; that this depression is not entirely due to either the cyanide or the sulphate alone; that lime depresses lead and hence cannot be used for insuring alkalinity, but that sodium carbonate can be used;

and that copper sulphate added to a pulp in which blende and pyrite have been sickened by cyanide and zinc sulphate, permits the blende to be floated away from the pyrite.

The most enlightening part of the work consisted in microscopic study of the surface effects of the solutions. Individual grains of the various sulphides, half-coated with paraffin, were fastened to the shaft of an agitation-froth machine and this was run for 20 min. with a solution of zinc sulphate and sodium cyanide. The sulphide particles were then removed, washed free of paraffin and microphotographed. The photographs showed substantially complete loss of luster by the pyrite and sphalerite surfaces, while the galena surface was unaffected.

This work may explain the differential action of these reagents when the gangue is one that does not adsorb at the sulphide surfaces under the conditions of the flotation operation, but it was impossible to duplicate the tests at Columbia University. On the other hand, the Columbia work showed that with a typical clayey slime which adsorbed heavily on galena, sphalerite, pyrite and chalcopyrite in the presence of pine oil and sodium carbonate or bicarbonate, addition of potassium cyanide and zinc sulphate substantially prevented adsorption at the galena or chalcopyrite surfaces while adsorption on sphalerite and pyrite was, if anything, increased.

Sulphur dioxide is a powerful retarder of blende flotation. It is particularly useful when the galena is relatively difficult to float and flotation conditions must, therefore, be intensified, or when a galena-blende collective float is to be separated.

Shellshear (*115 P 616*) points out that it is very difficult to secure differential flotation of a collective float. This is because a part of the differential phenomenon is selective prevention of filming of the sulphide minerals by collective agents. After all sulphides are filmed as in the case in a collective float, one of the means of differentiation has been removed and more of the burden is consequently placed on the others, resulting in added difficulties. Acid is frequently an aid to differential flotation of lead in the presence of SO_2. On the other hand it is more usual to find that lead flotation is best effected in neutral or alkaline pulp with acid added for zinc flotation, if at all.

Control. The difference in floatability between different sulphides is much less than the difference between sulphides as a class and the rock-forming minerals as a class, hence it follows that differential flotation is a much more delicate operation than collective flotation. Close control of the effective flotation factors is essential to success and regularity of operation is important.

List of agents for differential flotation patented in the United States prior to Jan. 1, 1926.

Acacia, 1,446,376.
Acid, 1,126,965, 1,182,890, 1,260,668, 1,269,157, 1,446,376, 1,469,042.
Albumin, 1,499,872.
Alkali, 956,381, 1,142,821, 1,157,176, 1,203,372, 1,203,373, 1,203,374, 1,257,990, 1,261,810, 1,317,945, 1,446,376, 1,469,042, 1,478,697.
Alkaline carbonate, 1,301,551.
Alkaline salt, 1,421,585, 1,427,235.
Alkaline sulphite, 1,486,297.
Ammonia, 1,254,173.
Barium chloride, 1,203,372, 1,203,374.
Barium sulphate, 1,446,376.
Bicarbonate, 1,203,372 (see also Sodium ——).
Bichromate, 1,102,738, 1,142,821, 1,257,990 (see also Potassium ——).
Bi-sulphites, 1,274,505.
Bleaching powder, 1,300,516.
Calcium chloride, 1,203,372, 1,203,373, 1,203,374.
  hydrate, 1,203,373, 1,203,374, 1,254,173.
  nitrate, 1,203,372, 1,203,373.
  sulphate, 1,203,372, 1,446,376.
  sulphite, 1,486,297.
Carbonaceous material, 1,261,810.
Carbonate, 1,203,372, 1,486,297.
  of an alkali, 1,486,297.
  of an alkali metal, 1,486,297.
Charcoal, 1,261,810.
Chloride of an alkali metal, 1,182,890, 1,203,372, 1,203,373, 1,203,374.
  alkaline earth, 1,182,890, 1,203,372, 1,203,373.
  a metal, 1,203,372, 1,203,374 (see also Specific metals).

Starch, 1,499,872.
Sulphates, 1,203,372 (see also Specific metals).
Sulphide of an alkali, 1,469,042 (see also Sodium ——).
  alkaline earth, 1,469,042.
Sulphites, 1,182,890, 1,274,505, 1,478,697, 1,486,297.
Sulphur, 1,401,435.
  acids (lower), 1,182,890.
  dioxide, 1,274,505, 1,486,297.
Sulphuric acid (see also Acid), 967,671, 1,020,353, 1,269,157, 1,274,505, 1,401,435, 1,486,297.
Sulphurous acid, 1,274,505.
Tannin, 1,499,872.
Thiosulphites, 1,182,890, 1,274,505.
Tri-sodium phosphate, 1,446,376.
Zinc sulphate, 1,203,372, 1,421,585, 1,427,235.

Parsons (*Bull. 617, Mines branch, Canada Dept. of Mines, 1923*) gives the following summary of flotation agents found useful for differential work at the laboratory of the Bureau. For floating galena in the presence of zinc and iron sulphides: A mixture of coal tar and coal-tar creosote; cresylic acid; thiocarbanilid; steam-distilled pine oil; light hardwood-creosote oil; lime (but see Gates and Jacobsen, p. 871); sodium sulphite. For floating blende from iron sulphides after lead or copper sulphide has been removed; K. and K. oil No. 2, Southwestern Engineering Co.; Barrett No. 634 coal-tar creosote; sodium creosote from hardwood; thiocarbanilid and xylidin (General Engineering Co. Y-Z mixture); thiocarbanilid and orthotoluidin (Gen'l Engineering Co. T-T mixture); fuel oil, 34° Bé., G. W. Oil Co.; Barrett water-gas tar; copper sulphate; soda ash. For floating copper sulphides from zinc and iron sulphides: a mixture of coal tar and coal-tar creosote; xylidin and alpha-naphthylamine (Gen'l Engineering Co. X-Y mixture); neutral fractions of hardwood oils; lime. For floating copper sulphides from iron sulphides; Barrett No. 634; X-Y mixture; T-T mixture; Y-Z mixture; Thio-fizzan (Gen'l Engineering Co.); sodium resinate; paraffin-base fuel oils; lime; soda ash. For floating copper-nickel sulphides from iron sulphides: Thio-fizzan; T-T mixture; X-Y mixture; paraffin-base fuel oil; mixtures of coal-tar and coal-tar creosote; soda ash. For floating molybdenite and graphite from iron sulphides: kerosene; lime. For frothing agents: steam-distilled pine oil; Fumol (Canadian Electro Products Co.); Ketone oil (Standard Chemical Co.).

PROCESSES

Processes of differential separation may be divided into three groups as follows:

1. Processes in which the surfaces of the particles of one of the normally floatable minerals are permanently changed by chemical action so as to render the particles non-floatable. The chemical action utilized may be either pyro-chemical or hydro-chemical.

2. Processes in which the surfaces of the particles of one of the normally floatable minerals are temporarily changed so as to render these particles non-floatable, but in which the deadening effect may be subsequently eliminated or overcome by suitable treatment.

3. Processes in which the activity of one or more of the physical phenomena that combine to effect flotation is limited or controlled to such an extent that at first only the most readily floated of the floatable constituents is raised.

Some of the patented processes do not fall easily into any of the three groups.

20. Processes involving permanent change of one of the floatable minerals

These are not properly differential-flotation processes, for the reason that before flotation is attempted particles of an originally floatable class have been permanently changed into the non-floatable class by an irreversible chemical reaction and subsequent flotation differentiates only between readily-floatable and non-floatable particles rather than between two minerals of the readily-floatable class.

The dry-chemical patents in this class follow.

Fractional roasting

Wentworth (938,732/1909) points out that different compounds of the same base metal differ widely in their behavior in skin flotation, their susceptibility to oiling and their ability to precipitate gas from solution onto their surfaces and that these differences can be utilized to effect separation by flotation. He points out further the differences in the roasting temperatures of different metallic sulphides and that, if mixed sulphides are roasted at a temperature below the oxidizing temperature of one of them but above that of the others, the latter are converted into non-floatable material while the former retains its floatability. Iron and lead sulphides are converted into oxides and sulphates by roasting at a dull red heat, while zinc is unaffected at this temperature, hence flotation treatment subsequent to a low-temperature roast of a mixture of the three sulphides results in flotation of the zinc sulphide away from the oxidized and non-floatable iron and lead compounds. Wentworth classes chalcopyrite among the easily-roasted sulphides.

Ramage (949,002/1910) describes a process similar in general principle to Wentworth, but states that chalcopyrite is more resistant to oxidation than blende. He recommends roasting a mixture of pyrite, blende and chalcopyrite at 600° C. to decompose pyrite, floating blende and chalcopyrite as a collective concentrate, roasting this at 700° C. to decompose blende and dissolving the oxidized blende from the roasted residue with sulphuric acid. Elsewhere in the same patent he recommends a roasting temperature of 800° C. to decompose cobaltite, niccolite and sulphides and sulpharsenides of silver, leaving chalcopyrite unchanged and floatable. Ralston (*110 P 980*) questions these statements in so far as they set up such relatively great refractoriness for chalcopyrite.

Horwood (1,020,353/1912) describes slow roasting of a collective sulphide concentrate, *e.g.*, galena-pyrite-blende, at say 400° to 500° C. to sulphatize the galena and oxidize the pyrite, and subsequent flotation of the unaffected blende. He also describes a wet chemical method of effecting the same result. In a later patent (1,108,440/1914) Horwood describes an improvement consisting in a water wash prior to roasting in order to remove soluble salts and thus lessen the oxidation of zinc in the roasting operation. He claimed also that the water wash causes silver to be deadened with the lead and that such roasted material could be subsequently floated at 120° F. instead of at 180° as formerly.

Roasting is the difficult part of this process. The extent of sulphatization necessary depends upon the character of the ore and the fineness of grinding. Horwood (*16 Aa 229*) says that with Broken Hill slimes, 75 per cent. sulphatization is necessary while with granular material of the same composition 25 per cent. is sufficient, and that with some ores, even when slimed, 10 per cent. is sufficient. Clark (*89 J 460*) states that in roasting a pyrite-galena-blende concentrate the pyrite oxidizes first at 300 to 400° C., then the galena, and that about three hours is required for the roast. At the Zinc Corporation (*Pro. Austr. I.M.E. (1913) No. 12*) roaster feed assayed 39 per cent. Zn, 16 per cent. Pb and 18 oz. Ag; rough zinc concentrate, 49.5 per cent. Zn, 6 per cent. Pb and 11 oz. Ag; lead residue, 9 per cent. Zn, 47 per cent. Pb and 45 oz. Ag. The roaster was an Edwards duplex-type, 14 × 102-ft. with 12 panels and 48 rabbles. Feed contained 10 to 12 per cent. water. Fuel consumption was 4.8 per cent. of the ore charged. It was necessary to sulphatize about 30 per cent. of the lead to effect good results in the furnace. Rain (*113 P 529*) says that for proper roasting the ore must be crushed to 80-mesh. The roast should start at a low temperature and be gradually raised to 500° C. and the charge rabbled freely. Only the surface of the particles need be sulphatized. Control is effected by determining the necessary degree of roasting by a flotation test, calibrating this chemically, then using chemical control. Heller (*119 P 151*) describes an elaborate trial of the process on a copper-zinc ore at the Afterthought mine on a scale of 275 to 400 tons original feed per 24 hr. The feed was ground wet to 48-mesh, a collective float, recovering 90 per cent. of the copper and 85 per cent. of the zinc, was made with stove oil and Pensacola No. 80. The best assay for the collective float was 30 per cent. Zn, 6 per cent. Cu, 18 per cent Fe, 10 per cent. insoluble, 6 per cent. alumina and 4 per cent. lime. If there was less silica, the roast was too quick; if the concentrate was too low-grade, the copper residue was likewise low-grade. Roasting was done in a 25-ft. 9-hearth Wedge-type Skinner furnace with the five lower hearths arranged for rapid cooling by the removal of the brick lining and quick withdrawal of hot gases. The best temperature range was 920° F. maximum and 400° F. or lower on the bottom hearth. Slow cooling was particularly important; quick cooling killed selective action in the float. The zinc froth assayed 2.6 per cent Cu, 47.1 per cent. Zn, 4.2 per cent. Fe, 3.3 per cent. $BaSO_4$, 4.4 per cent. CaO, 3.8 per cent. Al_2O_3, 3.2 per cent. SiO_2; copper residue, 7.2 per cent. Cu, 12.3 per cent. Zn, 23.4 per cent Fe, 8.2 per cent. $BaSO_4$, 12.7 per cent. CaO, 10.5 per cent. Al_2O_3, 10.4 per cent. SiO_2. There was about 8 oz. Ag per ton in each concentrate. The costs were: collective flotation, 10¢ per ton; flotation of roasted material, 15¢; roasting and cooling, 30¢; royalty, 50¢; total milling cost, $2.09.

Wood (1,263,503/1918) describes the production of a collective float of molybdenite and pyrrhotite followed by high-temperature drying, *i.e.*, substantially flash roasting, to very slightly oxidize the iron, with subsequent flotation of the molybdenite.

The flotation processes described in the specifications of these various patents are the old-time processes of skin flotation and chemical-generation (see Art. 2 and 4) but the method of the patents is equally applicable to both agitation-froth and bubble-column processes. No extensive application of any of the processes has ever been made, and no practice exists at present.

The wet-chemical processes of this class, like the dry-chemical, all depend on reactions with the lead and iron minerals to change the surfaces of these while zinc and copper sulphides are left unaffected. A distinct disadvantage is the fact that silver sulphides are not attacked and therefore go with the zinc.

Ramage (967,671/1910) treated a finely-ground, un-oiled ore containing a mixture of lead, iron and zinc sulphides with a 10 per cent. solution of sodium nitrate or sodium chloride and sulphuric acid at 140° F., forming a pulp containing 25 to 30 per cent. solids. As a result blende rose in the form of a heavy, spongy froth. Subsequently raising the temperature to 180° F. caused iron sulphides to be raised while the lead was permanently oxidized or chloridized and stayed behind with the gangue.

Wentworth (970,002 and 980,035/1910) proposes treating moist ground ore with chlorine (or another halogen) in order to chemically change and deaden the surfaces of some of the floatable minerals. He states that at blende surfaces an oily-appearing substance is formed which may be chloride of sulphur and which accentuates the floatability of the blende, while at pyrite surfaces a water-soluble compound is formed which induces wetting and sinking of the affected particles. Chalcopyrite is placed in the non-affected class.

Mac Gregor (972,459/1910) has the same idea.

Horwood (1,020,353/1912) describes digestion in nitrated sulphuric acid solution to sulphatize galena and oxidize pyrite, leaving blende substantially unchanged.

Greenway and Lowry (1,102,738/1914) describe digestion in a solution containing a salt of chromium, *e.g.*, sodium or potassium bichromate, in order to render galena and iron unfloatable. After digestion the chromate solution is decanted and the residue floated with organic reagents in the usual manner. They cite the following EXAMPLES: (1) Chalcopyrite-pyrite ore crushed to 100-mesh and digested 30 min. in a hot 1 per cent. solution of sodium bichromate; solution decanted and the residue floated by the agitation-froth process using 1 lb. of eucalyptus oil per ton of ore. Assays: Feed, 6.5 per cent. Cu and 35 per cent. Fe; concentrate, 19.0 per cent. Cu and 30.2. per cent. Fe; tailing, 0.7 per cent. Cu and 36.2 per cent. Fe. (2) A galena-blende collective concentrate similarly treated. Assays: Feed 18.6 per cent. Pb and 32.2 per cent. Zn; concentrate, 47.2 per cent. Zn and 6.3 per cent. Pb; tailing, 31.6 per cent. Pb and 16.3 per cent. Zn. (3) A molybdenite-pyrite ore floated with 1 lb. of eucalyptus oil per ton at 120° F. in a 0.25 per cent. solution of sodium bichromate. The pulp contained 20 per cent. solids. Assays: Feed, 15 per cent. molybdenite and 25 per cent. pyrite; concentrate, 93 per cent. molybdenite and 4.9 per cent. pyrite.

Lavers (1,142,821/1915) describes the use of chromate in a purposely alkaline solution *e.g.*, 1 per cent. sodium carbonate, preferably at 120° to 150° F. EXAMPLES: (1) Lead-zinc-iron ore treated by agitation-froth flotation in a pulp containing 20 per cent. solids at 130° F. adding 22 lb. of sodium carbonate, 6 lb. of sodium bichromate and 0.5 lb. each of eucalyptus oil and kerosene per ton of ore. Assays: Feed, 9 per cent. Pb, 28.2 per cent. Zn and 14.2 per cent. Fe; concentrate, 50.1 per cent. Zn, 4.25 per cent. Pb and 8.3 per cent. Fe; tailing not given, and probably, therefore, not worth giving. (2) A lead-zinc ore, agitation-froth flotation, 20 per cent. solids, 130° F., 24 lb. sodium carbonate and 1 lb. eucalyptus oil per ton. From a feed assaying 11.6 per cent. Pb and 13.4 per cent. Zn a collective concentrate assaying 22.2 per cent. Pb and 27.4 per cent. Zn was obtained. This concentrate was re-floated at 130° F. with 24 lb. sodium carbonate, 6 lb. sodium bichromate, 0.12 lb. eucalyptus oil and 0.75 lb. kerosene per ton of ore producing a float concentrate assaying 48.6 per cent. Zn and 7.5 per cent. Pb and a leady residue assaying 55.9 per cent. Pb and 8.9 per cent. Zn.

Coghill and Anderson (*TP 283, USBM*) report an extensive series of tests on complex lead-zinc-iron ores from Colorado mines, using slightly-acid dichromate solutions with oil. They found that, in the laboratory, at least, the following procedure was applicable to all the ores tested: (1) Crush to about 50-mesh in such a way as to produce as little fine lead as possible, separate − 120-mesh material and table the oversize to recover lead, (2) Re-grind table tailing to 120-mesh and join with the original slime. (3) Float with coal tar, cresylic acid (or steam-distilled pine oil or xylidin) and Na_2S to obtain a differential lead concentrate; add more of the frothing agents and make a second froth for tabling; finally add Cleveland Cliffs No. 2 and float the balance of the mixed sulphides and leave a final tailing. (4) Table the second overflow above and obtain a lead concentrate and tailing. Re-grind and re-float the tailing with further coal tar, cresylic acid and sodium sulphide; collect lead concentrate and send tailing to join the froth obtained with Cleveland

Cliffs oil. (5) Table the Cleveland Cliffs-oil froth (together with the re-floated-middling underflow) and make lead concentrate and tailing. (6) Re-float this tailing with acid dichromate solution (1 lb. of dichromate per 4 per cent. of zinc and 0.1 lb. H_2SO_4 per lb. of dichromate) and a minute amount of the Cleveland Cliffs oil or No. 350 Pensacola Tar and Turpentine Co. oil; clean the froth one or more times as necessary to grade up the zinc concentrate, returning the middling to the dichromate rougher cell. The underflow of the dichromate cell is an iron-rich product. By this method they obtained results shown in Table 25. They found that while the acid dichromate would hold back coarse lead, it would not hold back fine lead and that its principal useful function was in holding down iron. It was necessary to grind to 120-mesh to float the zinc in the presence of dichromate.

Table 25. Results of treatment of Colorado complex ore. (*After Coghill and Anderson*)

Terry (1,254,173/1918) states that ammonia in solution oxidizes iron sufficiently to prevent oil coating. On the other hand it dissolves oxide from partially-oxidized lead, zinc and copper sulphides. He describes mixing a pulp first with ammonia, then with oil in a closed vessel to exclude air, then floating by the cascade method. Prior treatment of the ore in a ball mill with calcium hydrate and sodium thiosulphate are also recommended. Ammonia solution of 0.04 to 0.06 per cent. strength is required and the pulp should be digested for some time prior to flotation. Treating an ore containing zinc, iron and copper sulphides, it was found necessary to remove ammonia before flotation or copper floated with zinc. On this ore neutral pine oil and neutralized wood-creosote oil were best, coal-tar creosote would not give differential action. Laboratory tests showed concentrate carrying 48 to 60 per cent. zinc and 2 to 15 per cent. iron from feeds carrying 4 to 25 per cent. each iron and zinc; recoveries, 60 to 90 per cent. The cost of the process would be high on account of the high price of ammonia (*19 CME 319*).

Pellegrini (1,233,398/1917) proposes differential separation of mixed base-metal oxide ores by preferential sulphidizing and says that the process is particularly suitable for separation of lead vanadanate from other lead salts, particularly the molybdate. He arranges the lead minerals in decreasing order of rate of sulphidizing as follows: Carbonate, oxide, molybdate and vanadanate. Hydrogen sulphide, sodium sulphide and the like, in limited amounts, are recommended for sulphidizing.

Smith (1,452,662/1923) states that in an ore containing oxidized minerals of lead, zinc and manganese, the lead may first be sulphidized by the usual soluble sulphides in alkaline solution in a thick pulp and subsequently diluted and floated and that thereafter the tailing should be thickened and acidified, after which zinc and manganese minerals may be sulphidized.

21. Processes in which organic or inorganic chemicals are used to retard flotation of one of the normally-floatable minerals

Under this heading are included all those processes in which some substance, usually a salt, is added to a flotation pulp for the purpose of rendering one of the ordinarily-floatable minerals temporarily non-floatable. The action of the reagents is, usually, to affect the degree of adsorption of gangue at the mineral surfaces, so that the particles of one sulphide are gangue-coated and hence readily water-wetted just like gangue particles themselves, while the particles of the other sulphide present normal lustrous surfaces to the action of the collecting agent.

Owen (1,157,176/1915) adds a small amount of an alkaline permanganate or a somewhat greater amount of manganese dioxide in a neutral or alkaline (*e.g.*, NaOH) solution to effect retardation of blende in the presence of lead, silver and copper sulphides. Heating to 120° F is recommended when the ore pulp reduces the manganese compound rapidly. Subsequent flotation with acid raises blende but acid prevents differential flotation. Eucalyptus oil is recommended. The process is claimed to be particularly applicable to weathered material and weathering for a few hours is suggested as advantageous with some current mill pulps. Weathered Broken Hill slime assaying 16 per cent. Pb, 13.5 per cent. Zn and 17 oz. Ag per ton was floated in a pulp containing 20 to 25 per cent. solid with 2.5 lb. potassium permanganate and 0.3 lb. eucalyptus oil per ton of ore. Concentrate assayed 60.5 per cent. Pb, 11.8 per cent. Zn and 54 oz. Ag per ton; 15 lb. of sulphuric acid per ton of ore was then added to the residue and flotation continued. Concentrate assayed 43.2 per cent. Zn, 6.2 per cent. Pb and 11.2 oz. Ag per ton; tailing, 2.0 per cent Pb, 1.6 per cent. Zn and 3.0 oz. Ag per ton. Fahrenwald (*4 UId 19*) reports a test using about 0.25 lb. per ton of permanganate on a Cœur d'Alene ore containing organic matter and therefore difficult. Without permanganate the concentrate assayed 36.6 per cent. Pb and 22 per cent. Zn and represented 62 per cent. recovery of the lead; with permanganate the corresponding figures were 49.8 per cent. Pb, 14.3 per cent Zn and 65.5 per cent. recovery. Shellshear says that a small quantity of permanganate will keep down zinc and produce a high-grade lead float. An excess will keep down both sulphides unless heat and acid are used, when the lead can be floated. The process is economically impracticable on account of the high cost of permanganate.

Bradford (1,182,890/1916) states that with oleic acid and a temperature of 120° to 160° F. blende will float away from galena and pyrite in a solution, preferably weakly acid, of one or more chlorides of the alkaline metals or alkaline earths. The best strength of acid solution is between 0.1 and 0.2 per cent.; 1 per cent. solution causes galena and pyrite to float. The quantity of salt may vary widely, but 10 per cent. is suitable. Sodium chloride is preferred on account of cheapness. The lower sulphur acids and their salts (sulphites and thiosulphates) are stated to further retard galena and pyrite. With crude ores the oil may sometimes be omitted.

Shellshear (*115 P 616*) says that lead chloride is found in solution, but the fact that the lead can be subsequently floated by use of potassium permanganate or copper sulphate indicates that any surface change is exceedingly minute. The process yields clean zinc concentrate and the recovery of zinc is high.

Lyster (1,203,374/1916) states that at normal temperatures in a neutral or alkaline solution of a chloride of a metal, *e.g.*, NaCl, KCl, $BaCl_2$, $CaCl_2$, $MgCl_2$, with or without an organic frothing agent as the case may be, galena floats in preference to blende. Solution strengths range from 300 to 800 grains of chloride per gal. plus 1.8 to 18 grains $Ca(OH)_2$. Two pounds of eucalpytus oil per ton of ore is stated as a suitable kind and quantity of organic agent.

Lyster (1,203,372/1916) states that flotation at temperatures below 100° F. with, say 2 to 5 lb. per ton of eucalyptus oil in a neutral or alkaline, but not acid, solution of a sulphate, chloride or nitrate of calcium, magnesium, sodium or potassium; or a sulphate of manganese, zinc, or iron; or barium chloride; or a carbonate or bicarbonate of sodium or potassium; or any mixtures of these salts will cause galena to float in preference to zinc. The solution strengths recommended are 160 to 800 grains per gal. In patent 1,203,373/1916, the same patentee states that flotation at a temperature below 100° F. with eucalyptus oil or other frothing agent in alkaline solution, causes galena to rise in preference to blende. Examples of solution composition are: Sodium carbonate, 500 grains per gal.; sodium bicarbonate, 600 gr.; calcium chloride, 300 gr. with 300 gr. calcium hydrate, calcium nitrate 300 ft. with 18 gr. calcium hydrate. He warns that with certain ores, as the calcitic ores of Broken Hill, excessive alkalinity retards galena flotation. Patent 1,203,375/1916, to the same patentee adds nothing new.

Freeman (*36 Aa 95*) says that Lyster's process is workable with ores that contain blende and galena with large differences in floatability, but that the differentiating action of the salts is not nearly so intense as that of sulphur dioxide (Bradford) and that the latter is used when blende and galena are of varieties close together in floatability. Ralston (*110 P 980*) points out that these patents contemplate a minute amount of oil, excessive agitation and a crowded spitzkasten, all of which conditions, irrespective of the kind and quantity of salts present, would tend toward differential flotation.

Faul and Lavers (1,257,990/1918) describe flotation of blende from galena effected by adding metallic mercury, mercury amalgam or a mercury salt to the pulp. Retardation of galena may be aided by a bichromate in an alkaline medium (see also Pat 1,142,821). EXAMPLE. Feed containing 9 per cent. galena, 45 per cent. blende and 30 per cent. pyrite was made into a pulp with potassium bichromate, 0.4 per cent. on the ore; sodium silicate, 0.2 per cent. on the ore and 0.5 lb. per ton of cresol and floated at 140° F. in a wooden agitation machine containing metallic mercury. A froth concentrate was separated assaying 1.7 per cent. Pb, 51.5 per cent. Zn and 8.6 per cent. Fe. It is stated that similar results were obtained when sodium carbonate alone or sodium carbonate and hydrogen sulphide replaced the potassium bichromate and sodium silicate of the example.

The results stated in this patent differ so little from those described by one of the same patentees in 1,142,821 (p. 876) as to lead to the suspicion that the presence of mercury had little or no effect. See also Freeman, pat. 1,301,551.

Callow (1,269,157/1918) prescribes the use of sodium acid sulphate ($NaHSO_4$) or salt cake or niter cake and an acid, preferably sulphuric, to retard flotation of one of the sulphides present in a complex ore. The process may be applied to crude ore or to a collective concentrate. EXAMPLE. A feed containing 14 per cent. Pb, 18 per cent. Fe and 16.5 per cent. Zn was ground with a small amount of an organic frothing agent. Niter cake in an amount equivalent to 100 lb. per ton of ore and about 2 lb. per ton of sulphuric acid were added in the flotation cell. The concentrate assayed 5 per cent. Pb, 45 per cent. Zn, 7 per cent. Fe and 3 per cent. insoluble. The residue was treated on a shaking table and yielded a concentrate assaying 30 per cent. Pb, 6 per cent. Zn, 25 per cent. Fe and 1 per cent. insoluble and a tailing containing 3 per cent. Pb and 3 per cent. Zn.

The quantity of niter cake used would indicate that the surface of the lead sulphide was permanently deadened by a lead sulphate film.

Hebbard (1,261,810/1918) states that the addition to an alkaline or neutral, but not acid, pulp of 1 to 2 lb. per ton of powdered charcoal, graphite or like carbonaceous material will cause certain sulphides such as galena to float in preference to certain others such as blende. Flotation of blende can then be effected by ordinary methods in an acid pulp. EXAMPLE. Feed containing 8.2 oz. Ag per ton, 4.2 per cent. Pb and 17.3 per cent. Zn was floated in reclaimed water (containing a minute amount of organic flotation agent) with 1.7 lb. per ton of powdered coke. The first froth assayed 53.2 oz. Ag per ton, 58.6 per cent. Pb and 13.8 per cent. Zn. Tailing and recovery are not stated.

Bradford (1,274,505/1918). In general terms this patent describes pretreatment of a pulp with a reducing gas more or less soluble in the water of the pulp to prevent blende from floating with galena and pyrite. Bradford names sulphur dioxide and hydrogen sulphide as examples of such gases. Practically sulphur dioxide only has been useful. This gas may be externally generated and introduced into the pulp, or generated in the pulp by the action of acid on sulphites, bisulphites or thiosulphates. Blende may be subsequently floated by de-gassing the solution or decanting and adding sulphuric acid and heating. The amount of reducing agent varies, but 8 oz. to 8 lb. per ton of ore is suggested.

Performance. In the United States the Bradford process was given a thorough trial at MIDVALE, UTAH (*121 P 455*) treating 500 tons per 24 hr. of dump and current tailing from the U. S. S. R. AND M. Co. plant. Combined current and dump tailing was thickened to 25 per cent. solids, a rough collective float made in Janney mechanical-air machines, tailing was sent to waste and the concentrate cleaned and re-cleaned in pneumatic cells. Clean concentrate was thickened to 20 per cent. solids then sent through four gasifying tanks in series; SO_2 was pumped into the first two, the other two gave sufficient storage to allow three-hours' contact with the gas before flotation. The gasified pulp was floated with additional oil as necessary in Fagergren bubble-column machines, yielding lead float and a leady zinc tailing. The latter was de-gassed with heat and sulphuric acid, then treated in Fagergren cells for zinc. Results are shown in Table 26.

Riddell (*19 CME 823*) summarizes operating conditions at BROKEN HILL plants as follows: Organic agents were not used at JUNCTION NORTH; SO_2 only in an amount equivalent

to 1.5 lb. sulphur per ton of slimes was added. Pulp density in lead flotation should not exceed 27 per cent. solids or the grade of the lead concentrate falls off. Temperature in lead flotation must be kept below 90° F. or zinc floats also. Acidity must be kept below 0.03 per cent. free acid or zinc floats; on the other hand lead does not float well in a neutral pulp. The supply of SO_2 must be regular. Typical lead concentrate assays 63 per cent. Pb; typical zinc concentrate, 50 per cent. Zn. Shellshear (*115 P 614*) warns that excess of SO_2 will temporarily render all sulphides unfloatable, zinc, iron and lead being prevented in the order named. The action of the sulphur dioxide is unaffected by the nature and amount of salts in solution, within reasonable limits, *i.e.*, any likely to be met with when there is no plant addition. At Broken Hill Proprietary (*117 P 407*) 20 to 25 tons per hr. were treated in machines with special centrifugal pumps for agitators, discharging the aerated pulp into cylindro-conical froth-separating boxes. Pulp contained 23 to 26 per cent. solids, acidity was between 0.025 and 0.03 per cent., temperature 85 to 90° F.; 1.5 to 2 lb. sodium hyposulphite per ton of solid was added to the pulp before agitation and air and sulphur dioxide were admitted at the pumps. Lead was floated in 9 cells in series. Tailing was diluted to 20 per cent. solids, temperature raised to 125° F., acidity raised to 0.3 per cent. and zinc floated. Results are given in Table 27. See also flow-sheet of Central mine.

Williams (1,300,516/1919) describes the addition of bleaching powder ± a persulphate, *e.g.*, ammonium persulphate, to retard flotation of blende. Examples. (1) Lead-zinc ore, 25 lb. per ton each of bleaching powder and ammonium persulphate with no organic frothing agent. (2) Bleaching powder, 17.5 lb. per ton; eucalyptus oil, 0.25 lb. per ton. (3) Bleaching powder, 7 lb. per ton; iron-ammonium alum, 10 lb. per ton; no organic frothing agent. (4) Bleaching powder, 17.5 lb. per ton; iron-ammonium alum, 3.5 lb. per ton; eucalyptus oil, 0.25 lb. per ton. The feed carried 10 to 20 per cent. Pb, 16 to 24 per cent. Zn and about 7 oz. Ag per ton; concentrates assayed 50 to 60 per cent. Pb, 12 to 15 per cent. Zn and 35 to 50 oz. Ag. The best recovery was 85 per cent. of the lead.

Freeman (1,301,551/1919) develops a theory to explain conflicting results obtained in differential flotation of galena from blende in alkaline carbonate solutions. He states that when copper, silver, mercury or their salts or any metal or the salt of any metal electronegative to copper is present in or in contact with an alkaline or acid pulp containing blende, the blende becomes "metallized," (*i.e.*, coated with the metal) and then floats as readily as galena, thereby preventing differential flotation. Hence to effect differential separation, exclude such metals and their salts. He further states that both oil and acid aid blende flotation, the latter particularly if flotation is performed in a copper vessel. He recom-

mends treatment in a 1 to 10 per cent. solution of alkaline carbonate, without frothing agent, in an iron or wooden vessel. Heat aids the separation. The pulp should carry 20 to 25 per cent. solids. The best temperature is about 60° C. Freeman claims that copperizing will cause blende to float away from iron sulphides, if essential oil is used. Results of tests are given in Table 28.

Table 28. Tests recorded in Freeman patent, No. 1,301,551

a All tests by agitation-froth process. *b* 2.5 per cent. sodium carbonate solution. *c* Made by boiling with 4 per cent. sulphuric acid solution. *d* Collective float first washed and aerated with a small quantity of sodium sulphide. *e* Made with acid and eucalyptus oil in a copper machine. Drained, soaked 30 minutes in hydrogen-sulphide water, again drained, agitated in water to expel H_2S. *f* 3 per cent. sodium carbonate solution; 0.1 lb. eucalyptus oil per ton of ore. *g* Preceded by 1-min. contact. *h* Made as in test No. 9, except that a wooden vessel was used. *i* 3 per cent. sodium carbonate solution. *j* Preceded by 2-min. contact. *wi* wrought-iron.

Edser and Sulman (1,337,548/1920) state that differential separation of lead from zinc can be effected by a flotation operation with a soluble soap in the presence of a proper amount of sodium silicate. The quantity of sodium silicate is important, *e.g.*, 5 lb. per ton of ore is sufficient to produce the differential effect while 3 lb. permits a collective float. The silicate is preferably added as a 40 per cent. solution made by adding the commercial substance (140° Twaddell) to water. Sodium palmitate, stearate, oleate or resinate are mentioned as suitable soaps. The amount varies with the ore but 4 to 5 lb. per ton is usually sufficient. Soft water should be used to prevent formation of insoluble soaps. Examples. (1) 500 gm. lead-zinc ore freshly ground to 80-mesh; 1380 cc. soft water; sodium silicate, 16 lb. per ton and sodium oleate, 4 lb. per ton were used to float the lead. Further soft water to make a total of 2200 cc. was added and a second froth taken. (2) A similar ore, in a 20 per cent. pulp made by adding soft water containing 0.25 per cent. commercial sodium silicate with sodium oleate, 5 lb. per ton of ore, was floated in a sub-aeration machine. (3) The same ore and other conditions as in (2) except that the solution contained 0.125 per cent. sodium silicate. Results are given in Table 29. Comparison of tests (2) and (3) shows the effect of reduction in the amount of sodium silicate, the froth in test (3) being a collective concentrate, rather than a differential float.

Faul and Lavers (1,375,087/1921). This patent is substantially the same as 1,257,990, except that the specific metal is copper instead of mercury. Operation in an alkaline pulp is specified and the addition of a bichromate is recommended. Examples. (1) Feed: 250 lb. lead-zinc sulphide ore assaying 31.5 per cent. Zn, 13.5 per cent. Fe and 7.8 per cent. Pb floated at 140° F. with 0.5 lb. per ton of eucalyptus oil in a solution containing 0.1 per cent. potassium bichromate. The flotation machine was made of wood and lined with copper. Pulp contained 20 per cent. solids. Froth concentrate assayed 50 per cent. Zn, 7.2 per cent. Fe and 6.9 per cent. Pb and tailing, 7.3 per cent. Zn, 20.9 per cent. Fe and 8.1 per cent. Pb. (2) A feed assaying 32 per cent. Zn, 15 per cent. Fe, and 8 per cent. Pb was floated at 130° F., with 0.5 lb. of cresol and 20 lb. carbonate of copper per ton of ore in a 0.1-per cent. solution of potassium bichromate. The pulp contained 20 per cent. solids.

Concentrate assayed 53 per cent. Zn, 6 per cent. Fe and 4 per cent. Pb. Other experiments are cited in pulps containing sodium carbonate with or without sodium hydrogen sulphate in a copper-lined machine.

The results cited in these tests are not sufficiently superior to those in 1,102,738 and 1,142,821, presumably without copper, to warrant the claim of the present patent that copper is an essential factor in the differential effect.

Dosenbach (1,377,189/1921) is for the use of deterrent agents in atomizing flotation. (Art. 14.)

Palmer, Seale and Nevett (1,401,435/1921). The essence of this patent, in so far as it deals with differential flotation, is that the presence of elemental sulphur in the pulp, preferably in solution, causes one sulphide, *e.g.*, blende, to become temporarily less susceptible to flotation. The sulphur may be merely mechanically intermixed. The quantity necessary will ordinarily be less than 10 lb. per ton of ore. The quantity of oil and acid should be small and the temperature kept low. Several methods are stated to be available for getting the sulphur into solution, but one recommended is to boil powdered sulphur in a weak aqueous solution of sulphuric acid to which has been added a small amount of coal tar.

The sulphur solution is made with oil, whenever the method is indicated, and probably in all cases. It is quite likely that the differential effect is largely due to the small quantity of oil. Tests at Columbia University indicate that in most cases the same effect is obtained without as with sulphur present.

The process is said to have been used successfully at the Junction North Mine, Broken Hill, and to be cheaper than the Bradford sulphur-dioxide process, as it requires only heating to 120° F. to float blende after galena has been removed (*36 Aa 97*).

Sheridan and Griswold (1,421,585/1922). The essence of this patent is flotation of galena from associated iron and/or zinc sulphides by pre-treatment of the pulp with a cyanide and an alkaline salt. The cyanide may be alkaline, alkaline-earth or metallic and the quantity will usually range from a fraction of a pound to 4 lb. per ton of ore. Sodium carbonate is a suitable alkaline salt, in quantities ranging from 1 to 10 lb. per ton of ore. Sodium bicarbonate may replace the carbonate. Zinc sulphate in quantity ranging from a fraction of a pound to 4 lb. per ton of ore may be a useful addition to keep down blende.

The pulp may be heated to between 120° F. and boiling during pre-treatment; the necessary time is from 2 min. to several hours, and pre-treatment is usually best accomplished in a thick pulp. Flotation of galena is effected at a temperature of about 130° F. by diluting to about 20 per cent. solids, adding a minute amount of frothing agent and agitating or aerating. After lead is floated, add 1 to 5 lb. per ton of an appropriate alkali, *e.g.*, sodium hyroxide, and a frothing agent, when blende will float but iron stay down.

Examples. (1) In 65-mesh material, 50 per cent. solids, 1 hr. pre-treatment at 160° F. with 10 lb. sodium carbonate and 1 lb. sodium cyanide per ton of ore, diluted to 20 per cent. solids, oil added and the lead floated. (2) 65-mesh feed, 50 per cent. solids, 3-min. pre-agitation in a flotation machine with 5 lb. sodium carbonate, 2 lb. zinc sulphate and 1 lb. sodium cyanide per ton of ore; then diluted to 20 per cent. solids, oil added and the lead floated. After taking off the lead concentrate, 2 lb. of sodium hydroxide was added to the residue in the machine and flotation continued, yielding a zinc concentrate and a final tailing. Results are given in Table 30. For mill performances, see pp. 166 and 894.

Table 30. Results of differential-flotation tests on lead-zinc ore with cyanide

2	7.2	14.5	8.9	55.5	12.9	2.8	5.54	53.1	1.4	1.00	0.9	12.1

Table 31 shows the results of a test of Park City ore by this process. The coarsely-ground sample was first de-slimed, the sand was ground in a thick pulp in a pebble mill to the desired fineness, then the slimes together with 1.2 lb. sodium cyanide, 2.4 lb. zinc sulphate, 12 lb. sodium carbonate, and (probably) about 0.4 lb. Barrett No. 4 per ton of ore were floated at 60° F. in a Janney laboratory machine in a pulp containing 20 per cent. solids. After removal of lead concentrate 2 lb. copper sulphate, 0.4 lb. xanthate and 0.1 lb. pine oil were added and zinc was floated. The zinc concentrate was cleaned twice. Two lb. sodium sulphide and about 0.3 lb. Barrett No. 4 per ton were then added and a concentrate containing iron and oxidized lead taken. In another test the ore was first ground to 20-mesh and tabled, the tailing de-slimed, the sand ground in a pebble mill to substantially 100-mesh, and the slimes together with 0.4 lb. sodium cyanide, 0.8 lb. zinc sulphate, 8 lb. sodium carbonate and 0.5 lb. Barrett No. 4 per ton added and ground 10 min. longer, then floated at 60° F. in a 20-per cent.-solid pulp in a Janney laboratory machine to make a lead concentrate which was cleaned. The lead tailing was re-treated with 1 lb. copper sulphate, 0.32 lb. T-T mixture and 0.12 lb. pine oil per ton, making a zinc concentrate which was cleaned. The zinc tailing was re-floated with 1 lb. sodium sulphide and 0.3 lb. Barrett No. 4 per ton of ore to get the oxidized lead.

The tabling test yielded by far the better lead tailing. Zinc tailing is too high in both tests and the reagent cost, estimated at $0.50 per ton is also high.

The patentee's theory is that the cyanide cleans the galena surfaces and deadens the zinc and iron surfaces by forming films of the respective metal cyanides and that the alkaline salts react with the iron cyanide to form hydrated oxides that permanently deaden the iron. The cyanide is most active in neutral solution, hence it may be best to defer addition of the alkaline salt. The caustic soda in the zinc-flotation period removes the zinc cyanide and exposes a cleaned sulphide surface. This treatment is not always necessary. The zinc sulphate may help to form a more complex and less soluble film on the zinc blende or it may remove hydroxylion. But see p. 844.

Sheridan and Griswold (1,427,235/1922). In this patent the same patentees describe treatment of copper-iron ores by the same methods.

Examples. (1) 65-mesh feed, pre-agitation for 2 min. at 160° F. with 5 lb. sodium bicarbonate and 1 lb. potassium cyanide in a pulp containing 50 per cent. solids. Dilute, add

oil and float. (2) As above except that the temperature was 150° F. and 2 lb. zinc sulphate was added in addition to the other reagents in the pre-agitation period. After the first froth, a lead concentrate, was taken, 2 lb. sodium hydroxide was added and the pulp agitated for 2 min. then more oil and a rough zinc concentrate was removed, which was later cleaned. (3) Ore was floated without pre-treatment at 113° F. using 3 lb. sodium bicarbonate and 1 lb. cyanide. (With oil.) (4) 80-mesh feed no pre-treatment, flotation at 55° F. with 2 lb. sodium hydroxide, 1 lb. sodium cyanide and oil. Results are given in Table 32.

a After cleaning. Cleaner tailing assayed 3.28 per cent. Cu, 17.6 per cent. Fe, 13.2 per cent. Zn and 6.77 per cent. Pb. *b* In first concentrate: 85.6 per cent. of the lead and 65.4 per cent. of copper; in zinc cleaner concentrate, 67 per cent. of the zinc.

Stevens (1,429,544/1922) prescribes an agent for effecting differential flotation that is a solvent for the sulphide to be retarded but not for the one to be floated, or, if not initially a differential solvent, is saturated with the sulphide to be floated but not with the one to be retarded. Cyanide is mentioned as a typical solvent.

The principle that appears to underlie this patent is that solution of a substance involves wetting of that substance by the solution. It follows that a substance thus wetted will not be wetted (*i.e.*, filmed) by an organic flotation agent, and will not, therefore, be in any way affected by gas introduced into or generated in the pulp and hence cannot be floated. Stevens' instructions for lead-zinc separation direct a procedure that is opposed to mill performances.

Hellstrand (1,469,042/1923) describes the use of a sulphide or polysulphide of an alkali or an alkaline earth in pre-treatment of a thick pulp in order to prevent zinc from floating while sulphides of lead, copper and iron float. Later the zinc can be floated by adding more oil together with an acid or alkali.

Examples. (1) Feed: Lead-zinc-copper-iron ore ground to 65-mesh, 4 lb. commercial sodium sulphide (62 per cent. Na_2S) and 0.1 lb. oil (90 per cent. coal-tar creosote and 10 per cent. pine oil) per ton of ore, mixed with the ore in a thick pulp. Lead concentrate floated in a pulp containing 25 per cent. solids upon the addition of 0.15 lb. of the same oil mixture. Tailing was acidified, heated to 95° F. and re-frothed with additional oil to raise zinc. (2) Similar ore pulp, 7 lb. commercial sodium sulphide and 0.1 lb. coal-tar creosote per ton of ore in pre-treatment. Lead concentrate floated in a pulp containing 20 per cent. solids with addition of 0.1 lb. pine oil per ton. Further addition of 2 lb. sodium carbonate and 2 lb. of a mixture of coal-tar oil, coal-tar creosote and pine oil raised the zinc. Results are given in Table 33.

Table 34 shows the results obtained in a test by this process treating Park City ore (*15 UU 55*). The sample was de-slimed, the sands were then ground in a pebble mill to the desired fineness, after which the slimes together with 10 lb. per ton of sodium sulphide, 0.4 lb. of thiocarbanilid and 0.5 lb. of Barrett No. 4, were added and lead was floated in a Janney laboratory machine in a pulp containing 20 per cent. solids, at 60° F. The concentrate was cleaned once, the tailing was re-floated after adding 0.12 lb. of T-T mixture (thiocarbanilid and orthotoluidin), 0.9 lb. yellow pine oil and 1.5 lb. of copper sulphate per ton of ore. Pulp consistency and temperature were the same as in the first flotation. Concentrate was cleaned twice. Weights and assays of all products are shown in the table. Table 34 shows the results of another test on the same ore in which a lead concentrate was made on tables prior to flotation. The procedure was the same as in the preceding

test except that the reagents used for lead flotation were 12 lb. sodium sulphide, 0.4 lb. thiocarbanilid, 0.16 lb. Barrett No. 4 and 0.16 lb. straw-colored cresylic acid per ton of ore; and in zinc flotation 4 lb. of T-T mixture and 2 lb. of copper sulphate.

Comparison of the tests shows much lower lead tailing by the combination treatment. The zinc tailing is too high in both cases and the consumption of reagents is excessive.

At Timber Butte (see p. 165) (*120 J 687*) 6.4 lb. of commercial sodium sulphide and 0.21 lb. Barrett No. 4 per ton were added in the primary grinding mills and a small amount of frothing agent (cresylic acid, 0.05 lb.) at the lead cells. Concentrate was about 8.5 per cent. of the feed and assayed 53 oz. Ag, 43.5 per cent. Pb, 12.0 per cent. Zn, 13.7 per cent. Fe and 5.0 per cent. insol.; 1.8 lb. sodium carbonate, 0.85 lb. copper sulphate, 1.2 lb. Barrett No. 634 and 0.15 lb. steam-distilled pine oil per ton were added to the lead tailing and this was floated in an M. S. machine and the concentrate cleaned three times in Callow cells. Concentrate represented 17 per cent. of the original flotation feed and assayed 13.0 oz. Ag., 56.1 per cent. Zn, 6.9 per cent. Pb, 2.4 per cent. Fe; 3.5 per cent. insol. Tailing assayed 1.7 oz. Ag.; 0.7 per cent. Pb, 1.1 per cent. Zn and 2.7 per cent. Fe. On an easier ore at the same mine (Elm Orlu), adding 5.7 lb. sodium sulphide and 0.25 lb. Barrett No. 4 at the grinding mill and 0.08 lb. pine oil at the lead machine; 40 lb. sulphuric acid, 0.65 lb. Barrett No. 4 and 0.80 lb. pine oil to the zinc-machine feed, with temperatures of 54° F. in the lead cells and 100° F. in the zinc cells, the results were as shown in Table 35.

Bragg (1,478,697/1923) describes the flotation of galena from blende in a slightly alkaline solution by the use of a small amount of a soluble sulphite, *e.g.*, sodium sulphite. He recommends lime for producing alkalinity but mentions also sodium sulphide, sodium carbonate, soda ash, and caustic soda. As flotation agents he mentions thiocarbanilid with slightly acidulated aldol. After flotation of galena the pulp should be dewatered or otherwise treated to decrease the sulphite concentration. To float zinc, add further alkali, *e.g.*, sodium carbonate and copper sulphate together with more thiocarbanilid and, say xylidin. The quantities recommended in the lead-flotation operation are 1 lb. sulphite, 1 lb. lime and about 0.5 lb. thiocarbanilid per ton of ore. These should be added in the grinding mill. In zinc flotation use about 5 lb. sodium carbonate, 1 lb. copper sulphate, and 0.4 lb. of a mixture of 85 parts xylidin and 15 parts thiocarbanilid, per ton of ore.

Pallanch (1,486,297/1924) describes the use of an alkaline sulphite, *e.g.*, sodium or calcium, and recommends sulphuric acid to destroy the sulphite. He also recommends simultaneous addition of sulphur dioxide gas and a hydrate or carbonate of an alkali or alkaline metal in order to form the desired sulphite *in situ*. The quantities indicated are 2 lb. calcium sulphite per ton for lead flotation and 5 lb. per ton of sulphuric acid to destroy the sulphite. The claims are specific to calcium sulphite.

Tucker and Edser (1,497,310/1924) describe the use of a "product obtained by adding to a solution of a soap, such as sodium oleate, a solution of an alkaline sulphide or sulphydrate; or by treating the solution of an alkaline sulphide with a fatty acid; or by mixing or combining materials or ingredients necessary to produce soluble soaps and alkaline sulphides, as for example by treating an alkaline hydrate or carbonate with sulphur and adding a fatty acid; or by treating a solution of an alkaline sulphide containing sulphur in excess of the normal sulphide with a fatty acid; or by adding a soluble soap to an aqueous solution of sulphuretted hydrogen." They cite a concentrate containing 60 per cent. Pb and 12 per cent. Zn made by use of such a reagent from a feed containing 17.6 per cent. lead and 34 per cent. Zn. They claim also that the reagent is useful to float oxides and give an example of 88 per cent. recovery of wolframite in a concentrate assaying 16.8 per cent. WO_3 from a feed containing 4.1 per cent. WO_3.

Price (1,499,872/1924) describes a process for differential flotation of different varieties of bituminous coal by the use of organic colloids, *e.g.*, starch granulose, tannic acid, gelatines (glue), albumens, caramel, dextrine, etc. The effect is to retard flotation of all of the varieties of coal, but if the amount added is limited, the result is claimed to be to keep down the high-ash non-coking fusain variety, while the balance floats. Many varieties of starch may be used, *e.g.*, rice, wheat, potato, maize. "Soluble starch," tapioca and maize flour are also applicable. Several varieties of glue are named; both egg and blood albumen; casein in alkaline solution, animal glutin, and agar-agar. In the examples given cresol and kerosene were used as flotation agents.

McArthur (1,552,936/1925) describes the use of a cyanide alone or with a hydroxide to effect differential separation of lead, silver and copper from zinc and iron in a collective-flotation concentrate. The operation consists in thickening the collective concentrate, treating for some time, say 30 min., with the cyanide and hydroxide, then floating.

Examples. A concentrate assaying 14.8 oz. Ag, 4.6 per cent. Pb, 56.8 per cent. Zn, and 2.3 per cent. Fe was thickened to 35 per cent. solids, agitated for 30 min. with 5 lb. per ton of sodium cyanide, then floated in a Callow cell. Overflow assayed 40.0 oz. Ag, 44.1 per cent. Pb, 26.4 per cent. Zn and 3.6 per cent. Fe; residue, 12 oz. Ag, 1 per cent. Pb, 60 per cent. Zn and 2.1 per cent. Fe. Similar treatment of a similar product, using 7.5 lb. per ton of sodium hydroxide and 2.2 lb. of sodium cyanide gave a float assaying 45 oz. Ag, 60 per cent. Pb, 14 per cent. Zn and 2.4 per cent. Fe and a residue containing 12 oz. Ag, 0.5 per cent. Pb, 60 per cent. Zn and 3 per cent. Fe.

McArthur (1,552,937/1925) describes a similar process in which a halogen is used with the cyanide. This method he applies both to collective concentrate and to primary ore. He states that the iron may be floated with the lead or left in the final tailing as desired by varying the relative proportions of halogen and cyanide.

Examples. 1500 gm. of −10-mesh ore with 750 cc. of water, 0.8 lb. per ton of bromine and 0.4 lb. of sodium cyanide were ground in a ball mill until the sulphides were free and of flotation size, then floated with Barrett No. 4 making a silver-lead float. One lb. of copper

sulphate, 4 lb. sodium carbonate and 0.2 lb. Barrett No. 634 per ton were then added and a zinc float made. Assays are given in Table 36, line 1. The halogen-cyanide ratio was large

Table 36. Performances of McArthur process

and iron came up with the lead. In a similar test using 0.4 lb. per ton of bromine, 1.0 lb. of sodium cyanide and 0.3 lb. of Barrett No. 4 for the first float and 1 lb. of copper sulphate, 3 lb. sodium carbonate and 0.3 lb. Barrett No. 634 for the second, the iron was kept down. See line 2. A collective concentrate was thickened to 35 per cent. solids and treated 30 min. with 1 lb. bromine and 2 lb. sodium cyanide per ton of solids, then floated in a Callow cell. Assays are given in line 3. A relatively large amount of bromine was used and iron came up with the lead. In a similar test using 0.3 lb. bromine and 2.5 lb. of sodium cyanide flotation of iron was inhibited. See line 4.

22. Control processes

Nutter and Lavers (1,067,485/1913). This patent is an early attempt to explain and generalize the then-known physical principles underlying differential flotation. It states that the process depends on difference in the inherent floatability of minerals and that by careful control and regulation of the factors in a flotation operation that go to produce flotation, the net effect can be so adjusted as to raise the most floatable mineral while the others remain submerged. The patentees name the following flotation factors over which control is to be exercised: amount and character of agitation and aeration, chemical constitution of the solution employed, the percentage of solids in the pulp, the pulp temperature and the amount and nature of the organic flotation agent.

They also noted that in a collective froth, particularly one made with a minute amount of organic reagent, the particles of one of the sulphides are generally much smaller than those of the other and they point out that such material is readily susceptible to gravity treatment. As an example of control they state that if a copper-zinc sulphide ore is floated in a cold neutral pulp with a minute amount of cresol or eucalyptus oil, the froth is relatively rich in copper, but contains some fine zinc and some yet finer gangue. By heating the remaining pulp, adding acid and floating, a froth relatively high in zinc is raised. The zinc sulphide is coarser than that in the first concentrate, but the copper sulphide is still coarser. By adding oleic acid the coarsest of the zinc and copper sulphide particles may be raised.

Higgins (1,236,933/1917) makes a specific application of this idea by suggesting preparation of flotation feed by hydraulic classification. He reasons that by treating together grains of

minerals of different floatability that are equal-settling in water, the gravitational pull that resists flotation will be the same on all grains and differences in floatability will have full play. He states that the arrangement pyrite, galena, blende, gangue is one of decreasing floatability. In his experiments he used generally from 0.06 to 0.12 lb. eucalyptus oil per ton of ore and floated in a 0.1 to 0.3 per cent. solution of sodium carbonate. He cites a test on classified feed in 0.088 per cent. sodium carbonate solution. After adding 0.19 lb. eucalyptus oil, he frothed in a sub-aeration machine and collected separately the froths overflowing in the intervals 0 to 3 min., 4 to 8 min. and 9 to 12 min. inclusive, respectively. He then added 0.19 lb. more of eucalyptus oil and collected froth for six minutes. The assays of the products are shown in Table 37. Higgins (1,236,934/1917) develops another variant

Table 37. Differential flotation of classified feed

of the same idea in prescribing close sizing of the feed in preparation for differential flotation with the idea that the resulting difference in settling rate of the particles in water should affect the net effective floatability, enhancing the inherent differences in some cases, reversing them in others. Sizing should be as close as possible; between 80- and 100-mesh, 100- and 120-, and 120- and 150-mesh are recommended.

Examples. (1) A lead-zinc ore sized between 120- and 150-mesh was floated in a solution containing 0.11 per cent. dry sodium carbonate. Froths were collected for four separate intervals following oil additions as shown in Table 38. Assay results are given in the

Table 38. Differential flotation of sized feed

same table. A sub-aeration machine is recommended for the bubble-column action as distinguished from the permanent and stable bubble attachment in the agitation-froth machine.

These experiments are interesting but impracticable, on account of the impossibility of accurate commercial sizing and classification at these fine sizes.

Hebbard and Harvey (1,260,668/1918) describe another variant on the theme of Nutter and Lavers. They point out that flotation with a limited amount of an emulsifying agent (meaning an organic frothing agent) and a limited amount of acid will float galena in the presence of blende and that the addition of more of the frothing agent and further agitation and aeration will raise the blende. They state that if water reclaimed from a previous flotation operation (containing, therefore, dissolved frothing agents) is used, no organic agent need be added in the first frothing. Using such reclaimed water and 22 lb. of acid per ton of solid they obtained on the first of a string of 12 flotation cells a concentrate assaying 66

per cent. Pb and 9.8 per cent. Zn from a feed containing 19 per cent. Pb and 21 per cent. Zn. The combined concentrate from the 12 boxes assayed 50.5 per cent. Pb and 21.2 per cent. Zn.

Schwarz (1,317,945/1919) states that a phenol plus a small amount of a resin soap used in neutral or alkaline pulp will float galena and molybdenite away from blende. He says that the separation is better in a pneumatic cell; the zinc also tends to float in an agitation machine. Resin soap may be made by boiling together two parts of resin, one of caustic soda and 97 parts water, until the resin goes into solution. After the lead and molybdenum have floated, the zinc may be raised by adding further soap and acid. Quantities mentioned are 2 lb. carbolic acid and 0.5 lb. per ton of the soap for the lead float and 10 lb. additional soap and 5 to 10 lb. per ton of acid for the zinc. Pulp consistency should be 16 to 25 per cent. solids.

Borcherdt (1,445,989/1923) sets up the theory that colloidal matter in the ore itself inhibits flotation and that the inhibitory action has a differential incidence on different minerals. He directs step-removal of the colloidal material to permit successive removal of different sulphides. In treating a lead-iron-zinc ore the direction is to add first about 0.5 lb. per ton of rosin soap and float, which will remove some of the inhibitory colloidal material; then add, *e.g.*, wood-creosote oil and float galena; float off further colloid after addition of 0.25 lb. per ton more of rosin soap; next add a small amount of pine oil and crude petroleum in emulsion and float blende; add another 0.25 lb. of rosin soap and float off more colloid and finally some more of pine oil-petroleum emulsion and about 0.5 lb. per ton of sulphuric acid in order to raise pyrite.

This is very close to Schwarz (1,317,945) differing, apparently, only in that the so-called colloid froth is collected separately.

Borcherdt 1,446,376/1923) enlarges on the theoretical matter of the previous patent and describes a variation in operation involving first complete removal of the ore colloid and later partial return of the same or addition of other colloids in order to utilize, under control, the inhibitory effect. He states that the ore colloids are derived from clay, shale and chert. Other colloids that may be used are: sodium silicate, acacia, and colloidal precipitates of barium or calcium sulphate, ferric oxide or hydrate, and magnesium hydrate. The guiding principle to be followed in the choice of a colloidal inhibitory agent is that colloids adsorb on surfaces of opposite polarity and hence a colloid of opposite sign to that of the mineral to be inhibited should be chosen. For dispersing the ore colloids prior to removal, sodium silicate, alkaline or acid agents, salts, foundry molasses, tri-sodium phosphate and gum arabic are mentioned. If colloid is to be removed by flotation, soaps (especially rosin soaps), oils having a high pitch content and ordinary flotation oils in excess are recommended and preliminary emulsification of those agents is said to be desirable. Emulsified creosote oil may be used for a differential galena float: pine, crude oil and copper sulphate to float zinc after removal of the inhibiting colloid. An illustrative flow-sheet shows "de-colloiding" followed by rough flotation, return of part of the colloid to the froth concentrate and differential flotation. In (1,454,838/1923) the same patentee describes step removal of colloids to effect differential separation, *e.g.*, a small amount of sodium silicate is added, the pulp thickened by decantation of part of the slime, the thick product is diluted and the lead floated with creosote oil; more silicate is added to the tailing, more slime decanted, the thick pulp is diluted with fresh water and zinc floated with petroleum and pine oil and copper sulphate.

23. Miscellaneous processes

The following patents are not to be grouped with any of the foregoing nor do they form in themselves a rational group:

Haultain (1,226,330/1917) and **Sundberg** (1,326,545/1919) depend upon complicated schemes for re-treatment of flotation concentrates in order to utilize the difference in floatability, under given conditions, that is inherent in minerals. Thus, galena being more easily floated than blende under given conditions, the first concentrate of the primary machine will contain a higher proportion of lead to zinc than was present in the original feed. By re-treating this concentrate under similar conditions a further increase in the lead-zinc ratio will be effected. The increase in the lead-zinc ratio is set forth by Sundberg as being of the nature of a geometrical progression, hence a small number of re-treatments is expected to produce large differentiation. Actually the ratio does not increase rapidly and there is a large amount of middling formed that cannot be graded up practically and must be joined with concentrate or tailing, thus ruining results.

Peck (1,420,138 and 1,420,139/1922) describes an impracticable extension of the principle set up in Higgins (1,236,934). He proposes to mount a couple of pneumatic cells in a vertical-spindle centrifugal machine, placing the canvas "bottoms" parallel to the spindle, and by controlling the centrifugal force, increasing the difference in the resistance offered by heavy and light sulphide particles to gas-bubble buoying. He would thus float blende from galena.

Lockwood and Samuel (956,381/1910) claim that preliminary agitation of a ground ore in a solution of a substance such as caustic alkali or sodium or potassium silicate results in cracking apart attached sulphides such as blende and galena, thus freeing them for separation by any means, *e.g.*, table concentration.

Lockwood (1,043,850/1912) claims that the silicate of an alkali metal in a pulp being oiled with the magnetic paint of the Murex process (see Sec. 13, Art. 18) will cause differential oiling of sulphides, or oiling of oxides or carbonates in preference to gangue or oiling of gangue in preference to sulphide. Differences in the amount of silicate and in the oils used for the paint produce the differences in behavior. The patent gives several examples. Any differential oiling that occurs here is a result of differential gangue adsorption.

Emerson (1,126,965/1915) describes treatment of a table concentrate containing blende and other sulphides by immersion in a 10-per cent. acid bath, which is said to result in preferential agglomeration of the blende by gas bubbles. The agglomerates are buoyant enough to rise slightly above the settled mass and are to be skimmed away by a submerged bucket conveyor.

Bacon (1,312,668/1919) describes selective separation of the oxidized minerals of iron, copper, lead and zinc by differential sulphidization. See p. 897.

Thornhill (1,338,264/1920) points out that in ordinary flotation concentration, using certain oils such as coal oil (kerosene), certain minerals, notably molybdenite, flocculate more completely than others, *e.g.*, iron or copper pyrite, and that by screening the flotation concentrate the molybdenite floccules will remain on the screen.

24. Mill performances of differential flotation

Lead-zinc ores

Zinc Corporation, Broken Hill. Feed: Zinc middling assaying 9.2 per cent. Zn, 14.3 per cent. Pb and 2.6 oz. Ag per ton. Treated in a pulp containing 33 per cent. solid in a 10-compartment 24-in. Hebbard (sub-aeration) machine with spindles running at 700 r.p.m. Oil: 0.2 lb. per ton of 1-to-1 mixture of eucalyptus oil and tar. Lead concentrate removed from all boxes. Tailing, with 0.3 lb. of eucalyptus oil and 0.6 lb. copper sulphate per ton of solid, sent to a 14-compartment machine. Rough zinc concentrate assayed 39 per cent. Zn and was cleaned to 42–43 per cent. Zn. Rougher tailing, 2 per cent. Zn, 0.5 per cent. Pb and 0.5 oz. Ag per ton. Recoveries: 85 per cent. Pb, 68.2 per cent. Ag, 50 per cent. Zn.

Broken Hill South (*28 MM 9*). Current slime was treated in nine 3.5 × 7-ft. circular under-driven sub-aeration machines with 18-in. disk impellers, in series. Capacity, 9 tons solid per hr.; 200 kw. for the whole plant. Each impeller drew in 2200 cu. ft. of air per hr. The best pulp consistency was 45 per cent. solids. Oil, 0.05 lb. eucalyptus per ton. Lead concentrate assayed 61 per cent. Pb, 47 oz. Ag and 8.4 per cent. Zn; tailing, 2.5 per cent. Pb, 1.5 oz. Ag and 13.9 per cent. Zn; recovery of lead, 80 per cent., silver 84 per cent. Flotation of the tailing for blende has been discontinued and this material is being impounded. Over 99 per cent. of the float galena passed a 0.063-mm. screen. The silver was apparently in an easily floated mineral free from the lead and zinc at this size. The circuit water contained 370 grains of dissolved salts per gallon. Detailed costs are given in Table 39. Central Mine, Broken Hill (*118 P 149*). Dump slime and current leady

tailing from the gravity plant were treated in 10-compartment sub-aeration machines. Galena float was taken off in the first three boxes; acid but no oil was added; the water, however, was reclaimed from zinc-flotation products and therefore contained oil. Blende was floated from the tailing of the lead machines on addition of acid and eucalyptus oil and heating to 130° F. Results are given in Table 40. The lead concentrate was much finer than the zinc as is shown in Table 41. Also the coarser sizes were higher in zinc in both concentrates. Cœur d'Alene, 1918 practice (*105 J 741*). Ziegler states that "starva-

tion" quantities of pine oil or wood creosote were the usual reagents for lead flotation. Also, that a light coal-tar distillate made soluble in strong caustic soda solution floated lead almost entirely free from zinc. A small amount of pine oil dissolved in a large amount of wood alcohol also raised lead, but with it considerable fine blende. Sodium chloride or sodium carbonate aided in galena flotation at times, but the action was erratic. Additions of copper sulphate and pine oil were made to raise zinc. At the tailing plant at WALLACE (*106 J 528*) a feed sizing 10 per cent. on 48-mesh and 60 per cent. through 200-mesh was treated in a pulp containing 13.3 per cent. solids in a K. and K. machine with about 0.5 lb. per ton of pine oil. The bubble column was carried 14 in. deep and the top 3 in. scraped as lead concentrate, which was tabled, yielding a lead streak assaying 70 to 75 per cent. Pb and 3 per cent. Zn; middling 40 per cent. Zn and 10 per cent. Pb and slime, 30 per cent. Pb and 10 per cent. Zn. Tailing of the first machine was treated in a second of the same type with 0.5 lb. each of Pensacola Tar and Turpentine Co. No. 350 (wood creosote) and coal-tar oil. The concentrate was tabled yielding a lead streak assaying 60 per cent. Pb and 3 per cent. Zn and a zinc residue carrying 35 per cent. Zn and 12 per cent. Pb. Parker (*114 J 629*) describes the use of sodium sulphide at BUNKER HILL AND SULLIVAN. It was added at the ball mill in order to get about 15 min. contact with the ore before lead flotation was attempted. Oil was added at the flotation cell. Galena concentrate was cleaned with the addition of more sulphide. The best results in zinc flotation were obtained by grinding lead-section tailing with oil. SLOCAN, B. C. (*114 J 679*). Early practice at the SURPRISE mill was to float lead in neutral pulp with 0.1 lb. cresylic acid per ton in a Hebbard machine, then add 5 lb. of water-gas tar and 0.6 lb. per ton of Cleveland Cliffs hardwood creosote and float zinc in an M. S. machine. The original feed assayed 1.5 to 2.5 per cent. Pb, 10 to 15 per cent. Zn and 25 to 30 oz. Ag per ton; lead concentrate, 40 to 45 per cent. Pb, 25 to 30 per cent. Zn and

200 to 300 oz. Ag, but the recovery was low and the operation delicate. Tailing from the M. S. machine assayed 6 oz. Ag, 5 per cent. Zn and a trace of lead. Re-treatment of tailing in a Hynes machine with 0.3 lb. water-gas tar, 0.02 lb. of Pensacola No. 350 pine oil yielded a concentrate assaying 10 per cent. Zn, which was returned to the M. S. machine, and a tailing containing 2 oz. Ag and 1.7 per cent. Zn was made. Later, at the ROSEBERRY mill in the same district, the same procedure was used for lead, but lead-machine tailing, sizing 60 to 75 per cent. through 150-mesh, was thickened to 30 to 35 per cent. solid and sent through four Hynes machines in series, the first three making concentrate assaying 40 to 45 per cent. Zn and 45 to 95 oz. Ag and the last a middling containing 10 to 12 per cent. Zn. Tailing assayed 0.6 to 3.0 per cent. Zn and 0.5 to 3.7 oz. Ag, depending on the ore. The oils were water-gas tar and Cleveland Cliffs hardwood creosote ranging from 0.75 to 1.65 and 0.21 to 0.55 lb. per ton of each respectively. CONSOLIDATED MINING AND SMELTING CO. OF CANADA (*Bull. 617, Canada Dep't of Mines, Mines Branch, 1923*). Ore from the Sullivan mine of this company was ground to pass 65-mesh in a ball mill. A mixture of coal tar and coal-tar creosote together with 5 lb. per ton of soda ash was fed to the ball mill. A little cresylic acid and 0.1 lb. sodium cyanide per ton were added at the head of the lead cells. Tailing from lead flotation was sent to a mixer and Barrett No. 634, T-T mixture and 1 lb. per ton of copper sulphate were added and the pulp was sent to the zinc cells. Results are shown in Table 42. (For performance at the KIMBERLEY mill of this company see

Table 42. Laboratory test on Sullivan ore of Consolidated Mining and Smelting Co. of Canada

p. 166.) In the zinc mill at Anaconda the feed contains 10 to 11 per cent. Zn, 2.25 per cent. Pb and considerable pyrite. It is floated in agitation-froth and pneumatic machines with 2.5 lb. CaO per ton and about 0.6 lb. of T-T mixture to make a collective concentrate of lead and zinc and drop iron. Concentrate assays 48–49 per cent. Zn, 9 10 per cent. Pb, 4 per cent. FeO and 4 per cent. insol.; tailing 0.7 per cent. Zn. The concentrate is thickened to 65 per cent. solids, agitated in M. S. beater boxes for 15 min. at 50 per cent. solids and 140° F. with about 2 lb. per ton of a mixture of potassium cyanide and zinc sulphate (in theoretical combining proportions), then discharged into Callow cells, with a small amount of additional frothing agent. The overflow is cleaned once in a pneumatic cell; final overflow assays 72 to 75 per cent. Pb, 5 to 7 per cent. Zn and 0.5 per cent. insol., representing 50 to 55 per cent. recovery of lead. Tailing from the rougher and cleaner machines combined assays 53 per cent. Zn, 4 to 5.5 per cent. Pb, 4 per cent. FeO and 4.5 to 5 per cent. insol., making about 92 per cent. recovery of zinc.

At UTAH APEX thiocarbanilid (dry), 0.06 lb. per ton; soda ash, 2 to 4 lb.; xanthate, 0.10 lb.; cyanide, 0.10 lb.; and zinc sulphate, 0.30 lb. are fed to the ball mills; pine oil, 0.05 lb., to a centrifugal pump ahead of the pneumatic flotation cells, and lead is floated. Alkalinity is maintained constant by half-hourly titrations and pulp density by hourly determinations. The tailing of the lead cells is pumped to a contact tank together with soda ash, 1 to 2 lb.; copper sulphate, 1.5 lb.; T and T, 0.10; cyanide, 0.10; zinc sulphate, 0.20; pine oil, 0.40 lb. per ton. From the contact tank the pulp passes to a pneumatic rougher, the early froth to a cleaner, the later froth and the cleaner tailing back to the head of the rougher. Zinc is floated and iron depressed. For flotation results see Table 17.

For performance at SUNNYSIDE MINING AND MILLING CO. see p. 180; at TIMBER BUTTE, see p. 165 and Table 35.

Copper-iron ores

At Rossland, B. C., a pyrrhotite-chalcopyrite-gold concentrate from coarse jigs was ground and floated to drop pyrrhotite. (*115 J 568.*) Mill operation yielded a concentrate assaying 0.91 oz. Au, 4.66 per cent. Cu and 28.5 per cent. Fe as sulphide when treating Wilfley-table tailing carrying 0.074 oz. Ag, 0.30 per cent. Cu and 6.3 per cent. Fe. Tailing assayed 0.043 oz. Au, 0.10 per cent. Cu and 5.2 per cent. Fe. The pulp was ground to 5 per cent. +60-mesh and 86 per cent. −120-mesh; it carried 20 per cent. solids. The Bureau of Mines reports some differential effect on chalcopyrite, pyrrhotite and pyrite with soda ash and sodium hydroxide in the presence of coal tar and creosote. (*Bul. 205 USBM 53.*) On an oxidized feed carrying 0.04 oz. Au and 0.35 per cent. Cu a concentrate carrying 0.34 oz. Au and 8.03 per cent. Cu and tailing, 0.01 oz. Au and 0.13 per cent. Cu were made. At Cia. de Cobre Magistral-Ameca (*116 J 1106*) an ore containing chalcopyrite, bornite, chalcocite and pyrite in a quartz gangue was treated in a K. and K. machine with an oil mixture consisting of a solution of 0.3 lb. heavy Mexican asphalt-base fuel oil in 0.1 lb. per ton of gasoline for the differential effect and 0.1 lb. per ton of steam-distilled pine oil for frothing. Daily recoveries were 93 to 95 per cent. in a concentrate assaying 26 to 28 per cent. Cu. Coghill (*TP 182 USBM*) reports tests on chalcopyrite-pyrrhotite ores of Oregon, using starvation quantities (0.1 lb. per ton) of Flotco No. 1 (Flotation Oil and Chemical Co., N. Y.). The feed assayed 1.3 to 3.2 per cent. Cu, tailing 0.12 to 0.90 per cent. and cleaner concentrate 25 to 30 per cent. The ore contained about $2 per ton in gold in metallic state which was freed by crushing and was not recovered in the froth. The tests indicated that the pulp should not be ground in the presence of "insoluble" oil, nor in a disk pulverizer and that iron in the pulp from grinding machines was probably harmful. An anonymous writer (*116 P 167*) describes flotation of chalcopyrite from pyrite and pyrrhotite using a salt solution of substantially the composition of sea water and no oil and also with sea water alone. With the latter, from a feed assaying 1.75 per cent. Cu, concentrate was made assaying 21.6 per cent. Cu and tailing assaying 0.09 per cent. Cu. Middling contained 0.71 per cent. Cu but was small in bulk and could be expected to disappear in circulation. Tests on other ores indicated that cranky operation was to be expected. At Moctezuma Copper Co. (*118 J 445*) 90 per cent. of the pyritic iron is rejected and a chalcopyrite concentrate made assaying 28 per cent. Cu, 29 per cent. Fe and 8 per cent. insoluble. The sulphide content is practically pure chalcopyrite. The feed is ground to 12 per cent. on 48-mesh, 52 per cent. through 200-mesh and is floated in Callow cells. The tailing assays 0.31 per cent. Cu. Concentrate is cleaned three times. The lower rougher cells are run counter-current. Originally the oil mixture consisted of gas-works coal tar and steam-distilled pine oil and it was found that the best quantity was the minimum possible, viz.: 0.35 lb. per ton. Later T-T mixture (20 per cent. thiocarbanilid and 80 per cent. orthotoluidin) with lime and pine oil were found to give the best results. Lime is added at the ball mills, the other reagents to classifier overflow. Consumption is 0.28 lb. per ton of T-T mixture, 0.14 lb. per ton of pine oil, and 5 to 6 lb. of lime, the latter sufficient to show 0.15 to 0.35 lb. of CaO content per ton of tailing water. Lower alkalinity causes higher tailing loss; higher makes froth hard to clean. See p. 102 for work at Phelps Dodge Morenci branch. At Cananea (*121 J 507*) a high-iron chalcopyrite-pyrite ore with small amounts of chalcocite, bornite, sphalerite and galena in a quartz-feldspar gangue is floated differentially, using lime to depress the iron. Present results compared to those using gravity concentration and collective flotation follows:

Item	Last Half 1923			First Half 1925		
Cost per ton (concentrating	$0.83			$0.90		
Ratio of concentration	2.575			10.18		
Recovery, Cu	87.40			91.17		
Recovery, Ag	88.21			90.18		
Recovery, Au	95.80			88.82		
Assays, per cent.	Cu	Fe	Insol.	Cu	Fe	Insol.
Feed	1.95	16.7	....	1.91	15.7	......
Concentrate	4.38	36.0	15.20	17.69	30.2	7.3
Tailing	0.297	5.2	......	0.17	12.1	......
Power consumed, kw.-hr. per ton	15.8			18.20		
Coal tar, pounds per ton	1.243			....		
Fuel oil, pounds per ton	1.137			....		
Pine oil, pounds per ton	0.608			0.227		
Xanthate (Z-3), pounds per ton	....			0.090		
Lime, pounds per ton	....			11.18		
Moisture in concentrate	11.4 *a*			9.1		

a Average of gravity concentrate at 7.76 per cent. and flotation concentrate at 18.67 per cent.

Results with T-T mixture were the same as with xanthate. An enormous economy in smelting charge per pound of copper results from the change. The mill water comes from the mine and contains large quantities of iron salts; it is added to the tailing thickeners and there neutralized with lime, the gelatinous precipitate thus produced is dragged down rapidly by the settling pulp solids.

CANADA DEP'T OF MINES (*Bul. 617, Mines Branch, 1923*) reported tests on ore which contained 3 per cent. copper as chalcopyrite, 39 per cent. Fe as pyrite and 8 per cent. insoluble and required to be ground to 100-mesh to free the minerals. Ten pounds lime per ton of ore was added to the ball mill and by maintaining the pulp between 25 and 28 per cent. solids a 22-per cent. Cu concentrate representing 95 per cent. recovery was obtained.

Zinc-iron ores

Most present-day practice uses sodium carbonate or bicarbonate with or without cyanide and zinc sulphate or copper sulphate to hold down iron. At MAGMA COPPER Co. blende was floated from pyrite using a mixture of fuel oil, 34° Bé. and G. N. S. No. 17 together with 0.1 lb. copper sulphate per ton of ore (*4 UId 18*). The concentrate was later tabled to separate galena from blende. The cost of the flotation operation alone was $0.34 per ton (1918); filtering concentrate cost 7¢ per ton on the basis of 185 tons feed per day. The total milling cost was $1.10 per ton including $0.22 for sorting, (*114 P 662*). In the Canada Dept. of Mines laboratory (*Bul. 617, Mines Branch, 1923*) it was found that in a pulp made alkaline with soda ash, iron was usually held down. If not, lime was added to the ball mill and the pulp then de-watered and made distinctly alkaline with soda ash. Copper sulphate frequently increased the recovery of zinc.

Copper-zinc-iron ore

CANADA DEP'T OF MINES, (*Bul. 617, Mines Branch, 1923*). Ore contained 7 per cent. chalcopyrite, 7 per cent. blende, 73 per cent. iron sulphides and 13 per cent. non-metallic minerals. It required to be ground to 200-mesh to free the minerals. An excess of lime above that required for high-grade copper concentrate was added in the grinding mill and prevented pyrite and blende from floating. After floating the chalcopyrite, the pulp was dewatered to remove part of the lime and fresh water and soda ash were added. Results are shown in Table 43.

Table 43. Laboratory test of copper-zinc-iron ore

Product	Assay				Distribution, per cent.		
	Cu, per cent.	Zn, per cent.	Fe, per cent.	Au, ounces	Cu	Zn	Au

FLOTATION OF NON-METALLIC MINERALS

As early as 1885 EVERSON had the idea of separating oxidized minerals of copper and lead from the ordinary gangue minerals by the selective action of organic compounds in the presence of water, but her process of separation, even as applied to sulphides, was not practical, and the conception languished. In 1905 SCHWARZ conceived the idea of producing a sulphide film on the surface of the oxidized minerals of the base metals and thereafter floating them as sulphides. This conception, in many variations, appears in a number of subsequent patented proposals, but, with a few notable exceptions, *e.g.*, the flotation of lead carbonate at SHATTUCK-ARIZONA (see p. 188), has not been commercially effected. It has shown promise with carbonates of copper (azurite and malachite), but has failed with the silicate, and the

latter forms so important a part of most oxidized-copper deposits that, unless it responds, the process is a commercial failure. An obvious departure from sulphide filming, particularly for copper ores, was complete solution of the oxidized compounds and subsequent precipitation in floatable form, *e.g.*, as sulphide or metallic copper. A large amount of experimentation on both small and large scales has been done on this method, but with the exception of Chino Copper Co., no particularly close approach to success has been made. The difficulties have been numerous. Precipitated copper sulphide is difficult to float. Copper sulphides present in the ore do not dissolve and the presence of the precipitated sulphide or of some of the reagents or reaction compounds incident to solution or precipitation inhibits their flotation. The same is true, in a measure, when metallic copper is precipitated. Precipitation of metallic copper in floatable form has proved difficult and expensive and regeneration and re-use of solutions has been complicated by fouling. Precipitation by sponge iron, as developed at Chino, has been the most promising method. A large part of the problem of successful operation was the economical production of the sponge. More recently various patentees have reverted to the Everson conception and proposed direct flotation of the oxidized base-metal minerals by the use of certain reagents, principally of a class including soluble soaps, whose action is speculated to be a chemical reaction with the surface layer of the mineral to be floated, resulting in the formation of an organic-film coating that will act similarly to an oiled-sulphide surface.

In the course of investigations along the latter line, experimenters have found that there are differences in floatability of non-metallic minerals. Coal has been found to be easy to float away from slate and other non-carbonaceous impurities, and differential flotation of coking and non-coking varieties of bituminous coal has been described. (See p. 888.) Phosphate minerals have been separated from quartz and other silicates, hornblende from feldspar and quartz; calcined alumina from silicate impurities, and calcite and fluorite are quite readily separated from quartz.

25. Flotation of oxidized base-metal minerals

The proposed methods may be classified into three general groups, *viz.*: (1) sulphide filming; (2) solution and precipitation as sulphide or metal; (3) selective oxide-flotation. None of the methods has had any general success, and it is safe to say that the problem has not, as yet, been solved. Each ore appears to be a separate problem, amenable to a partial solution by any one of the three methods, but only in rare cases responding satisfactorily.

Sulphide-filming processes are described in the following patents.

Schwarz (807,501/1905) describes treating oxide ores with a soluble sulphide, *e.g.*, sodium or potassium sulphides or polysulphides, in solution, in order to convert the oxidized surfaces to sulphide surfaces prior to separation from the rocky gangue by reason of the selective action of oils.

Terry (1,094,760/1914) describes the use of hydrogen sulphide in water for sulphide filming of base-metal oxides and carbonates, after which froth flotation is effected. He notes also that hydrogen sulphide will precipitate sulphides from base-metal solutions and claims that such precipitated sulphides aid flotation of original sulphides and sulphide-filmed particles, but this is not general experience. A base-metal solution, *e.g.*, copper sulphate, may be added to produce sulphide precipitate. The process may be carried on in neutral, acid or alkaline solutions, with or without heat.

Bacon (1,140,866/1915) recommends neutralizing the excess of soluble sulphide over that used for filming and simultaneously making the solution faintly acid. Sulphur dioxide is suggested for neutralization and acidification. In some cases flotation is better in neutral or

slightly alkaline solutions, but it is necessary in such cases to destroy the excess of soluble sulphide or render it innocuous before flotation.

Bacon (1,180,816/1916) states that filming by soluble sulphides is much more efficiently performed with the pulp under pressure. He cites an example in which hydrogen sulphide is used and the pressure in the filming chamber is 20 lb. per sq. in.

Martin (1,236,856/1917) recommends monosulphides, polysulphides or hydrosulphides of sodium, potassium and calcium to effect direct selection of oxidized particles without filming. This last qualification is apparently an effort to escape the incidence of previous patents covering filming by soluble sulphides. Martin cites in defense of his claim that copper carbonate particles thus floated are green and hence, according to him, non-sulphidized, but this fact is, of course, no proof of his contention. He recommends making the polysulphide solutions by boiling for ten minutes the following mixtures: (1) 52 parts sodium hydroxide, 48 parts flowers of sulphur, 6000 parts water; (2) 47 parts lime, 53 parts flowers of sulphur, 6000 parts water; (3) 44.6 parts lime, 50.4 parts flowers of sulphur, 1 part sodium hydroxide, 6000 parts water; (4) fused sodium sulphide of commerce (sodium polysulphide) may be used.

Example. 500 gm. copper sulphide-carbonate ore, 1500 cc. water at normal temperature, 10 cc. of solution (1) above, 1 lb. per ton of a mixture of 90 per cent. gas-tar creosote and 10 per cent. yellow pine oil. Solution (3) was used with reconstructed oils (see p. 847) on slimes carrying 0.9 per cent. Cu of which 0.3 per cent. was oxidized. According to Martin, the concentrate assayed 10 per cent. copper and tailing about 0.1 per cent.

Bacon (1,312,668/1919) describes making soluble sulphides by heating alkaline or alkaline-earth materials, *e.g.*, lime or the hydroxides, carbonates or borates of alkalies or alkaline-earths with metallic sulphides or concentrate, and subsequent separation of metallic oxides from ores and of the metallic oxides produced, by using the soluble sulphide for filming and flotation. He notes also that those native oxidized minerals whose sulphides are insoluble in acids may be separated from those whose sulphides are soluble by sulphidizing and floating in an acid pulp, and that subsequently the second mineral may be sulphidized by rendering the pulp alkaline. Thus copper minerals may be sulphidized in the presence of iron, or lead in the presence of zinc.

Thompson (1,334,721/1920) recommends treatment of a sulphidized pulp by blowing with air prior to flotation. In case hydrogen sulphide has been used as the sulphidizing agent this treatment removes the residual gas, which, in certain instances, appears to interfere with subsequent flotation. Thompson describes a porous-bottom launder as suitable for the blowing treatment.

Callow, Thompson and Terry (1,334,733/1920) recommend simultaneous sulphidizing and oiling of the pulp, preferably during grinding. They also mention that further subsequent sulphidization may, in some cases, be beneficial and that in some cases blowing before flotation, as described by Thompson (1,334,721), is advantageous. In patent 1,334,734, the same patentees describe oiling of the pulp prior to sulphidization as preferable in certain cases.

Palmer, Seale and Nevett (1,401,435/1921) claim that "elemental sulphur" or sulphur in solution, prepared as described on p. 882 will float weathered sulphides and will accelerate the action of sulphidizing agents on oxidized ores.

Ellis (1,425,185; 1,425,186; 1,425,187/1922) claims that the use of salts containing ions of high valence, such as sodium pyrophosphate, titanium chloride, etc., has beneficial effect in flotation of oxides, carbonates or hydroxides either with or without sulphidizing.

Borcherdt (1,446,375/1923) recommends removal of colloidal constituents of the ore prior to sulphidizing and flotation. If the colloids are de-flocculated, removal is effected by simple overflow (decantation); otherwise dispersion must first be effected by adding suitable reagents, *e.g.*, sodium silicate, gum arabic, foundry molasses, sodium tri-phosphate, etc. Acidity should be neutralized before dispersing by means of lime, caustic soda and the like. If an excessive amount of flocculating salts, such as magnesium sulphate, is present, they should be removed by washing prior to de-flocculation.

Smith (1,452,662/1923) describes a process in several steps, as follows: (1) Grind to suitable size, preferably -30-mesh. (2) Separate the ground product into sands and slimes. (3) Sulphidize each portion separately in the same manner preferably in a thick, slightly-alkaline pulp at a temperature of about 50° C., using a soluble sulphide. (4) Thicken as much as possible, then oil the thickened pulp with a "filler oil," *e.g.*, petroleum sludge. The quantity of oil used should be sufficient to fill about 20 per cent. of the voids in the mass of solid material. (5) Add a flotation oil such as crude turpentine. (6) Discharge the oiled pulp into a flotation cell containing four or five times its volume of clean, cold water and agitate slightly in a way equivalent to shaking a few times in a test-tube.

Smith (1,459,167/1923) describes sulphidizing in the presence of a so-called preparation oil in a thick pulp, removing the water, adding a comparatively large quantity of water uncontaminated by preparation oil, and producing a froth concentrate by any of the customary methods. Alternatively dilution alone may replace decantation of the preparation

oil and dilution. The laboratory examples of the patent show about 70 to 80 per cent. recovery of silver and 85 or 90 per cent. recovery of lead.

Eberenz (1,505,323/1924) describes flotation of oxidized minerals (together with sulphides) by the use of hydrogen sulphide in an agitation-froth machine with air excluded or with some "other reducing or non-oxygenous reagent," *e.g.*, an alkaline sulphide, and adding an inert gas such as nitrogen or carbon dioxide for levitation. The pulp is preferably neutral but may be either slightly acid or slightly alkaline. It is stated that a small amount of resin may be added to improve frothing. An agitation-froth machine with sealed agitation chamber is pictured for effecting the operation.

Smith (1,551,588/1925) describes a method for oxidized or mixed sulphide and oxide copper ores, consisting in pre-treatment by slow agitation in a thick pulp with a mixture of gases, principally H_2S, CO_2 and H, and subsequently floating in a more dilute pulp by the usual methods. The patent contains also a description of a method for making the hydrogen sulphide free of various deleterious sulphur compounds.

Nokes (1,444,552/1923) recommends preparing an oxidized ore for flotation by incorporating with it, as by grinding, a reagent made by melting together a normally solid hydrocarbon, such as paraffin, and an alkaline sulphide; thereafter floating with a suitable frothing agent, such as pine oil.

Example. 500 gm. of oxidized silver ore with 500 gm. water was ground to 80 per cent. −80-mesh in a ball mill with a mixture consisting of 2.5 gm. sodium sulphide and 1.75 gm. paraffin, fused as above, and 0.12 gm. yellow pine oil. Excess water was decanted from the ground pulp, and it was floated with 1200 cc. water, 0.25 gm. reconstructed pine oil and 0.75 gm. of a mixture of 50 per cent. benzol, 20 per cent. reconstructed pine oil and 30 per cent. petroleum. From a feed assaying 0.24 oz. Au, 33.36 oz. Ag, and 4.35 per cent. Mn a concentrate was made assaying 3.50 oz. Au, 374 oz. Ag and 4.50 per cent. Mn and the tailing assayed 0.04 oz. Au and 4.96 oz. Ag.

This patent contemplates simultaneous sulphidizing and oiling because of the immediate proximity of the paraffin and sulphide when the latter is freed in the water by grinding.

Solution-and-precipitation methods have been less frequently described in the patent office than either of the other classes, but more large-scale experimental work has been done on them. The method is practically restricted in application to copper and zinc ores. Lead is excluded because of the difficulty of rendering it water soluble. With completely oxidized copper ores and with zinc ores the method comes into competition with highly efficient hydrometallurgical processes and so far has failed utterly in the competition. This practically restricts its application to copper ores containing mixed sulphides and oxides, the former under ordinary circumstances readily amenable to flotation concentration and not readily soluble in commercial-leaching solvents. Most of the large porphyry-copper companies have experimented with the patented methods and with unpatented variants, but with the exception of Chino Copper Co., as previously mentioned, none has approached success. At Chino the process involved solution in dilute sulphuric acid, precipitation of metallic copper in the pulp by means of sponge iron, and flotation of the sulphide and metallic copper at one operation.

Sulman and Picard (1,333,688/1920) describe what they claim to be an improved method for precipitating copper as sulphide for flotation purposes. This consists in mixing with the ore pulp containing dissolved copper a powdered mixture of calcium and ferrous sulphides. This mixture is made by heating together pyrite or copper pyrite and an equivalent of lime at a low red heat and cooling out of contact with air or, in another method, by heating together with the above ingredients an amount of carbon equivalent to the oxygen present. In precipitation the solution should be slightly to strongly acid, according to the copper content. If the solution contains more than 0.2 to 0.4 per cent. copper, acid in an amount equivalent to 3 to 5 per cent. is necessary, if rapid precipitation is desired.

The patentees also state, like Terry (1,094,760), that flotation of the sulphides present in the original ore is enhanced by the presence of the precipitated sulphide.

Terry (1,541,292/1925) describes a method especially adapted to copper ore, consisting in dissolving the oxidized copper compound in sulphuric acid solution, precipitating with lime, calcium carbonate, an alkali-metal carbonate or sponge iron, then treating the pulp with acetylene to form a copper acetylide and floating this by the usual methods. It is desirable that these reactions be confined to the surface of the mineral. He states that the same method is applicable also to silver and mercury minerals. **Terry** (1,541,293/1925),

describes the use of an ammoniacal solution containing a small amount of copper, followed by acetylene to produce the copper-acetylide coating. This patent is applicable also to sulphide ores.

Cremer (1.550,512/1925) recommends solution and precipitation of the oxidized mineral as sulphide, using the precipitated colloidal or semi-colloidal metallic sulphide as an agent to float primary sulphide of the same metal also present in an ore pulp.

Nevill (1,551,605/1925) describes a process for floating cement copper in a pulp containing ferrous sulphate by using a neutral or reducing gas such as coal gas instead of air as the levitating agent, thus preventing oxidation of the cement-copper surface or formation of ferric sulphate and solution of copper thereby.

Selective-oxide flotation. The methods proposed comprise two varieties, *viz.:* (1) Methods in which chemical reaction probably occurs between the surface of the oxidized metal-bearing mineral and one of the reagents used to effect flotation, resulting in coating of the mineral particles with the reagent. (2) Methods in which differences in surface are depended upon in precisely the same way as in ordinary sulphide flotation. The first may be called CHEMICAL-COATING METHODS; the second, OXIDE-FLOTATION METHODS.

Chemical-coating methods

It is not impossible that Nokes (1,444,552, p. 899) is in this class.

Whitaker (1,457,680/1923) recommends coating oxide particles with insoluble or slightly soluble soaps, which soap surfaces then act like sulphides in flotation processes. Thus an oxidized copper ore may be treated with a dilute solution of acetic, sulphurous, sulphuric or hydrochloric acid, forming at the surface of the copper particles the corresponding copper salt, which will then react with certain saturated or unsaturated fatty acids or their glycerides, or vegetable or animal oils containing the acids or glycerides. Oleic and stearic acids are named.

Sulman and Edser (1,492,904/1924) describe a non-sulphidizing process for oxidized ores comprising the addition of a soluble soap, *e.g.*, sodium oleate, stearate, palmitate or resinate, in an amount that will leave a small amount of free soap in solution, usually varying between 0.1 and 1 per cent.; also in some instances, in addition, about 1 per cent. or less on the ore of certain oils, *e.g.*, kerosene, gas oil or other hydrocarbon oils; or certain soluble salts of alkaline reaction, such as sodium silicate or sodium phosphate; or silicic acid sol; and, in some cases, caustic alkali. The pulp water should be free of substances such as calcium or similar salts or acids that will decompose the soap. Some ores may require a frothing agent in addition to the soap.

The patentees claim that the method is applicable not only to the usual oxidized ores but also to sulphides, sulphur, carbonaceous materials and for separation of hornblende or hematite from feldspar and quartz.

Clark (1,548,351/1925) describes a method for oxidized lead ores in which the ore is treated with a chromate, preferably of copper or in the presence of a dissolved copper salt, or by some other substance which reacts with the oxidized lead and forms at its surface a coating with oxidizing powers; subsequently adding an organic agent capable of being oxidized by the substance formed at the lead-mineral surface, thereby coating the lead mineral with an organic oxidation product, and thereafter floating by the usual methods. Copper bichromate or sodium bichromate and copper sulphate are recommended for the initial treatment in neutral or slightly acid pulps and aniline oil or an acid salt of aniline, linseed oil, turpentine, pine oil or the like for the organic coating compound. Calcium hypochlorite (bleaching powder), hydrogen peroxide or ferric cyanide together with the above organic substances are recommended for alkaline pulps. With some ores preliminary treatment in alkaline or neutral solutions with copper sulphate or potassium-copper cyanide followed by coating treatment with acetylene or other oxidizable organic substances is recommended.

Oxide flotation

Everson (348,157/1886) (p. 790) states that her process is applicable to "oxides and carbonates of copper and the carbonate of lead," but there is no evidence in the patent that any different treatment was contemplated for these minerals from that designed for minerals of metallic luster.

Lockwood (1,043,851/1912) states that metallic carbonates, oxides and silicates may be oiled and thereafter separated by froth flotation, by agitating the oil and ore together in a thick aqueous pulp containing a small amount of an alkaline carbonate alone or together with a small amount of a silicate of an alkaline metal, *e.g.*, sodium silicate. In the examples given he used in one case 6.2 lb. soda ash per ton of water in a 50 per cent. pulp; in another,

the proportions were 1.25 lb. soda ash and 40 lb. sodium silicate per ton of water in a pulp containing 48 per cent. solids.

Wiser (1,288,350/1918) describes the use of sodium resinate with ordinary frothing agents in order to float mixed sulphides and oxide minerals. Resinate solution may be made by boiling together rosin and a solution containing an excess above the combining proportion of sodium carbonate or sodium hydroxide, *e.g.*, 1 part soda with 6 parts rosin and enough water to make a 5-per cent. solution, is suitable. The amount of sodium resinate recommended is 0.25 to 10 lb. per ton, conveniently added as a solution of 5 to 10 per cent. strength. The resinate may, in some cases be used without other frothing agent. The pulp should generally be strongly alkaline, but may be near neutrality. In some cases sodium sulphide in addition to the resinate improves recovery of both oxides and sulphides, and oils containing sulphur may also be useful.

Luckenback (1,386,716/1921) claims that oxidized minerals may be floated by the use of reagents made by dissolving resinous substances, particularly copal, shellac, or rosin or mixtures thereof in a solvent such as a water solution of caustic soda, borax, or ammonia, or in alcohol. Oleic acid, grease or tallow or other oily substances capable of reacting with the above mixture or some of its constituents in such a way that the "oil constituents [are] neutralized" may be added.

Luckenback (1,417,262/1922) describes the use of "a reagent comprising a liquefied resin or combination of resins" for treatment of carbonates, oxides and silicates of metals, as well as for minerals of metallic luster. He states that the resin "may be liquefied by means of an alkali, or alcohol, and may be combined with the reaction product of an alkaline metal and a fatty acid" (soap). The patented reagent may be used in conjunction with a normally unsaponifiable oil or oily substance, if desired. He recommends lac in alcohol, oleic acid and caustic soda or ammonia. The examples cited do not give much promise of success of the process.

Luckenback (1,417,263/1922) describes a reagent made by mixing the reaction product of a resin and an alkali other than caustic soda (alkaline resinate), a normally unsaponifiable resinous substance, *e.g.*, copal, mastic, congo, caoutchouc and the reaction product of an alkali and a fatty acid, *e.g.*, sodium oleate. Sodium oleate may replace the resinate with certain ores. The example of the patent does not indicate commercial utility.

Christensen (1,467,354/1923) describes a non-sulphidizing process for concentrating oxidized ores and, more generally, for separating non-silicate non-metallic minerals from silicates by froth flotation. Essentially the treatment comprises the agitation-froth process with the following limitations; (1) the ore should be ground and oiling of the pulp carried on out of the presence of metals, *i.e.*, grinding in a pebble mill and oiling in an agitation machine with non-metal walls and a non-metal, or at least, not an iron, impeller. (2) The oil should be one containing a goodly proportion of a fatty or resin acid or a similar compound. Typical oils of this class are fish oils, such as menhaden or salmon oil; liver oils such as cod-liver oil; blubber oils such as whale oil; tallow dissolved in other oils, sperm oil, linseed oil, castor oil, olive oil, cocoanut oil and palm oil; oleic and stearic acids; rosin dissolved in kerosene or coal-tar oil. (3) The quantity of oil should be relatively large, *e.g.*, 10 to 15 per cent. of the weight of the minerals to be concentrated. Experiments are cited to show that the silicate mineral in the concentrate decreases with increase in oil quantity up to 4.5 per cent. by weight on a given lead ore and 6 per cent. on a given manganite ore. (4) The water of the pulp should be free of electrolytes. The patentee states that with a manganite-porphyry ore he made a 60-per cent. Mn concentrate and 94 per cent. recovery from a 30-per cent. feed; with a copper-carbonate sandstone ore, 46-per cent. concentrate and 98 per cent. recovery from 12-per cent. feed, also 38-per cent. concentrate and 94 per cent. recovery from a 2-per cent. feed; and with a lead-silver-gold ore in silicified limestone assaying 0.25 oz. Au, 17.2 oz. Ag and 11.8 per cent. Pb he recovered 95 per cent. of the gold, 91 per cent. of the silver and 96 per cent. of the lead in a concentrate assaying 0.07 oz. Au, 45 oz. Ag and 32.6 per cent. Pb.

Tucker and Edser (1,497,310/1924) describe a selective-oxide process both for differential separation and for floating oxidized ores (see p. 888).

26. Flotation of coal

Flotation of coal from the associated rocky impurities (see Sec. 2, Art. 12) is an operation similar to the flotation of sulphide minerals from the usual gangues and the underlying principles are the same in both operations. Some differences in procedure follow from the differences between run-of-mine coal and metalliferous ores. Thus, on account of the lower specific gravity of coal, it is unnecessary to grind it as fine as metalliferous mineral must be ground; 16- to 30-mesh is ordinarily sufficiently fine provided the coal is freed from

waste at these sizes. Peterson (*Bul. 117 CMI 62*) found that − 10-mesh coal was readily lifted. For the same reason, a less coherent froth may be employed. The oil that goes with the concentrate (coal) has fuel value, hence, if oil is cheap enough, considerable quantities may be used and will aid in the subsequent dewatering. The proportion of valuable mineral to waste in the feed is much greater in coal than in metal separation, the valuable material is less valuable and cleanliness of concentrate not so important, hence the operation need not be so careful, cleaning is generally unnecessary and the volume of material treated in a machine may be pushed up to a point that largely compensates for the low specific gravity. Almost any oil that will froth may be used but coal-tar oils and wood-tar oils are the most usual. The reagent generally adopted in England, where there has been some actual washery use of the process for bituminous coal, is two parts of cresylic acid to one part paraffin (kerosene) or gas oil (gasolene). The froth is preferably voluminous and tender and pulp density should be lower than in ore flotation,

particularly if much clay is present, otherwise, without cleaning, the froth will be of low grade. When pyrite is present, it is best to remove it by gravity concentration prior to flotation for the reason that it floats with the coal.

Bacon (1,329,493/1920) states that bituminous coal, if properly crushed and mixed with a small amount of oil or oil mixture or equivalent froth-forming agent can be separated from slate and other non-carbonaceous impurities by ordinary flotation processes. He recommends grinding to 48-mesh in such a way as to produce sharp-edged rather than rounded grains, *e.g.*, in a ball mill rather than in a crusher of the type of a disk pulverizer. As useful flotation agents, he names coke-oven light oil, pine oil, "cold-weather mixture," and petroleum. The pulp may be either acid or alkaline.

Bates (1,552,197/1925) states that pulverizing with oil in a thick pulp at a temperature well above atmospheric is best for subsequent flotation, especially when the surfaces of the coal have become oxidized, as in coal from dumps, caved workings and the like.

Price (1,499,872/1924) describes differential flotation of different grades of bituminous coal, claiming that colloids such as tannin, starch, albumin and glue depress the already low floating tendency of the non-coking constituent.

Performance. Tables 44 and 45 show the results obtained by flotation on various kinds of coals and washery products. For flow-sheet of an operation in a British washery see p. 70.

Applicability. The DISADVANTAGES of froth-flotation in coal cleaning are numerous. The outstanding one is the difficulty of utilizing the product. Dewatering concentrate is difficult and expensive. The fine coal can be readily coked on a small scale, but the possibility of coking on a large scale in present-day furnaces is not clearly established. Transportation would entail some loss and unloading, especially in freezing weather, would be difficult and expensive. Storage and handling of the dry product would be dangerous. Briquetting is a possible outlet for anthracite, but requires education of domestic consumers. The process tends to increase the sulphur content of the washed coal above that of the feed. Another possible outlet is in the form of Trent amalgam (Sec. 14, Art. 4), and it may easily turn out cheaper

to prepare the latter by concentrating by froth flotation and then forming the amalgam than to concentrate and make the amalgam in the same step.

As the situation stands at present, the process is available, at a cost of between $0.05 and $0.10 per ton of raw fines fed, to treat low-sulphur washery fines and will make a satisfactory low-ash coal. Dewatering may easily more than double the cost per ton of washed coal.

Dewatering coal-flotation concentrate. Tupholme (*24 CA 277*) describes a method in which the froth concentrate in a pulp with water is agitated with 3 to 10 per cent. of oil, tars or other hydrocarbon or carbonaceous liquids, reckoned by weight on the solid coal, as a result of which irregular agglomerates are formed that may be separated from the water by draining, filtration, or pressure. This is, of course, the old Cattermole process (see Sec. 14, Art. 4), applied to coal. It is claimed further that reduction in ash may be made at the same time, the unagglomerated refuse passing off with the water. No commercial application is cited.

27. Flotation of miscellaneous non-metallic mineral substances

Alumina

Hornsey (1,255,749/1918) describes flotation of alumina from associated impurities by means of a small amount (2 lb. per ton) of oleic acid or other oil or frothing agent. According to the patent, the method of procedure is the same as that followed with sulphide ores.

Phosphates

Broadbridge and Edser (1,547,732/1925) describe flotation of phosphates such as phosphorite, apatite and the like away from silicates, calcium carbonate, ferric oxides, aluminates, etc., by means of a frothing agent such as oleic acid or soap and a dispersing agent such as sodium silicate. They also suggest pre-emulsification of the frothing agent by agitation in water in the presence of a small amount of sodium carbonate, sodium resinate or sodium oleate. Example. — 80-mesh dry-ground feed containing 20.5 per cent. P_2O_5 was floated with 2-lb. sodium silicate (60° Bé.) and 2.3 lb. per ton of oleic acid. The froth assayed 35.4 per cent. P_2O_5, and 10.3 per cent. insoluble and represented 94.5 per cent. recovery. Tailing assayed 1.05 per cent. P_2O_5. In a similar test on — 60-mesh material assaying 52 per cent. calcium phosphate, using 1 lb. of oleic acid and 1 lb. of sodium silicate, concentrate assayed 79.3 per cent. calcium phosphate and tailing 1.8 per cent. Recovery was 98.2 per cent.

Cassiterite

Edser describes (*29 IMM 263*) flotation of a mixture of Nigerian cassiterite and quartz gangue, ground to pass 80-mesh, in a 4 : 1 pulp with soft water and a small amount of sodium oleate solution and alkali. He states that several Cornish ores have shown recoveries of 80 to 90 per cent. in a concentrate assaying 20 to 25 per cent. metallic tin.

Sulphur

The fact that sulphur could be floated has been recognized since early in flotation history. Hyde (*Minerals investigation series, USBM, No. 15*) found that under favorable circumstances 80 per cent. recovery in a concentrate assaying upwards of 80 per cent. S could be made. The oils that he found could be used were pine oils, wood and coal-tar creosotes, cresylic acid, coal tar, kerosene. Carbolic creosote or a mixture of equal parts kerosene and Pensacola T. and T. Co. No. 80 pine oil gave the best results. Sherman (*14 UU 82*) reports an extensive series of tests on ores containing native sulphur in a gangue of quarzite and feldspar. The lots tested assayed 15 and 32 per cent. S respectively. The work showed that the feed should be ground to pass a 200-mesh screen in order to free the sulphur and produce high-grade concentrat . A pulp containing 20 per cent. solids was best in a centrifugal bubble-column machine (Fahrenwald) and either acid or alkaline pulp could be used. The best tests gave about 80 per cent. recovery in a concentrate containing about 90 per cent. S. In this test about 1 lb. per ton of Genasco flotation oil was used in an alkaline pulp. The best of the numerous reagents used were the Genasco; T–T and X–Y mixtures, 0.25 lb. per ton; Barrett No. 4, 1 lb.; a gas-works distillate, 2 to 3 lb.; amyl alcohol, 0.25 lb.

Miscellaneous

See Christensen, 1,467,354; Sulman and Edser, 1,492,904.

SECTION 13

MAGNETIC SEPARATION

1. Introduction

Magnetic separation depends upon the fact that minerals differ in permeability and, therefore, in their behavior in magnetic fields. Some minerals, *e.g.*, magnetite and franklinite, are readily attracted to the poles of a magnet in fields of relatively low intensity, while others, such as quartz and the acid silicates, are apparently unaffected by the most powerful fields. Certain other substances, of which metallic bismuth is, perhaps, the best-known example, are actually repelled from the magnet poles in very powerful fields. Experiment shows that all substances are permeable to some extent and that attraction and repulsion depend on the relative permeabilities of the substance and the medium in which it is tested. Physical terminology classes substances that are attracted to the poles in a magnetic field in air as PARAMAGNETIC and those that are repelled as DIAMAGNETIC. For ore-dressing purposes minerals can be better classified as strongly magnetic (the physicist's FERROMAGNETIC), weakly magnetic, and non-magnetic. Such classification is shown in Table 1. Any mineral in the strongly-magnetic class can be separated readily from any in the classes that follow it, and any pure mineral in the weakly-magnetic class from any pure minerals in the non-magnetic class; but the values given in the table are not to be depended upon to determine the possibilities of separation in any given case, without some confirming experiment, for the reason that small amounts of impurity, mechanically or chemically held, may change markedly the position of a given mineral in the list. Thus certain sphalerites containing small percentages of iron are attracted in strong fields and readily separated from pyrite and quartz; iron-bearing garnet is sufficiently magnetic to be separated from quartz and other acid silicates and corundum; magnetic galena occurs at one of the Cœur d'Alene mines, and similar examples of divergence from the tabular order are not infrequent.

Elementary sulphur is diamagnetic while oxygen is paramagnetic and, probably dependent upon these facts, no pure sulphide, except pyrrhotite, is found in the list of magnetic substances while many of these substances are high in oxygen content. On the other hand, research makes it appear probable that permeability is due to molecular structure rather than to chemical compo-

sition. Heat affects permeability, usually decreasing it, but a ferruginous blende is cited that was readily separable (magnetic) when warm but separable with difficulty when cold.

The most important separations in concentration practice are: Tramp iron from crude ores; magnetite in ores from associated gangue minerals such as quartz, feldspars, hornblende, garnet, and apatite; iron from zinc-iron gravity concentrate, *e.g.*, roasted pyrite from unaltered blende, pyrrhotite from blende, ferruginous blende from pyrite, siderite from blende, roasted siderite from blende; iron from copper-iron gravity concentrate, *e.g.*, siderite from chalcopyrite, pyrrhotite from chalcopyrite; franklinite from willemite, zincite and calcite; wolframite from cassiterite; and magnetite and ilmenite from monazite sands. Other examples of separations made by magnetic means are, the magnetic material being in each case named first: hematite from silica; siderite from cryolite; rhodonite and ferruginous garnet from blende; some copper carbonates from silicious gangue; garnets and basic silicates from diamondiferous sands; burnt magnesite from lime and alumina; hornblende from apatite; rutile from apatite; garnet from metamorphic silicates; garnet from corundum; biotite from metamorphic silicates; leucite from lava; chromite from silicates; iron introduced in mining and grinding from ceramics; limonite from silicious and aluminous gangue; roasted hematite and limonite from gangue minerals.

2. Theory

Definitions. A MAGNET is a body possessing certain electrical properties that cause it, when freely suspended, to align itself in the magnetic meridian (roughly north-south in middle latitudes). It has the ability to draw to itself through short distances small pieces of iron and steel and certain other sub-

stances, all of which are known as magnetic substances, although they are generally not magnets themselves. This attractive force exerted by magnets is due to a field of force surrounding them which, both for purposes of illustration and numerical calculation is conceived to be made up of LINES OF FORCE as shown in Fig. 1.

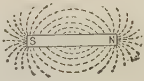

FIG. 1.—Lines of force surrounding a bar magnet.

If such a magnet is placed under a sheet of cardboard or glass and iron filings are dusted above it and agitated by tapping the sheet in order to give them freedom of movement, they will arrange themselves in chains, end-to-end, in a pattern similar to that of the dotted lines. If the same magnet is so suspended as to be free to move horizontally, then, if not near a mass of highly magnetic material or another magnet, it will swing around until it finally comes to rest in an approximately north-south direction, and one particular end of any given magnet will always point north. This is called the north-seeking or north pole, and, from the fact that it was usually marked with a cross, is now called the (+) or POSITIVE POLE; the other is called the (−) or NEGATIVE POLE. Lines of magnetic force are conceived to be directed from north pole to south pole outside the magnet and from south pole to north pole inside the magnet and to close, i.e., to form closed circuits.

Lines of force outside the magnet, in passing through different media, diverge or converge according to the relative permeability of the media. A highly permeable body is one that concentrates or draws together the lines of force in its vicinity and the PERMEABILITY of a body may be thought of as the ratio of the concentration or crowding of the lines in a given area through the body in a given field to the spacing in air at the same position, the body being absent. Thus Fig. 2 represents the effect of a piece of magnetite, with relatively high permeability, in concentrating the lines of force in the magnetic field around a bar magnet.

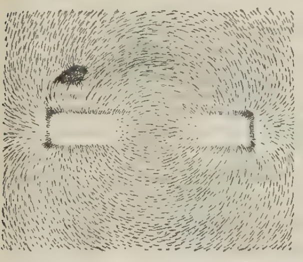

FIG. 2.—Magnetic field containing a large particle of magnetite.

Electromagnetism. When an electric current flows through any conductor, a magnetic field is set up in the medium surrounding the conductor. If the conductor is wound in a helical coil a magnetic circuit is set up in which the lines of force are approximately axial through the coil and curved without in a manner entirely similar to the field of a magnet of the same shape and size as the coil, in fact the coil itself may be regarded as a magnet. If the length of the coil is great in proportion to its diameter, the strength of the magnetic field in the interior of the coil is given by the equation $H = 4\pi AN/10l$, where H is conceived of as the number of lines of magnetic force per square centimeter of the medium, A is the current flowing in the coil, expressed in amperes; N is the number of turns or windings, and l is the length of the coil in centimeters. If the diameter of the coil is relatively great with respect to the length, $H = 2\pi NA/10r$, where r is the radius of the coil in centimeters. The product AN is called the AMPERE TURNS of the magnet coil. If a soft-iron core is inserted in the coil, the number of lines of force within the coil is enormously increased, with corresponding increase in the strength of the magnetic field, and the combination becomes a typical electromagnet. In such a magnet the magnetic field continues as long as current flows through the coil; its strength depends on the strength of the coil field and the permeability of the core; and the field ceases

except, perhaps, for a weak residual permanent field, when the current stops. The driving force in a magnetic circuit, conceived to cause the lines of force to penetrate the different media in the circuit, is called the MAGNETO MOTIVE FORCE, M. It is expressed numerically as

$$M = Hl = 4\pi AN/10 = \text{(approximately) } 1.25AN.$$

This force is conceived to create a magnetic flow or MAGNETIC FLUX in the magnetic circuit, which varies directly as the magneto motive force and inversely as a quality of the circuit, analogous to the resistance of an electrical conductor, known as RELUCTANCE, R. The unit of reluctance is RELUCTIVITY, ρ, and is defined as the reluctance of a magnetic circuit 1 cm. long and 1 sq. cm. in transverse section. The total reluctance of a homogeneous circuit l cm. long and S cm. in transverse section is: $R = \rho l/S$. The relation between reluctivity ρ and PERMEABILITY μ is expressed in the equation $\rho = 1/\mu$. PERMEABILITY is expressed numerically in terms of field strength and flux density as $\mu = B/H$. Hence $\rho = H/B$.

SUSCEPTIBILITY K, which may be considered as the increase in the number of lines per square centimeter at a given point in a given magnetic field, caused by the introduction of a given substance, over the number that would be present at the same point in air alone, is related to permeability by the equation $\mu = 1 + 4\pi K$. It may also be considered as the ratio of the intensity of magnetization, I, to the magnetizing force H, or $K = I/H$. Since the mechanical effect on a particle of given size and shape at a given point in a given magnetic field is proportional to the intensity of magnetization of the particle, it follows that susceptibility is a direct measure of the relative response to be expected from different substances

when presented to a given magnetic field. Table 2 (Wilson, *59 Trans. IEE 319*) represents the latest published figures on susceptibility of minerals and is apparently the result of careful work, but the warning given in connection with Table 1 is to be remembered.

The total MAGNETIC FLUX, Z, in any circuit is given by the equation $Z = BS$ from which $M = B\rho l = Z\rho l/S$, and $AN/l = 0.8Z/\mu S$. This is the equation for determining the number of ampere turns required to produce a given total flux density in an electromagnetic field. But permeability varies with flux density, hence experimentally determined permeability curves showing the relation between flux density and permeability for the substances composing the magnetic circuit are required before the formula can be used. Also, since the magnetic circuit in an electromagnet is non-homogeneous, the reluctance of the different parts of the circuit must be calculated separately and summed to obtain the total reluctance.

EXAMPLE. Given an annealed Swedish-iron ring, 24 in. mean diameter and 3-in. cross-section, cut transversely and leaving an air gap of 0.75 in.; required NA to give a total flux $Z = 400{,}000$ C. G. S. units. The length of the iron circuit = 59.1 cm. $B = 400{,}000/39.82 = 10{,}050$. μ (from Table 3) corresponding to 10,050 (B) for iron is 1330. $R(\text{iron}) = \frac{l}{\mu S} = \frac{59.1}{1330 \times 39.82} = 0.0011$. $R(\text{air}) = \frac{l}{\mu S} = \frac{1.9}{1 \times 39.82} = 0.0478$. $R(\text{total}) = 0.0489$. $AN = 0.8Z\frac{l}{\mu S} = 0.8ZR\ (\text{total}) = 0.8\ (400{,}000)\ 0.0478 = 15{,}300$.

Tractive force. If a bar magnet is cut transversely and the cut ends are then placed in contact, the force F in dynes holding them together can be expressed by the equation $F = B^2S/8\pi$; but this equation is in no way applicable to the attractive force exerted by a magnet on a body separated from the poles by an air gap. The attractive force exerted on a small sphere in a magnetic field is $F = \frac{vK}{1 + \frac{4}{3}\pi K} \cdot \frac{dH_0^2}{dx}$, where K is the susceptibility $\left(= \frac{\mu - 1}{4\pi}\right)$, v = volume of sphere and H_0 is the magnetic force or field strength in the direction of a displacement, X. It follows from the above equation that when H_0 is constant, $F = 0$. Thus the sphere in the magnetic field between the flat-faced poles of the magnet shown in Fig. 3, *a* will not move toward either pole because of the fact that the field strength is the same across every section of the field adjacent to the sphere. On the other hand, in the case shown in Fig. 3, *b*, where one of the poles is wedge-shaped, the field increases in strength from the flat-faced pole to the wedge-shaped pole, which means that H_0 increases, and the sphere will tend to move toward the stronger field. If the sphere were diamagnetic instead of paramagnetic as illustrated, the coefficient $K/(1 + \frac{4}{3}\pi K)$ would be negative, indicating a tendency to move from a stronger to a weaker part of the field.

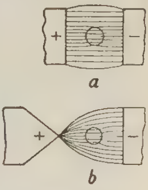

FIG. 3.

Design. It is impossible to proceed with theoretical analysis to the point of design of electromagnets for separation of ores. The last equation tells that the field must be of variable strength, and for this reason wedge-shaped pole pieces are used on the collecting poles, or other devices such as sharp projections on pole pieces or armatures, laminated pole pieces, armatures of alternate disks of magnetic and non-magnetic material, or parallel cylinders are employed as pole pieces for producing converging fields. The air gap between the collecting pole and the particle should be as small as possible, in order to

bring the particle to be collected into the stronger and more rapidly changing part of the field. But for determination of proper field strength and number of ampere turns to effect a given separation, it is necessary to resort to experiment with a magnet of known construction, and from the data thus obtained to draw the specifications for the desired magnet.

It is clear from the equation $AN = 0.8lZ/\mu S$, that for a given total flux density Z and with a given cross-section S, the number of ampere turns per unit of length (AN/l) is inversely proportional to the permeability of the core. Since iron and steel have the greatest permeability of any known substances they are used for magnet cores. The permeability of different kinds of iron and steel with different flux densities are given in Table 3. Mild

Table 3. Permeability and flux density of various materials for electromagnet cores

Flux density (B), C. G. S. units	Permeability (μ)			
	Cast iron	Annealed Swedish iron	Steel casting	Forged ingot iron
2,000	400	....	....	....
4,000	460	....	1620	....
6,000	300	1180	1880	....

14,000	20	900	900	1900
16,000	....	550	450	900
18,000	....	220	180	240

steel is now generally used for magnet cores, except where the highest possible permeability throughout a wide range of flux densities is required, when forged ingot iron is employed. At New Jersey Zinc Co. Swedish cast steel for cores, pole pieces and pole points is specified to contain not more than 0.06 per cent. C, 0.025 per cent. P, 0.025 per cent. S, 0.30 per cent. Mn, 0.30 per cent. Si, and to be thoroughly annealed.

The same equation shows that a given magnetic flux is dependent upon the product of the current flowing and the number of turns of wire around the core per unit of length. Hence by increasing the number of turns the current can be decreased and *vice versa*. On the other hand, as the diameter of the coil increases with respect to the length, the magnetic effect of a given number of ampere turns decreases. Ordinary design makes the length of the coil 5 to 10 times the diameter. The amount of current that can be safely carried through a given wire is limited by the heating; a general rule in well-ventilated core windings is that the current shall not exceed 2.5 amp. per sq. mm. of copper wire. Enclosed magnets must carry less current. Asbestos-covered wire should be used in high-intensity magnets to prevent break-down of insulation and lessen fire risk, and careful waterproofing is also essential. Winding specifications for Wetherill-Rowand high-intensity magnets at New Jersey Zinc Co. call for the wound spool to stand 10,000 volts; temperature not to exceed 70° F. above the surrounding air with 125-volt direct current. One spool answering this specification was wound with No. 13 wire, 37 layers, 233 turns per layer, 55.56 ohms resistance per spool. Protective rope winding, ¼-in. manila, free from moisture before winding.

Effect of size of particle on strength of field required is dependent on the method of presentation. Attractive force is proportional to the product of magnetic masses and inversely proportional to the square of the distance between them. But the magnetic masses in a given field, while proportional to the volumes of the particles, act as though concentrated at the extremities of the particles and with a large particle the distance to the like pole, which is repelled by the magnet pole, is relatively greater with respect to the distance to the unlike pole than is the case with a small particle. Hence the counter-repulsive force due to this pole is relatively less, and the net attractive force relatively greater. Therefore, although gravity, acting against the magnetic

attraction, is likewise proportional to the respective volumes of the particles, and, considering volume alone, the net attractive force per unit of volume is the same for all particles of the same mineral at the same distance from the poles, irrespective of size, nevertheless, where concentration of magnetic mass at the poles is taken into consideration, the greater net force is exerted on the larger particle. Moreover, if the material to be treated is presented resting on a supporting surface below the magnet pole, so that the particles must be lifted to the pole, then the unlike induced pole in the larger particle will be nearer the magnet pole than that of the smaller particle and this, in addition to the fact that the like induced pole will be relatively further away, results in a net effective force on the larger particle considerably greater than on the smaller, or, conversely, the larger particle can be separated in a weaker field. Further, the smaller particle may be so deeply buried in the mass of material as to be less free to move than the larger particle, and for this reason, also, requires a stronger current. When the magnet is under the presenting surface, a somewhat reverse condition holds, and a weaker field will suffice for the smaller particle. It follows, therefore, that if the particles are not pure, but are composed of a mixture of magnetic and non-magnetic minerals, they must be closely sized, if clean products are desired. Also, if a field of high intensity is necessary, the air gap must be small and close sizing is essential in order that the large pieces may not touch the magnet poles when the gap is sufficiently small with respect to the small particles. With highly-magnetic feeds the tendency for the larger magnetic particles to entrain gangue and for the larger middling particles to attract and hold small particles of magnetic mineral also calls for sizing of the feed.

Time required to induce magnetism. Evidence is conflicting as to whether or not there is a distinct time element involved in the induction of maximum magnetization in a given particle in a given magnetic field. Thompson (*Electricity and Magnetism, p. 384*) cites the fact that a large electromagnet at the Royal Institution (London) requires about two seconds to reach maximum strength. *Truscott*, on the other hand, states that with 600,000 alternations per second the limit to the speed of magnetization of a piece of laminated iron was not reached. When, however, the question is one of the speed of passage of minerals through a magnetic field, the result is the same as though time were an essential element.

When a mixture of magnetite, rhodonite and ferruginous blende, ground to pass a 0.75-mm. screen, was presented at different speeds to a given field, it was found that at a speed of 330 ft. per min. magnetite only was removed, at 230 ft. per min. some of the rhodonite but none of the blende came off, at 165 ft. per min. all of the rhodonite and some of the blende were lifted, at 130 ft. per min. more of the blende and at 100 ft. per min. all of the blende was recovered. It is true that the determining factor here may well have been the relation between final magnetic attraction and momentum of the particles and that the effective result of lowering belt speed was to lessen momentum rather than to allow time for greater magnetization. In so far as separator design and operation are concerned, however, the conclusion is clear that the allowable speed of passage of particles through the magnetic field is closely related to the permeability of the magnetic constituents; the lower the permeability the lower the allowable speed.

Forces employed to oppose magnetic attraction in separators are gravity, centrifugal force, friction, momentum of the particle, and the blow of a blast of air or water. When centrifugal force, momentum, or the force of fluid currents are the opposing forces, the magnitude and direction of the resultant force can be varied by varying either the magnetic force or the opposing force. When gravity or friction is the opposing force, control lies with the magnetic force alone.

Current. The energizing current is normally direct-current at 110 to 250 volts. Alternating-current has been used experimentally for energizing magnets for mineral separation, but the practice has not passed the experimental stage.

3. Types of magnetic separators

Separators are built to treat coarse or fine material, wet or dry, and the design differs somewhat according to the service. The design also differs according to whether the magnetic material is strongly or weakly magnetic, a field of high intensity being required for weakly-magnetic materials while one of low intensity will serve for strongly magnetic. In both types the working magnet may be either directly energized by a coil or may be energized by induction. Further classification may be made on the basis of the method of presentation of the material to the magnet as on a belt, pulley, drum, shaking tray, or by a free fall through air, etc.

The fundamental elements of every successful magnetic separator are (*a*) a magnetic field of sufficient intensity to cause a marked difference in the magnetic forces acting on the magnetic and non-magnetic particles in the mass to be separated; (*b*) a means for bringing the material to be separated to the magnetic field in such a way that the particles have sufficient freedom of movement under the influence of the magnetic forces to permit the magnetic particles to move away from the non-magnetic or *vice versa;* (*c*) a force or forces such as gravity, centrifugal force, or the friction of a solid or fluid acting against the magnetic force and serving to intensify the difference in direction of movement of the magnetic and non-magnetic particles; (*d*) a means for removing both magnetic and non-magnetic particles from the magnetic field after separation.

The underlying ideas of magnetic separation are old and are disclosed in a large number of patents, now expired. Existing patents are all for apparatus, covering various mechanical and electrical details, but not applying to basic principles.

Low-intensity machines are used principally for separating magnetite from non-magnetic gangues; magnetic oxides of iron, formed by roasting sulphides, from associated unaltered and non-magnetic sulphides; and for removing metallic iron from various non-metallic admixtures, as for instance, tramp iron from crude non-magnetic ores, flake iron from ground ceramics and the like, nails from brass-foundry refuse, etc. As a general rule it may be stated that the permeability must be greater than 20 when iron is taken as 100 in order to make a substance separable on a low-intensity machine. Typical machines of this class are described below.

Edison machine is the simplest in principle of the continuous machines. A stream of crushed highly-magnetic ore is allowed to fall freely in air past the pole piece of a primary electromagnet. As a result the magnetic material is deflected toward the magnet and falls into a suitable receptacle, while non-magnetic material falls vertically into an adjacent box. Although simple in principle, and not subject to the disadvantage of entrainment of gangue by concentrate, this machine has the disadvantage that the speed of presentation is high and the air gap is necessarily great, greatly different for different particles and hard to control. As a result the machine has had but little use in the mills.

4. Pulley separator

This type (Fig. 4) consists essentially of a belt conveyor with a magnetic head pulley, a device to distribute feed in a thin layer on the carrying portion of the belt, and a divided receiving chute to take the two discharge products.

The magnetic head pulley consists of an iron or steel pulley with a battery of electromagnets inside, mounted on the pulley shaft and revolving, therefore, with the pulley, current being supplied through slip rings on the pulley shaft. As ore passes over the head pulley, non-magnetic material is thrown free as in the ordinary belt-conveyor discharge, while magnetic material clings until separated by the divergence of the return belt from the under side of the magnetic pulley.

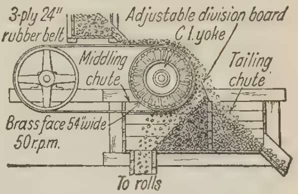

FIG. 4.—Pulley separator.

Size of HEAD PULLEY ranges from 12 × 12 in. to 48 × 60 in. SPEED is from 100 to 400 ft. per min. CAPACITY on feed passing 1.5- or 2-in. ring is from 15 to 25 tons per hour per ft. of pulley width. A machine with 24-in. belt at MT. HOPE (*99 J 562*) takes 12.5 amp. at 250 v.; at MOOSE MOUNTAIN (*99 J 974*) 21 amp. at 120 v.; at WITHERBEE, SHERMAN AND CO., (*48 A 254*) 25 amp. at 125 v. and at RICHARD mine (*115 J 973*) 31 amp. at 125 v. The magnets are usually so wound that the alternate poles are of opposite polarity, thus producing concentrated magnetic fields at and near the belt surface.

This type of machine, with the strong current usually employed, will hold everything that contains an appreciable amount of magnetic material and reject clean tailing. The concentrate, therefore, is usually a middling that must be further treated. In mills treating magnetite ores, pulley machines treat the reject from drum machines (Art. 5) and make tailing carrying from 8 to 12 per cent. Fe (a large part of this being non-magnetic iron). They thus materially reduce the load on the re-grinding machines.

Performance. At WITHERBEE, SHERMAN CO. (*90 J 959*) 20-in. pulley machines treat crude ore sized between 2- and 0.75-in. at the rate of 300 tons per machine per day and also treat the sized middling from drum machines. Each pulley carries 25 magnets and draws about 25 amp. at 125 volts. Feed is practically dry. Pulley speed, 40 to 50 r.p.m., giving a belt speed of 250 to 320 ft. per min. Feed assays 35 per cent. Fe and tailing 6 to 8 per cent. Rough concentrate is sent to drum machines. Pulley machines are also used to rough out tailing on the sizes ¾- to ⅜-in. and ⅜- to ¼-in. One man attends 17 separators of the drum and pulley types.

5. Ball-Norton drum separator

This machine (Fig. 5) consists of a closed drum of non-magnetic material, such as brass or bronze, revolving around a segment of a stationary electromagnet which covers between ½ and ⅔ of the face of the drum as shown. These magnets are wound so that adjacent poles are of opposite polarity. Electrical connection is made through a hollow shaft. When ore, properly crushed to free the magnetic mineral, is fed onto the upper part of the drum, in the direction of rotation, the non-magnetic portion rebounds or slides off while the magnetic material is drawn down to the face of the drum by the magnetic force. As any given magnetic particle is carried forward, however, from the field of one magnet into the field of the next, then, because of the fact that the change in position of the particle is more rapid than the change in polarity of the induced magnetism, the particle turns end for end in order

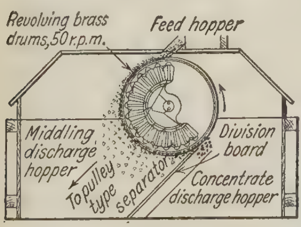

FIG. 5.—Ball-Norton drum-type separator.

to present the proper pole to the succeeding magnet. In so doing it leaves the surface of the drum and thereby frees any non-magnetic particle that may have been mechanically held by it in position on the drum. This winnowing effect is repeated from pole to pole until, by the time the bottom of the drum is reached, most of the non-magnetic and weakly-magnetic particles have been shaken out. This agitation of material by means of magnetic circuits of alternate polarity is one of the outstanding advances that has been made in the art of magnetic separation. At the point on the periphery where the segmental battery of magnets terminates the magnetic particles leave the drum by centrifugal force and gravity and fall into the concentrate hopper.

Drums are usually made 16 to 24 in. face, 24 to 36 in. diameter and are run at 350 to 400 ft. per min. peripheral speed. CURRENT varies with size of feed; at MT. HOPE (*99 J 562*) 6 amp. at 250 v. is used with 1.5- to 2-in. material, 4.5 amp. with 0.5- to 1.5-in. material and 3.75 amp. with 0.75- to 0.25-in. material. CAPACITY on magnetite ores is from 20 to 50 tons per hr. on coarse sizes (0.5- to 2-in.) and considerably less on finer feeds.

At MESABI IRON Co. a 30 × 30-in. drum drawing 7½ amp. at 110 volts was fed with de-slimed −4-mesh sand (58.2 per cent. water) at the rate of 8.7 tons per hr. Assays (magnetic Fe, per cent.) were: Feed, 36.7; concentrate, 48.2; tailing, 9.5.

At MT. HOPE manganese-steel shells were substituted for brass on the drum. These shells, ⅛-in. thick, lasted four times as long as the brass drums and the cost per ton was one-quarter as much. Roche substituted pure rubber bands for manganese steel at the RICHARD mine and found that the life of 3/16-in. rubber was three times that of the steel, with a further saving in installation time and power consumption. Roche used four bands on a 24-in. drum and found that the bands could be readily snapped on drums by merely lifting one end of the shaft out of its bearings.

The drum separator is essentially a roughing machine for making a clean concentrate and a middling for re-treatment. This middling is ordinarily sent to pulley machines (Art. 4).

Ball-Norton double-drum separator (Fig. 6) is an attempt to make finished concentrate on a drum-type machine. The first drum is run slowly with a strong field in an attempt to make a low-grade concentrate and clean tailing. The second drum (*G*) is fed by centrifugal force with the rough concentrate from the first. It is run at higher speed and with a weaker field; as a result low-grade material is dropped into middling compartment (*M*) and only high-grade concentrate is carried around to be thrown over into hopper (*C*). This machine is intended for finer feed than the single-drum machine, the size recommended by the makers being below 2.5-mm. On such material a CAPACITY of 15 to 20 tons of magnetite ore per hour is claimed on drums with 24-in. face, running the first drum at 40 r.p.m. and the second at 50, drawing 10.5 amp. and 13 amp. respectively. POWER required for driving is 0.5 to 0.75 hp.

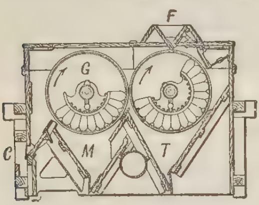

FIG. 6.—Ball-Norton double-drum separator.

Performance. Single-drum separators at WITHERBEE, SHERMAN Co., (*96 J 959*) are 30-in. diameter by 18-in. face, made of brass, rubber covered. Each contains 16 magnets. They run at 50 to 56 r.p.m., are used to treat sized feed − ¾ + ⅜-in. and − ⅜ + ¼-in. In one mill treating coarsely crystalline ore, material −2 +0.75-in. is also treated on drum machines. They make concentrate assaying about 60 to 65 per cent. Fe and a middling assaying about 18 per cent. from feeds ranging between 25 and 45 per cent. Fe. About 4 amp. at 125 v. are used on the coarse feeds, 7 amp. on finer feeds. One man attends 17 separators of the drum and pulley types. At REPLOGLE STEEL Co. 2-drum machines with drums 36-in. diam. by 28-in. face with 14 magnets per drum are run at 49 r.p.m.; feed rate is 14.9 tons per hr. Sizing test of feed and products is given in Table 4. Average assays: Feed, 33.4 per cent. Fe; concentrate, 62 per cent. Fe; tailing, 22.4 per cent. Fe. Iron in tailing is mostly hematite. Similar drum machines are used to treat re-ground middling from belt separators. Sizing test of feed is about the same as given in Table 4. Average assays: Feed, 26.8 per cent. Fe; concentrate, 57.4 per cent. Fe; tailing, 20.6 per cent. Fe (mostly hematite, goes to gravity mill). One of the separators in re-treatment service has 30 × 42-in. drums with 27 magnets in the upper drum and 45 in the lower. Average tonnage on re-treatment machines, 17 each.

Ball-Norton drum-pulley machine (Fig. 7) is a combination of the two machines just described, designed to economize floor space and head room and deliver, from one machine, finished concentrate and tailing and middling for re-treatment. Construction and operation of each part are the same as in the independent machines.

Table 4. Sizing tests of feed and products of Ball-Norton drum-type separators, Replogle Steel Co.

Screen, mesh	Weights, per cent.		
	Feed	Concentrate	Tailing
20	14.6	15.5	10.2
40	37.5	50.1	37.4
60	30.4	14.5	23.7
80	7.6	3.8	5.1
100	3.1	1.4	3.4
Through 100	6.8	14.8	20.1

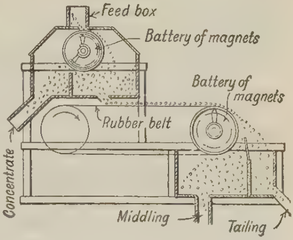

Fig. 7.—Ball-Norton combined drum and pulley machine.

Wenstrom separator is a drum-type machine for coarse feeds, used in Swedish mills in the same position as the single-drum Ball-Norton. The flanged drum is built up of alternate lamellæ of wood and soft iron. The electro-magnet is circular in cross-section but has annular grooves containing the winding and is wound in such a way that alternate poles have opposite polarity. It is placed eccentrically within the drum. Projections from the inner face of the iron drum lamellæ are so arranged that those of alternate lamellæ approach opposite poles of the magnet during their downward travel and are thus magnetized by induction; during their upward travel they are out of the effective field of the primary magnet and lose their induced magnetism. The effect is somewhat the same as in the Ball-Norton machine, except that the magnetic agitation of pulp on the drum is not so active in the Wenstrom machine.

This machine with 30 × 24-in. drum is said to require about 15 amp. at 110 volts and to treat from 5 to 10 tons of 1- to 2-in. magnetite ore per hour at 30 r.p.m.

6. Ball-Norton belt separator

This machine (Fig. 8) is adapted to the treatment of finely-ground dry ores containing a strongly magnetic mineral. Feed is introduced by means of a suitable feed device (*a*) onto feed belt (*b*), which carries the feed forward until, near the head pulley, it comes into the field of the battery of electromagnets (*c*). These magnets, of which there are 8 to 12, are wound so that alternate poles are of opposite polarity. Magnetic material is lifted to the under side of belt (*d*), which runs at a higher speed than belt (*b*), and is carried forward, clinging to the belt. By reason of the alternating polarity of the magnets the material cling-

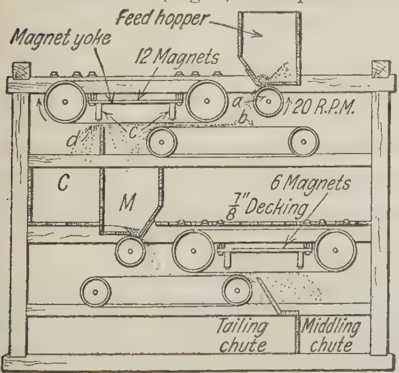

Fig. 8.—Ball-Norton belt separator, series type.

ing to the upper belt is turned over and over, forming depending loops in the air in passing from one field to the next, and in this manner weakly-magnetic middling and entangled non-magnetic material are winnowed out and fall in the hopper *M*. Strongly-magnetic material is carried forward until it passes out of the magnetic fields and falls into hopper (*C*) while non-magnetic material remains on the feed belt until it reaches the head pulley and is discharged therefrom, usually into the same hopper as the middling.

Usual belt speeds are 100 to 250 ft. per min. for the feed belt and 200 to 400 ft. per min. for the take-off belt, the lower speeds corresponding to the more weakly-magnetic material, such, for instance, as magnetite middling, and coarser sizes. In treating magnetite ore passing 0.25-in. screen, the current requirement for a 12-pole machine is from 4 amp. at 250 volts when lifting concentrate, to 8 to 10 amp. when lifting middling. The machine shown in Fig. 8 is a 2-deck machine of the series type in which middling from the first belt is re-treated on a second belt that makes a true middling, and a tailing that can be rejected.

In the 2-deck parallel machine, used for fine material that does not contain sufficient middling to justify re-grinding and re-treatment, clean concentrate and finished tailing are made on each deck and the use of multiple decks is resorted to only in order to increase capacity per unit of floor space. Where both series and parallel types are used in a mill, as at WITHERBEE, SHERMAN Co., the series type is used on coarser feeds, say +1/16-in. and the parallel type on the −1/16-in. material. Usual BELT WIDTHS are between 18 and 30 in. CAPACITY of a 24-in. machine on −1/4-in. crude magnetite ore is 20 to 25 tons per hr.; ROCHE (*115 J 972*) gives the capacity on magnetite ores crushed to pass 2.5-mm. as 1 long ton per ft. of belt width per hour but this is undoubtedly low. Capacity varies nearly in proportion to diameter of feed within the range of sizes treatable. Capacity is increased and grade of products is bettered, if feed is closely sized. At MT. HOPE (*99 J 563*) the sizes treated are: −5/16 +3/16-in., −3/16 +1/8-in. −1/8 +1/16-in. and −1/16-in. At REPLOGLE STEEL Co. double-deck separators are of the parallel-type, with 26-in. 2-ply belts and 10 magnets per deck. Speed of feed belts is 209 ft. per min.; magnet belts, 335 ft. per min. Average feed rate, 15 tons per hr. Sizing tests of feed and products are given in Table 5. Average assays: Feed, 31.4 per cent. Fe; concentrate, 61.1 per cent. Fe; tailing (middling) 27.0 per cent. Fe. Iron in tailing is mostly hematite.

Table 5. Sizing tests of feed and products of Ball-Norton belt-type separators at Replogle Steel Co.

Screen	Coarse feed, weight, per cent.			Fine feed, weight, per cent.		
	Feed	Concentrate	Tailing	Feed	Concentrate	Tailing
0.125-in.	10.3	....	....	....	....	....
10-mesh	8.0	25.6	33.4	....	....	....
20	42.4	31.8	44.9	....	....	....
40	20.3	28.0	11.8	33.0	26.6	32.9
60	8.1	6.8	5.5	27.8	48.2	40.0
80	3.3	2.0	1.1	10.7	4.4	8.1
100	1.8	1.5	0.5	5.9	4.4	5.8
Through 100	5.8	4.4	2.7	22.6	16.4	13.2

The same-sized separators at the same belt speeds are used to treat −20-mesh product at the rate of 10 tons per hr. Sizing tests of feed and products are given in Table 5. Average assays: Feed, 32.7 per cent. Fe; concentrate, 59.1 per cent. Fe; tailing, 19.9 per cent. Fe (hematite; to gravity mill).

7. Cleveland-Knowles separator

This machine (Fig. 9) is a relatively low-intensity machine that has had considerable vogue in the treatment of roasted blende-pyrite middling in the Wisconsin zinc district. It differs from the machines thus far described in that the magnetic material comes directly in contact with the primary-magnet poles and is removed mechanically by scraping, both of which practices are bad.

Feed is introduced over a suitable feeder from hopper (*a*) onto feed belt (*b*) and carried under and into the magnetic field of magnet (*c*). The essential parts of this magnet are shown in Fig. 9, *b*. A cylindrical cast-iron core (*d*) with beveled flange constituting the pole piece carries the winding (*e*) and a flanged shell (*f*) supported by the circular bridge plate (*g*), the shell forming the other pole. The annular gap, ½ in. wide, between the beveled pole pieces is filled with cast metallic zinc, which, being diamagnetic, crowds the external field into the air space below. Magnet (*c*) revolves at about 40 r.p.m. and is of greater diameter than the width of the feed belt. Magnetic material lifted from the belt by the field of this first magnet bridges across the gap and is carried out to the sides and there scraped off into hopper (*h*). Material remaining on the belt passes to the second magnet (*i*), which is made of magnet steel, is more heavily wound than the first, and has a stronger field. The less-magnetic material is removed here in a similar manner. Nonmagnetic tailing passes over the head pulley of the feed belt. Usual speed of feed belt is about 100 ft. per min. Current on first magnet ranges from 0.5 to 2 amp. and on second from 3 to 10. Machine is made in two belt widths, 12-in. and 21-in. Capacity on roasted pyrite-blende concentrate, −3⁄16-in., is about 1 ton per hour per foot of belt width.

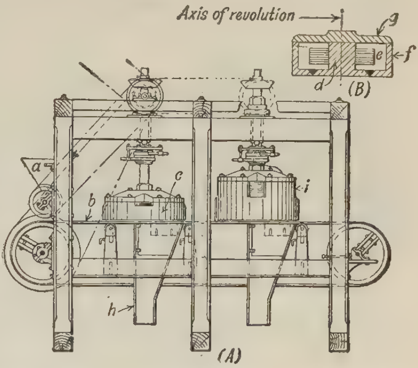

Fig. 9.—Cleveland-Knowles low-intensity separator.

Performances on roasted zinc-iron ores from various camps, compiled from figures furnished by the manufacturer, are shown in Table 6.

Table 6. Performances of Cleveland-Knowles separators on roasted pyrite-blende products. (*United Iron Works Co.*)

8. Dings tray-type separator

Dings reversing-field induced-magnet type separator is shown in Fig. 10. This is a low-intensity machine for treating highly-magnetic materials. The essential parts are the two fixed primary electro-magnets (*a*) with pole pieces (*b*) suspended above the feed tray or belt and shaped as circular arcs with chords equal to the tray width. Cast-aluminum, brass or bronze circular plates (*c*) about 26-in. diameter, carried on gear-driven inclined shafts (*d*), carry on their periphery Y-shaped laminated-steel segments (*e*) 1 to 2 in. long and spaced a similar distance edge-to-edge. The upper part of these segments closely engages the arc-shaped poles of the primary magnets while the lower

ends barely clear the bed of feed in the shaking tray (*f*). A steel bed-plate (*g*) underlies the tray and the magnetic circuit is substantially that indicated by the dotted lines (*h*) passing through core (*a*) and pole pieces (*b*), segments (*e*), air gaps between (*b*) and (*e*) and between (*e*) and (*g*), and completed through bed-plate (*g*). The segments at any given time above the tray are, therefore, magnets and lift magnetic material from the mass on the tray. As plate (*c*) revolves, any given segment passes out of the field of a given pole as it approaches the edge of the tray or belt and as it does so loses more and more its induced magnetism until it reaches the diameter perpendicular to the tray axis when its magnetic flux becomes zero. Further revolution causes it to approach the opposite pole of the primary magnet where induced magnetism of opposite polarity is effected. As a segment carrying magnetic material leaves a primary pole the least magnetic material is dropped out, due to the decreasing strength of field, and at the neutral point the most highly magnetic material is dropped. Since the diameter of the segment circle is 8 in. greater than the width of the tray, the magnetic concentrate drops clear of the tray into chutes (*i*) provided to receive it. The second magnet usually has more ampere-turns than the first, thus allowing it to pick up the magnetic material that the first passed, and the air gap of the second is adjusted to a smaller distance than the first. This adjustment is effected by changing the length of the tray-suspension rods (*j*), by means of hand wheels (*k*). Thus concentrate is delivered into hopper (i_1), middling into hopper (i_2) and tailing from the lower end of the tray.

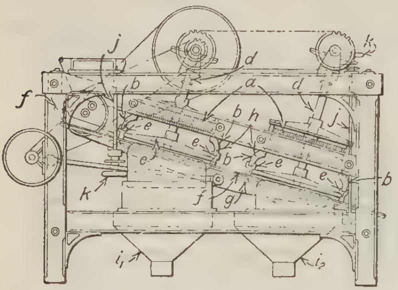

FIG. 10.—Dings tray-type low-intensity separator.

In another form of the same machine, the shaking tray is replaced by a rubber conveyor belt. The tray type is superior where hot roasted ores are being handled or where agitation of the feed is necessary to prevent entrainment of low-grade material in the concentrate; the belt is quieter and gives less trouble mechanically.

The standard width of belt or tray is 18 in. The tray is vibrated 450 to 500 times per min. and slopes about 4 in. per ft.; the belt is horizontal and runs between 50 and 100 ft. per min. CURRENT drawn is about 2 amp. on the first magnet and 3 on the second. CAPACITY on roasted zinc-iron concentrate passing 3⁄16-in. screen is about 1 to 2.5 per tons per hour.

Performance. *Roasted zinc-iron concentrate,* WISCONSIN (*107 J 1110*). Material was passed over two machines in series, the first a 2-disk shaking-tray rougher, and the second a 1-disk belt-type finisher. Shaking tray was made of maple with ¼-in. pressed asbestos liner, sloped 4 in. per ft. and vibrated 450 times per min. Magnets over first rougher disk drew 2 amp. at 225 volts when heated to 100° F.; over second disk, 3 amp. at the same temperature. Tips of secondary poles were spaced ⅜ to ½ in. above the top of the tray liner. Finisher had two 12-in. feed belts running at 70 ft. per min. and discharging at the center of the machine under an armature of solid steel 24 in. diameter and 6 in. thick, revolving on a vertical shaft. Primary-magnet poles were ¾ to ⅞ in. below the lower face of the revolving armature. These magnets had 6-in. cores and carried a current ranging from 9 amp. minimum cold and 7.5 amp. hot to 19 and 15 amp. maximum respectively. Capacity of the two machines was 40 to 45 tons per 24 hr. Cost of roasting and separating (1919) was $1.28 per ton, excluding overhead.

9. Knowles magnetic-belt separator

This machine (Fig. 11) uses the inductive principle to produce magnetism, during a part of their path, in soft-steel studs fastened to an endless belt. Referring to the figure (*a*) is a hopper feeding the electrically-reciprocated tray (*b*). The endless belt (*c*) is studded with about 200 soft-annealed steel rivets per square foot of area, heads on the pulley side, each rivet carrying a saucer-shaped washer with serrated edges. The belt passes around the pulleys (*d*) and around the adjustable directing roller (*e*) and travels so that the downwardly-sloping part goes with the feed stream. The primary electromagnet (*f*) is mounted on the frame so that the studded belt passes through the air gap. The upper pole only is wound. Both poles are chamfered to concentrate the magnetic flux and the upper is cut out to accommodate the directing roller (*e*). The studs in that part of the belt between the poles become powerful magnets by induction and attract magnetic particles from the feed while the non-magnetic particles slide down the tray into the tailing compartment (*g*). Intensity of magnetization in the studs is varied by varying the primary current and by changing the air gap between belt and upper pole by means of roller (*e*). As the magnetized studs pass to the left of the upper pole the induced magnetism weakens and they come more under the influence of the lower pole, the cylindrical pole-piece of which projects forward as shown. As a result their polarity is reversed. During the early part of this period of decreasing magnetism and changing polarity the least magnetic material leaves the studs and falls into compartment (*h*), constituting a middling. At the time of reversal the most magnetic material is dropped into compartment (*i*) as concentrate. By adjustment of splitters (*j*) considerable variation in the character of the products taken with a given electrical adjustment is possible.

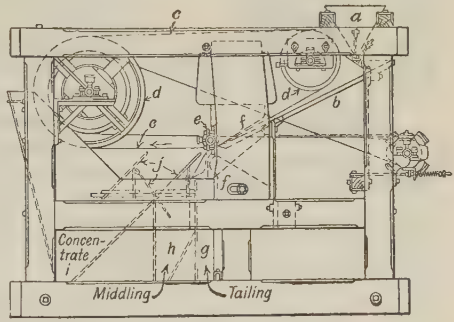

FIG. 11.—Knowles magnetic-belt separator.

Usual belt SPEED is 200 to 250 ft. per min. Machine is made in belt widths from 6 to 36 in. and CAPACITY on roasted blende-pyrite concentrate, $-\frac{3}{16}$-in., is slightly more than 1 ton per in. of belt width per 24 hr. CURRENT requirement at 110 volts ranges from 3 to 20 amp., depending upon the size of machine and the ore treated.

High-intensity machines are used for separating minerals that fall in the weakly magnetic class in Table 1. These machines must have very powerful magnets and a small air gap. As a result of this last requirement the feed must be relatively fine, it must be spread in a thin layer, best not more than one grain deep on the feeding surface, and, consequently the capacity of the machines is low in comparison to that of those treating strongly-magnetic material.

10. Wetherill separator

The Wetherill separator (Fig. 12) consists essentially of a flat-pole magnet (*a*) below and a wedge-pole magnet (*b*) above a flat conveyor belt (*c*) carrying the

feed stream. The lines of magnetic force converge sharply from the flat lower pole toward the lower edge of the upper pole so that magnetic particles travel toward the upper pole despite their greater proximity, when on the feed belt, to the lower pole. Cross belts (*d*) run directly under the upper poles in a direction at right angles to the feed belt and when magnetic particles rise from the feed belt toward the upper pole they come against the under side of these belts and friction causes them to be carried off to one side where they discharge into proper receptacles as concentrate. Removal is facilitated by a horn-shaped piece on the front side of the upper pole, by means of which the intensity of the field at this point is lessened. Non-magnetic tailing discharges over the head pulley of the feed conveyor.

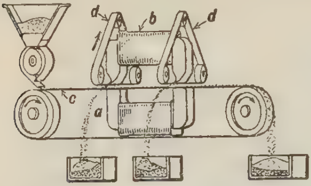

Fig. 12.—Wetherill magnetic separator (high-intensity type).

The machine is made with two, four or six poles and with feed-belt widths of 6 to 18 in. Each pair of magnets, *i.e.*, a 2-pole upper and a 2-pole lower, is wound in series to bring opposite poles together, and is provided with a separate ammeter and rheostat with small increments. The lower magnets are adjustable in order to bring the pole pieces level under the feed belt, the upper have an operating vertical adjustment by means of a hand wheel. Speeds of feed and take-off belts are adjustable by means of cone or step pulleys. Table 7 gives manufacturer's data on the various mill sizes. Width of poles is 18 in. in all machines.

Table 7. Sizes of Wetherill separators

Number of poles	Magnet wound for ampere turns			Maximum amperes at 110 volts direct current	Shipping weight, pounds
	First magnet	Second magnet	Third magnet		
2	30,000	....	....	6	14,000
2	60,000	....	....	14	15,000
2	100,000	....	....	30	16,000
4	30,000	60,000	....	20	22,000
4	30,000	100,000	....	36	23,000
4	60,000	100,000	....	44	24,000
6	30,000	60,000	100,000	50	30,000

Effect of adjustments. Variation in CURRENT strength varies the strength of the magnetic field and consequently, if the pole distance remains constant, the character and amount of products lifted from the feed belt. Too great current strength causes concentrate to cling under the upper poles and fail to discharge uniformly, with the result that clusters of concentrate build up and are scraped off by the feed belt or crowd material off the feed belt. The current drawn varies from about 5 amp. on the first magnet of a 6-pole (3-magnet) machine to 35 amp. on the last magnet. Variation in POLE DISTANCE is an important adjustment. If the pole distance is too great, current strength must be increased in order to make the desired recovery and difficulty in discharging concentrate results, as explained above. With too small pole distance the cross stream of concentrate brushes gangue off the feed belt into the concentrate receiver and thereby lowers the grade of concentrate. Pole distance depends upon the permeability of the concentrate and upon the size of feed particles. It may be as great as 1 in. plus the thickness of the feed belt (usually ¼ in.) on coarse material of relatively high permeability while it may

need to be as small as ⅛ in., if the permeability is low and the feed fine. Thickness of feed belt is preferably less than ¼ in., if the concentrate is very feebly magnetic; ⅛-in. is, however, the practical minimum. The take-off belt should be and is made as thin as possible, usually about $\frac{1}{32}$ in. thick. SPEED OF BELTS affects capacity and recovery. The feed belt is run as rapidly

as possible, in order to make capacity as large as possible, but if ore is fine, dusting limits the speed to between 200 and 300 ft. per min., while on coarser material a limit is imposed by the inability of the magnetic field to overcome the momentum of the particle. From this point of view, of course, the speed for feebly magnetic materials must be least and feed must be fairly uniform in size, while greater speed and less uniformity in feed size are allowable with more permeable substances. Effect of size of feed on speed is shown in Table 8. The usual speed of the feed belt is from 50 to 100 ft. per min. on feebly magnetic materials and from 100 to 300 ft. per min. with material of medium permeability. WIDTH OF FEED BELT also affects capacity but is practically limited to 18 in. because of the fact that with greater width the mass of material on the take-off belt is so great that it scrapes gangue off the feed belt unless the pole distance is made impossibly great. Ratio of concentration affects width of feed belt, a low ratio with the correspondingly great bulk of concentrate requiring a narrower belt than a high ratio. SPEED OF TAKE-OFF BELT is limited by the kind of material it is removing and the size of particles. It may be higher with strongly- than with weakly-magnetic material and higher with fine than coarse particles.

Richards gives 1000 ft. per min. allowable with strongly-magnetic concentrate and 200-ft. per min. for feebly magnetic. Removing franklinite at NEW JERSEY ZINC CO., the speed ranges from 570 ft. per min. on 2.5-mm. material to 1045 ft. per min. at 0.25-mm. (See Table 8.) The take-off belts on the early poles may run more rapidly than those on the later, as is likewise shown in Table 8. Speed of take-off belt is the limiting factor in the capacity of a machine when the ratio of concentration is low, while speed of feed belt limits when ratio is high. Young (*106 J 868*) recommends not more than 50 to 100 lb. per hr. per cross belt for a 6-in. machine. Capacity on wolframite-cassiterite ore is as low as 0.75 ton per 24 hr. on account of fineness and necessity for clean products (*120 P 379*). The feed must be perfectly dry in order to permit free movement between particles and not too fine or slime will stick to the feed belt.

Performance. At NEW JERSEY ZINC CO., Franklin mill, 6-pole 18-in. Wetherill-Rowand machines (Fig. 13) treat an ore containing franklinite, willemite, zincite and calcite and make

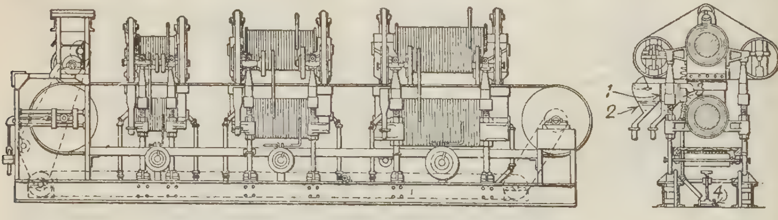

FIG. 13.—Wetherill-Rowand separator.

franklinite as concentrate. Two or more products are taken from each cross belt by means of the hoppers (1) and (2), etc., the most magnetic material being thrown farthest. Gangue swept off falls into (3) and thence by conveyor (4) back to the feed end. Adjustments are shown in Table 8. An approximate mineralogical analysis of the products of one separator is shown in Table 9. At ALGONQUIN MINE, Philipsburg, Mont. (*116 J 181*) pyrolusite and psilomelane occur in a silicious gangue. A Wetherill 6-pole machine (see Table 7) takes feed between 5- and 10-mesh. Speed of feed belt, 95 ft. per min.; take-off belt, 250 ft. per min. Concentrate from the first pole contained 10 per cent. Fe and was rejected; other poles delivered concentrate assaying 75 to 80 per cent. MnO_2; tailing assayed about 10 per cent. MnO_2. A second machine of the same type treating material $-10 + 100$-mesh made similar products except that the product of the first pole contained about 20 per cent. Fe. S. AND M. SYNDICATE (*120 P 379*). Feed: gravity concentrate containing wolframite, bismuthinite and cassiterite; 4-pole separator; weak current on first two poles removed magnetite and pyrrhotite; later poles with strong current removed a wolframite concentrate assaying 73 per cent. WO_3, 0.7 per cent. Sn and a trace of Bi; non-magnetic product

contained 63 per cent. Sn, 4 per cent. Bi and upward of 2 per cent. WO_3 depending on the amount of scheelite (non-magnetic) present. Recoveries were about 97 per cent. WO_3 and 99 per cent Sn. At SAKIET-SIDI-YOUSSEF, Algeria (*97 J 899*) a modification of the Wetherill machine (Fig. 14) was used to treat roasted blende-pyrite concentrate, assaying about 30 per cent. Zn before roasting. Belt (*a*) (14-in.) traveling at 175 ft. per min. carried the feed stream between two sets of powerful primary electromagnets (*b*) (*c*), with wedge-shaped pole pieces, the upper pole of (*b*) and both poles of (*c*) being enclosed in metallic drums. The first magnet drew 7 to 9 amp. at 40 volts and the second 10 to 12 amp. at the same voltage. Magnetic material drawn up against the first drum was thrown onto cross-belt (*d*) and thence discharged. Action at the second magnet was similar to that of a Mechernich separator (Art. 11). Two sizes were treated on separate machines, viz.: $-3 +1$-mm. and -1-mm. Each separator made four products: (*1*) highly-magnetic iron product assaying 17 to 18 per cent. Zn, (*2*) a less highly-magnetic iron product carrying 19 to 20 per cent Zn, (*3*) a zinc-iron middling assaying 27 to 28 per cent. Zn and (*4*) blende concentrate, 42 per cent. Zn. The last two products were mixed to yield a salable product assaying about 40 per cent. Zn and representing about 90 per cent. of the zinc in the original feed. ROASTING was done in a 5-hearth McDougall-type furnace, and cooling in a multi-tube rotary cooler, each tube individually water-jacketed; tubes were about 2.75 in. diameter; slope, 7 per cent.; 8 r.p.m.

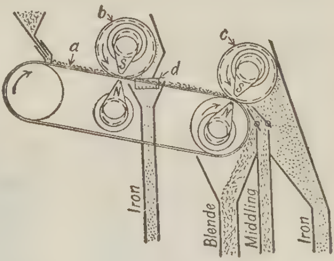

FIG. 14.—Wetherill-Mechernich separator.

11. Roller-type high-intensity separators

In these separators the feed is brought directly in contact with a pole or poles of the separating magnet, separation of the non-magnetic material is effected by gravity in the strongest part of the magnetic field and the concentrate is thrown off the roller by gravity and centrifugal force when it reaches the weak or neutral portion of the field.

Mechernich separator consists of two drums, the upper revolving and the lower stationary, set with axes horizontal and lying in a plane slightly inclined from the vertical. These form the pole-pieces of a powerful electromagnet. The external magnetic flux is concentrated in the plane of the axes. Feed is brought by a properly designed chute to the underside of the upper roller, the non-magnetic material immediately drops away while the magnetic clings until it reaches a weaker part of the field, where it leaves the roller under the combined forces of gravity and centrifugal action.

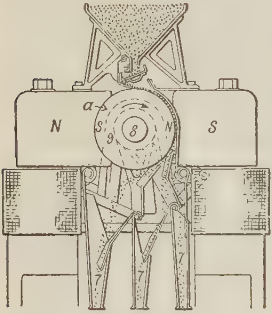

Fig. 15.—International separator.

This separator has had considerable use in Europe and has been used to separate rhodonite from blende at Broken Hill.

International separator (Fig. 15) places a revolving roller (a), built up of alternate radial projecting laminae of magnet steel and depressed laminae of non-magnetic material, between the poles of a powerful electromagnet. Induction causes each steel lamina to become a secondary magnet with field converging from the primary-magnet pole toward the projecting lamina; this field is most intense when the lamina is horizontal and becomes zero when the polarity of the strip reverses in passing from one pole to the other. Feed is introduced near the top of the roller in the direction of rotation, non-magnetic tailing discharges by gravity at or near the horizontal axial plane, while magnetic concentrate carries around on the under side until gravity and centrifugal force dislodge it near the bottom or lower neutral point of the roller.

Speed of roller is 75 to 100 r.p.m.; *Richards* gives the capacity of a machine with 24-in. roller as 2 to 4 tons per hr.

Motor separator is similar in general build and operation to the International except that the separating roller or armature is composed of a copper or brass shell with inner core of alternate disks of magnet steel and non-magnetic filler suitably wound to cause it to revolve when current is passed as well as to set up induced magnetic fields on the surface. No mechanical drive is necessary. The roller is about 30 in. long. This separator has been used in Europe to separate siderite from blende and at Broken Hill to make rhodonite as the highly-magnetic product, blende as intermediate, and a galena-quartz tailing.

Ullrich separator (Fig. 16). The essential parts are one or more concentric rings of wedge-shaped

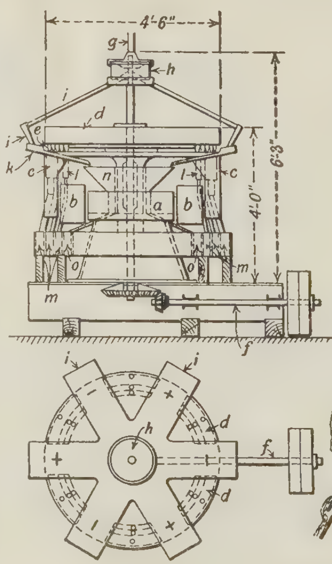

Fig. 16.—Ullrich separator.

pieces of soft iron (*e*) carried depending from a revolving table (*d*); powerful fixed magnets (*a*), radially disposed, with windings (*b*) and flat pole pieces (*c*) for energizing the suspended wedge pieces by induction; feed devices (*k*) that lead the feed in a thin uniform stream between the primary and secondary poles; suitably disposed receiving spouts (*l*) and (*m*), alternating with the fixed primary-magnet poles, for magnetic material, and a common central hopper (*n*) for tailing. As the wedges come over a pole and feed chute in the course of their revolution a strong magnetic field converging on the wedge is formed and magnetic material is drawn from the feed sole to the induced pole. On passing to the next radially disposed pole, which is of opposite polarity, the induced magnetism reverses sign and magnetic material is dropped or removed by a scraper. By varying the air gap between successive rings of secondary poles and the poles of the primary magnet from a maximum at the outer ring to a minimum at the inner, fields of increasing intensity are traversed by the radial feed streams, thus permitting the production of several classes of product in a very small space. The separator is made for either dry or wet service. In dry service the feed channels are shaking trays or traveling belts about 6 to 8 in. wide; in wet, they are shallow launders. In wet work the revolving table (*d*) is filled with water and discharges through pipes to form water sheaths around the wedges. These sheaths are continuous with the liquid in the feed launder (by reason of the small pole distance and the high surface tension of water) so that the movement of magnetic material to the poles is made under water.

Performance. Kranafeldt, writing as the distributors' representative (*34 CMJ*

703), states that the capacity on strongly magnetic material at 2-in. size is 7 tons per hr. while with fine material of the same character 4 tons per hr. can be treated. Capacity on feebly magnetic material passing a ⅜-in. screen is said to be 0.5 to 3 tons per hr. The data on performance in Table 10 are from the same source.

Wet machines, treating blende-siderite ore in SARDINIA (*100 J 911*) were fed material sized between 7- and 4-mm., 4- and 2-mm. and through 2-mm., each size on a separate machine. Feed pulp contained about 20 per cent. solids. Combined capacity of the three separators was 2.5 to 3 tons per hr. Power, 1.5 hp. for driving and 10 amp. at 125 volts for excitation of each machine. Assays: Feed, 34 per cent. Zn and 38 per cent Fe; concentrate, 53 per cent. Zn and 5 per cent. Fe; tailing, 2.5 per cent. Zn and 48 per cent. Fe. Recovery 96 per cent. Zn; 90 per cent. of siderite eliminated.

Rapid separator (Fig. 17) is another high-intensity machine in which powerful fields are induced in sharp-edged secondary poles overhanging the flat-pole primary magnets (*a*) placed below the upper run of an endless-belt conveyor (*b*). The secondary magnets are saucer-shaped rotating disks (*c*), with diameter several inches greater than the width of the belt. Any given point on a disk, when over the belt is also over the pole piece of a permanent magnet and therefore becomes magnetized and lifts magnetic material from the belt. As the disk revolves, this point travels to one side, induced magnetism is lessened, finally passes through zero in reversing polarity, and its load of magnetic material is discharged under the combined influence of gravity and centrifugal force. By tilting the axes of the disk shafts as shown, the effective strength of the secondary magnetic fields may be varied with the result that successively less-magnetic products are discharged as indicated in the figure.

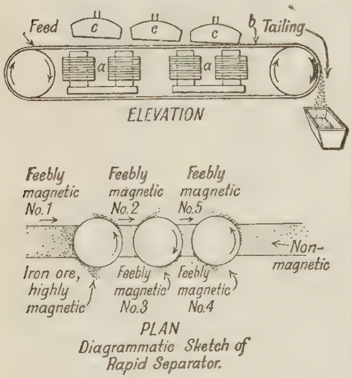

FIG. 17.—Rapid separator.

Laboratory machine has a feed belt 6 in. wide, commercial sizes are 12 and 15 in. Usual CURRENT requirement is from 2 to 10 amperes. Belt SPEED depends on magnetic character of the feed, but will range from 50 to 200 ft. per min. CAPACITY may be estimated from belt speed and size of feed.

Performance. At STOREY'S CREEK, Australia (*18 MM 266*), wolfram-tin separation is made. The feed contains 50 to 66 per cent. WO_3, magnetic concentrate assays 70 to 74 per cent. WO_3 and non-magnetic product 65 to 68 per cent. metallic tin. Capacity of separator is 1.5 tons per 24 hr.

12. Wet magnetic separation

Wet magnetic separation has lagged behind dry on account of the greater mechanical difficulties in presenting feed to the magnets and in cleaning concentrate. However, when the magnetic mineral is very finely disseminated, as is the case with many of the Swedish magnetites, certain of the Adirondack and Pennsylvania magnetite deposits, and the low-grade Mesabi magnetite ores, wet separation is essential. This is because with finely-divided feeds practically absolute dryness is necessary to permit freedom of movement between the particles on the feed sole, and with such dryness dusting is excessive. Furthermore powdered apatite clings with extreme tenacity to magnetite particles, so that when this common constituent of magnetite ores is present the concentrate will be high in phosphorus.

At Cornwall, Pa., it was found (*56 A 901*) that talc clung to the dry concentrate particles to such an extent that it was impossible to raise the iron content above 52 per cent., while by wet separation 58-per cent. concentrate was readily obtained.

With dry feeds finer than 30-mesh it is necessary to remove dust before concentration, or low-grade concentrate results. Many operators state that when it is necessary to grind to ⅛-in. or less in order to free the mineral, wet separation is preferable to dry.

In general, a stronger field is required to concentrate a given ore wet than dry. The speed of presentation must be slow and carefully regulated. If the feed is in a swiftly flowing stream, it is practically impossible to regulate the field properly and either the whole stream will pass by or practically the whole stream will be lifted. Many machines have been devised and patented for such service, but the number of successful machines is small. The best known are the Ullrich (Art. 11), Gröndal, Heberle, Dings-Roche, and Dings cross-belt machines and Davis magnetic log washer. The first two have been used to a considerable extent in Europe, the Dings-Roche in New Jersey and the Davis machine at the Mesabi Iron Co. All these have been used on highly-magnetic iron ores; there are but few instances of the successful use of high-intensity machines on wet pulps, the Weatherby machine at Northern Ore Co. (p. 169) being one.

In most wet magnetic separators the medium in which separation takes place is water instead of air. The permeability of water is, however, substantially the same as air so that no difficulty is met with on this score. It is advisable, however, that the separating surface dip into the water in order to eliminate the complication arising from the presence of a gas-liquid interface through which either tailing or concentrate or both must pass. Such an interface is the seat of forces that oppose its rupture (see Sec. 12, Art. 2) and when the particle is small, these forces are so great relatively to the other forces acting on the particle (gravity and magnetism, which depend on volume) that it is difficult to draw magnetic particles through such a surface film and substantially impossible to cause gangue to fall away from a magnetic-separating surface that is covered with a film of water surrounded by air. For this reason, in most wet machines, the separating surface is submerged during the time that magnetic material is being drawn to it and gangue is being washed out, and emerges from the body of water, if at all, only after washing of the concentrate is complete.

Heberle wet separator (Fig. 18) has had considerable use in Europe. It consists of deep tank in which a water-tight box of magnets m is suspended. An endless belt B about 30 in. wide, runs around pulleys in such direction that the downward run is close to the pole pieces of the magnets. Feed ground to at least 30-mesh, in the form of a freely-flowing pulp with water, is fed against the down-coming belt at A, magnetic material is drawn against the belt while non-magnetic settles in the body of water. Final separation is effected at the upper edge of a dividing baffle at the tail pulley; tailing passes out through compartment G, concentrate falls into hopper E and is discharged through standpipe F, slime overflows at H. Rated capacity is 35 tons per 24 hr.

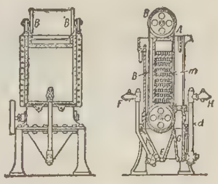

Fig. 18.—Heberle wet separator.

13. Gröndal separator

Gröndal drum-type wet magnetic separator (Fig. 19) consists essentially of the ordinary drum-type separator (a) 24- to 30-in. diameter and 17- to 32-in. face with alternating-pole magnets, mounted above a spitzkasten (b) in such a

way that the lower face of the drum just touches or just fails to touch the water surface. Magnets are made adjustable in angular position and the drum as a whole is adjustable vertically and horizontally. Feed is kept in suspension by rising water currents andall solid matter is forced to flow through the effective part of the magnetic field by means of properly disposed baffles (*c*). Sand tailing sinks to the bottom of the spitzkasten and is drawn off through appropriate ports; slime overflows with excess water as shown; concentrate adheres to the drum surface until it has been lifted sufficiently to be discharged over the side of the spitzkasten. At this point the bank of magnets ends and concentrate is washed off by a spray into a concentrate launder. When two drums are run in series, a strong current is carried in the first to lift all magnetic material as a rough concentrate for re-treatment on the second machine which, in turn, produces finished concentrate and a middling for re-grinding, re-treatment, or discard as tailing, according to the exigencies of the problem.

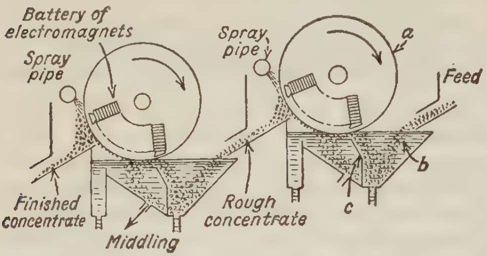

FIG. 19.—Gröndal drum-type wet magnetic separator.

In another form of this separator used in Europe, the drum surface is composed of alternating radial strips of non-magnetic material and iron. The primary magnet has a pointed pole piece directed vertically downward and mounted directly above the baffle in the spitzkasten. Hence the induced magnetism in the iron strips is greatest when the strips are submerged and decreases as they emerge, becoming sufficiently small by the time they reach the horizontal diameter of the drum to permit concentrate to be washed off.

Usual drum SPEED is from 30 to 50 r.p.m. Suitable FEED SIZES range from 8-mesh to 100-mesh. CAPACITY on magnetite ores is from 2 to 4 tons per foot of width of drum face per hour. CURRENT requirement is from 6 to 15 amp. at 110 volts and from 0.25 to 0.5 hp. is required to drive the drums. Water consumption is about 10 gal. per min. per ft. of drum width.

Performance. At BENSON MINES. N. Y., two machines were run in series, the second taking rough concentrate from the first; tailing from both was sent to waste. Two such pairs handled 700 to 750 tons per 24 hr. of 20-mesh feed assaying 30 per cent. Fe and about 0.35 per cent P, but the machines were somewhat overloaded and a third pair was installed. Titanium in the feed ran 3.5 per cent. and in the concentrate, 1 per cent. Table 11 gives sizing-assay test of concentrate. Tailing assayed about 8.5 per cent. Fe, not all magnetic. HANOVER BESSEMER IRON AND COPPER Co., Fierro, N. M., treated 400 tons per day of 30-mesh feed assaying 48 per cent. Fe, 0.6 per cent. Cu and 0.02 per cent. P on three sets of two Gröndal machines in series. Concentrate assayed 60 per cent. Fe, 0.2 per cent. Cu and 0.007 per cent. P. At BETHLEHEM STEEL Co., Lebanon, Pa., the ore consists of magnetite, pyrite and chalcopyrite in talc and ferro-magnesian silicates;

Table 11. Sizing-assay test of concentrate of Gröndal separators, Benson Mines Co., N. Y.

Screen, mm.	Weight, per cent.	Assays, per cent.	
		Iron	Phosphorus
0.833	3.0	47.65	0.060
0.589	11.2	53.72	0.057

0.104	9.2	61.76	0.044
0.074	3.8	62.10	0.045
−0.074	11.5	62.88	0.042

assay, 43 per cent. Fe, 1.8 per cent. S and 0.4 per cent. Cu. 3000 tons per day crushed to 30-mesh went to 20 Gröndal machines in sets of two in series. Concentrate assayed 60 per cent. Fe. 0.9 per cent. S, and 0.2 per cent. Cu. Sintering reduced S to less than 0.1 per cent.

Gröndal slime separator utilizes the fact that magnetized particles when free to move will bunch together, with unlike poles in contact so far as possible, the net effect being to reduce the external field to a minimum. A primary magnet with wedge-shaped pole piece is mounted above a spitzkasten through which the slime feed is run. Under the influence of the magnetic field the magnetic particles become magnetized, are drawn near together just below the water surface and there form agglomerates that sink and are drawn off from the bottom of the tank. In another form a strong horizontal surface current skims the enriched surface layer of slime from the tank before sufficient agglomeration has occurred to cause the magnetic material to sink.

Wiser-Chino machine designed and built at the plant of the CHINO CONSOLIDATED COPPER Co., is an exception to the general rule that magnetic separation of fine material should not take place through a two-phase interface. It consists of an ordinary drum-type separator mounted above the discharge end of a shaking deck actuated by an ordinary Wilfley-table head motion. The function of the table is merely to move the feed pulp in a thin film through the separating zone. At the Chino plant the machine treats copper concentrate containing some magnetite, the object being to recover clean magnetite for use in making sponge iron. Feed analyses 3 per cent. on 10-mesh and 15 per cent. −200-mesh. Feed rate, 150 tons per 24 hr. in a pulp containing 12 per cent. solids. Magnets draw 3 to 4 amp. at 250 volts. About 1 hp. is consumed in driving. Peripheral speed of drum is about 200 ft. per min. One man attends 8 machines. Typical assays are as follows: Feed, 11.41 per cent. Cu and 38 per cent. Fe; non-magnetic product, 13 37 per cent. Cu and 32.7 per cent. Fe; magnetic product, 0.61 per cent. Cu and 60.0 per cent. Fe.

Dings-Roche wet belt machine (Fig. 20) consists of an endless rubber vanner belt (*a*), 30 in. wide, 2-ply with 2-in. flanges, set on a slope of from 10 to 80°, usually 30°; a battery of 20 electromagnets 30 in. long, spaced 3 in. center to center, having alternating poles of opposite polarity, enclosed in a properly ventilated, waterproof copper box (*b*), all set underneath the upper run of the belt as shown. Feed is introduced at (*f*), concentrate is carried up-slope against a stream of wash water supplied through spray pipes (*c*), tailing flows down slope and discharges over the tail roller. Washing of concentrate is aided by the winnowing motion caused by the alternating polarity of the magnet poles. Concentrate is discharged by immersion of the belt in water box (*d*) aided by spray (*e*).

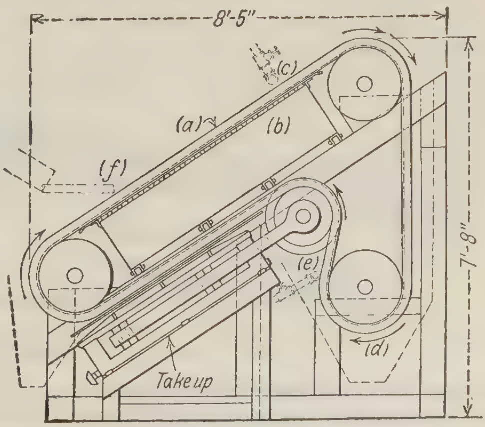

FIG. 20.—Dings-Roche wet belt separator.

Maximum SIZE OF FEED is 0.25-in. but the best results are obtained with material passing ⅛-in. or 1/16-in. screen. Current supply should be up to 20 amp. at 125 volts. One hp. is required for running a 2-belt unit. Belt SPEED is 200 ft. per min. Roche (*115 J 971*) states

the CAPACITY on magnetite ore to be 3 tons per hr. per ft. of belt width with a total water consumption of 2 gal. per min. per in. of belt width. CURRENT draft is 5 to 10 amp. at 125 volts. Table 12 gives comparative results obtained by this machine and a Ball-Norton belt-type machine treating ore from the RICHARD MINE.

Table 12. Comparison of concentrate made by Dings-Roche wet separator and Ball-Norton dry separator (*a*)

Screen size, mesh	Ball-Norton separator, per cent.		Dings-Roche separator, per cent.	
	Weight	Fe	Weight	Fe
20	34	54.06	37	55.16
30	22	57.03	22	69.03
60	20	62.61	20	68.31
80	14	59.01	20	67.22
100	7	51.03	0.5	66.41
200	2	43.21	0.25	66.03
300	1	41.16	0.25	61.09
Total.......	100	56.56	100.00	63.25

a Feed to both machines all through 8-mesh (0.084-in.) screen and on 300-mesh; assay, 48 per cent. magnetic Fe. Ball-Norton machine: tailing, 17.93 per cent. magnetic Fe; ratio of concentration, 1.28; recovery, 91.8 per cent. Dings-Roche machine: tailing, 2.19 per cent. magnetic iron; ratio of concentration, 1.33; recovery, 98.9 per cent.

Dings cross-belt wet separator is similar to the Wetherill machine (Art. 10) except that the feed belt has 0.25- to 0.75-in. side flanges to prevent slop. Sizes, determined by width of feed belt, are from 18- to 60-in. Feed pulp should contain about 20 per cent. solids.

The manufacturers claim that the machine will treat pulps containing 90 per cent. of −200-mesh material. Capacity of a 48-in. machine on 100-mesh magnetite is claimed to be 100 tons per 24 hr. (*121 P 218*). A current of 15 amp. was used to remove partly-roasted pyrrhotite from galena and blende.

14. Magnetic log washer

This machine takes its name from the fact that as originally designed it was similar to the ordinary two-log washer (Sec. 8, Art. 4) but had, additionally, a bank of primary magnets underneath the tank as shown in Fig. 21. In later

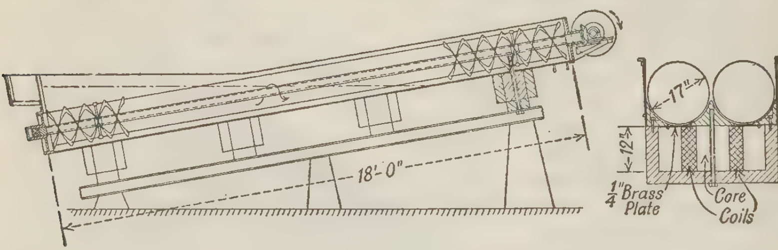

FIG. 21.—Magnetic log washer.

designs the log was replaced by a ribbon spiral and the action, apart from that of the magnets, is rather that of an Akins classifier (Sec. 6, Art. 6). The machine is essentially a slime machine, not suitable for treating anything coarser than 48-mesh feed and increasing in efficiency of treatment as the feed becomes finer. With coarser feed all +48-mesh material goes into the concentrate with resulting lowering of grade.

The action consists in drawing magnetic material to the bottom of the tank by means of the magnetic field, after which the deposited material is conveyed up slope against a stream of wash water, finally discharging over the upper lip while the gangue particles in suspension pass over the overflow lip.

Machines installed by Mesabi Iron Co., 14 ft. long and 2 ft. wide, with two spirals per tank, treated − 150-mesh feed containing about 35 per cent. magnetic Fe at the rate of 50 to 75 tons per 24 hr. and produced 65-per cent. concentrate and a tailing containing from 1 to 2 per cent. magnetic iron. The machines for the final installation at Mesabi are 18 ft. long and 6 ft. wide equipped with 4 spirals and will produce from 50 to 125 tons of concentrate per 24 hr., the amount depending on the difficulty experienced in washing concentrate. W. G. Swart states that this machine requires about 0.25 hp. for excitation and the same for mechanical operation and that it will recover 95 to 98 per cent. of the magnetic iron fed. Character of concentrate depends upon the extent to which mineral is freed, fineness of grinding and amount of washing. With grinding fine enough to permit gangue to be kept in suspension and to free the mineral with substantial completeness, concentrate assaying 65 to 70 per cent. Fe as magnetite is readily made. Wear with fine feed is negligible.

15. Weatherby separator

This is a high-intensity wet machine working on a different principle from any of the other machines described. It consists (Fig. 22) essentially of a small double side-inclined shaking table with Wilfley head motion and aluminum deck, 4 × 4 ft., with steel riffle cleats, all suspended by means of hickory hangers between the poles of a powerful primary electromagnet in such a position that the riffles are nearer the upper than the lower pole of the magnet. As a result the riffle cleats become secondary magnets with the field converging most sharply at their upper surface and magnetic material is therefore drawn to the top of the riffles and washed down slope while non-magnetic material progresses to the end.

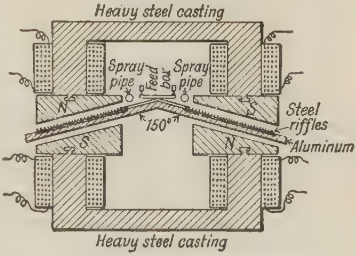

Fig. 22.—Weatherby separator.

Performance. At Northern Ore Co., Edwards, N. Y. (*115 J 1053*, *116 J 404*). The feed is jig and table concentrate passing 4.5-mesh and assaying 30 per cent. Zn (the blende contains 5 per cent. Fe and is magnetic). The feed pulp contains about 30 per cent. water. Concentrate assays 45 to 50 per cent. Zn; tailing, about 6 per cent. Zn. Concentrate assaying 56 per cent. Zn, which is practically pure ferruginous blende, can be made, but this is not economical procedure. Speed of table, 250 @ 1-in. strokes per min. Current draft, 15 amp. at 110 volts. Capacity, 22 tons per 24 hr. per table. The machine has been in successful operation at this mill for several years, but has not been installed elsewhere.

16. Guard magnets

Guard magnets are used in crushing plants to remove tramp iron and steel from the feed before it goes to a crusher incapable of handling it.

As an example of the economy of such an installation, it is stated (*112 J 728*) that at the Melones Mining Co. a magnetic pulley placed ahead of the primary crusher saved $1400 per month in delays and repairs.

Guard magnets are placed above or at the side of a chute or conveyor feeding the crusher. They are usually of the type employed for lifting scrap iron in handling plants, with manual control of current. They must be powerful in order to lift pieces of steel from rapidly-moving masses of coarse ore, and, as the load builds down, to hold it against blows of the material moving on the belt. Fig. 23 shows a typical installation over a conveyor belt. The magnet is hung on a sufficiently long suspension so that it can be swung aside for discharging. When there is danger that the load will build down sufficiently to interfere with material on the belt, it is well to guy the suspension rod with

wires that will complete a bell or light circuit and thus attract attention when the magnet is knocked forward.

Magnetic chute. Fig. 24 shows a method of applying a guard magnet to a chute. Magnets (*a*) are so arranged as to produce a strong field in the chute and catch and hold tramp iron until it is removed by an attendant. Just below

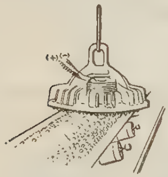

FIG. 23.—Mushroom magnet over belt conveyor.

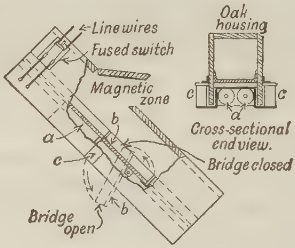

FIG. 24.—Dings magnetic chute.

the magnetic zone a tilting section (*b*) is placed in the chute bottom. This is held in closed position by the magnets (*c*) so long as there is current flowing through the guard magnet but if current is cut off, accidentally or otherwise, the tilting section is released and spills the released iron together with the feed stream onto the floor until such time as the feed is cut off or the tilting section closed and current flowing.

Pulley magnets (Art. 4) are frequently used as guard magnets.

Guard magnets cannot be used in plants treating magnetite ore, on account of the magnetic character of the ore itself. Also, guard magnets will not lift manganese steel, because of its low permeability. At the REPLOGLE STEEL CO. plant, vertical disk crushers set to ¼-in. were guarded by a screen with ¾-in. aperture sending oversize in closed circuit to a set of rolls. These were rugged enough to break up the steel fine enough to pass the disk machines without injury to them. At the UTAH COPPER CO., where manganese-steel dipper teeth are used on the steam shovels, close watch is kept on the shovels and when a tooth is missing a telephone message is immediately sent to the mill (18 miles distant) and particularly close watch is kept as the ore is unloaded into the mill bins and run over the unloading conveyors to the primary crusher, until the tooth is found and removed. These examples are typical of the expedients that must be adopted when guard magnets cannot be used.

Magnets in grinding-mill circuits are used in cyanide plants to remove iron introduced by abrasion from the crushing and grinding machines.

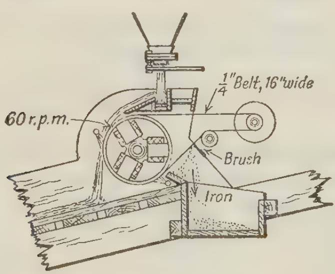

FIG. 25.—Pulley-type separator in tube-mill circuit at Simmer and Jack mill.

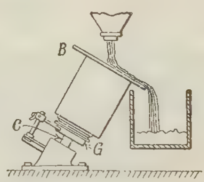

FIG. 26.—Brown electromagnet for tube-mill circuit.

Unless removed this iron, being difficult to grind, builds up to such an extent that it may amount to as much as 15 per cent. of the total circulating load (ALASKA-TREADWELL GOLD

Mining Co., *96 J 452*). Schmidt (*RMP*), states that as much as 900 lb. of metallic iron per day has been removed from a Rand tube-mill circuit and that prior to the introduction of a magnet at the Simmer and Jack mill it was necessary to open the tube-mill circuit for 15 min. each day, and pass the whole pulp to the cyanide plant without re-grinding, in order to clear out the accumulation of iron. Fig. 25 shows an application of a pulley-type separator (Art. 4) at this mill. Fig. 26 shows another type of separator in similar service (*90 J 445*). A flat disk-shaped cast-iron pole-piece (*B*) of an electromagnet with cast-iron core is mounted to revolve on shaft (*C*) which is inclined 35° from the vertical. Current enters through slip-ring *G*; the other end of the coil is grounded. Winding is encased water-tight by a zinc sheath soldered to the iron bobbin of the winding. The magnet is driven at 6 r.p.m. by a 0.5-hp. motor; exciting current is 2.5 amp. at 100 volts. Iron is caught on the rim of the plate and is scraped off by a piece of canvas belting.

A magnet used at Alaska-Treadwell is shown in Fig. 27. The magnet poles dip into the tube-mill discharge launder leading to a Dorr classifier. Current on a given pole is broken by a commutator when the pole-piece reaches a position above the apron. Fig. 28 shows a pair of oscillating magnets with curved pole-pieces that swing in a semi-cylindrical section of a main pulp launder at the Liberty Bell G. M. Co. Water jets wash the poles as they emerge from the pulp and current is cut off when the magnet reaches the highest point of the swing at which time it overhangs the edge of the launder. Each pole has 800 turns of wire

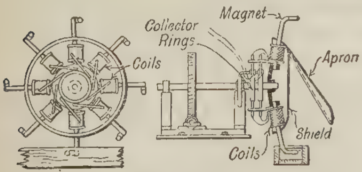

Fig. 27.—Magnet for tube-mill circuit at Alaska Treadwell.

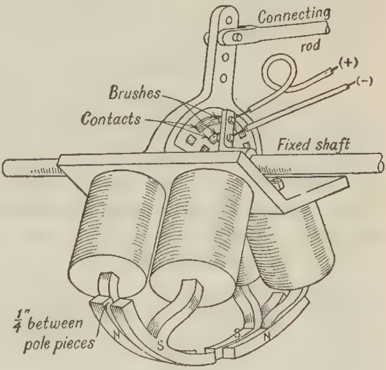

Fig. 28.—Pulp magnet at Liberty Bell.

and draws 2.0 to 4.0 amp. at 110 volts. The machine makes 4 to 5 oscillations per min. and requires about 0.1 hp. for driving. Feed rate is 100 tons of − 16-mesh material per 24 hr. in a pulp carrying about 10 per cent. solids. Removal of metallic iron is practically complete.

17. De-magnetizer

This consists of a conical coil carrying alternating current, surrounding an iron pipe carrying magnetized pulp. When an ore that has been over a magnetic separator is finely ground, there is sufficient residual magnetism in the magnetic particles to cause them to agglomerate and, in classification, to sink with the unground sands rather than overflow with the slimes. Effective closed-circuit grinding is thus prevented. Passage through a de-magnetizer remedies this difficulty.

The device is used on the discharge of ball mills feeding bowl classifiers at Mesabi Iron Co.

18. Murex process

The Murex process is a combination of magnetic separation with the differential-oiling phenomenon that is utilized in flotation processes (Sec. 12). It is applicable to the separation of sulphides and other minerals of metallic luster from minerals of non-metallic luster. Minerals of metallic luster become coated with oil when mixed with oil in an aqueous pulp, while minerals of non-metallic luster remain water-wet. In the Murex process the oil is first loaded with

powdered magnetite, then mixed with the aqueous pulp and the whole is presented in a thin film under the poles of a magnet, when the oil-coated minerals are attracted to the magnet because of the magnetite in the oily coating, while the non-coated gangue particles pass on. One oil mixture that has been used was composed of fuel oil, tar and resin. This had the power to hold the magnetite as well as to coat sulphides preferentially.

At CLAUSTHAL (*100 J 429*) the process was used, 3- to 4-mm. material being ground in a pebble mill in a thin pulp with the above oil mixture to effect coating, the product passed through a screen with a 2 × 4-mm. openings then spread out on a shaking table under an overhanging magnet. Galena was thus separated from barite and silicious gangue minerals. At DARWIN LEAD AND SILVER MINES (*104 J 58*) a 50-ton mill treated a partly oxidized lead-silver ore. A recovery of 80 to 85 per cent. of the mineral content was claimed at a cost of $1.78 per ton. Oil consumption was 15 lb. petroleum residuum and 0.8 lb. oleic acid; magnetite, 17 lb. per ton.

19. Roasting to increase permeability

Roasting is practiced in the case of many iron-bearing products in order to convert the iron-bearing mineral into a magnetic state. Fe_3O_4 and Fe_7S_8 are highly-magnetic compounds of iron while Fe_2O_3 (hematite), $2Fe_2O_3 \cdot 3H_2O$ (limonite), $FeCO_3$ (siderite), FeS_2 (pyrite) are feebly- or non-magnetic. These latter may, however, be converted to the magnetic state by proper roasting. Chalcopyrite, bornite and other complex sulphides containing iron are similarly rendered magnetic.

Hematite is changed to Fe_3O_4 by abstraction of oxygen. This can be effected by strong heating in air, less heat in a reducing atmosphere and a still lower heat when there is intimate admixture of a reducing substance such as hydrogen or carbon. Reducing roasting has had some commercial application in Europe and much experimentation has been done in this country. Theoretically only about 1 per cent. by weight of carbon or equivalent fuel would be necessary to effect the conversion of pure Fe_2O_3, if there were no heat losses, but the Minnesota School of Mines Experiment Station has determined that on a typical low-grade hematite ore from 5 to 10 per cent. by weight is necessary. Their conclusions as to operating conditions follow: (1) For efficient and rapid roasting the temperature should exceed 400° C. (2) Comparatively small increases in temperature effect considerable increases in efficiency. (3) Efficiency generally increases with increase in duration of roast. (4) Efficiency increases with decrease in size of particles, but this factor is less important than temperature and duration. (5) Simple heating in air produces little change in magnetic character. (6) The reducing agent should contain as little methane as possible, as this gas has low efficiency.

Siderite is converted to the magnetic oxide by calcining with restricted access of air. Over-roasting produces the feebly-magnetic ferric oxide, Fe_2O_3.

Pyrite may be converted by roasting either to Fe_7S_8 or to Fe_3O_4, both of which are highly magnetic, according to the character of the roast. When heated in the presence of air, pyrite (and marcasite) decrepitate at 60° C., and as the temperature is raised lose sulphur more and more rapidly until at about 400° C. the magnetic sulphide, Fe_7S_8 is formed, the sulphur igniting and passing off as SO_2 gas. If the period of subjection to heat is short (FLASH ROASTING), only the surface of the pyrite is altered, and Fe_7S_8 is formed, but this surface shell of magnetic material is sufficient to cause the particles to be lifted by the magnet in a field of high intensity. Further roasting at 500 to 600° C. with limited air and an atmosphere of CO, H and SO_2 results in conversion to the highly magnetic Fe_3O_4, more or less complete according to the duration of the roast and the size of the particles. Roasting to form the magnetic sulphide is hard to control, some of the more strongly magnetic oxide is sure to form, especially from the smaller particles, while the larger particles contain mixtures of the original material and the various possible products. The product is, therefore, difficult to separate on account of the varying permeability of the constituents, and for this reason it is frequently better to carry the roast to magnetic oxide. Over-roasting, especially if accompanied by access of air, causes conversion of Fe_3O_4 to the feebly-magnetic Fe_2O_3. Where conversion must be closely regulated the ore must be closely sized before roasting and, if complete conversion to oxide is desired, it should be ground to −2-mm. On the other hand, if the feed is too fine, it is difficult to obtain proper exposure to the furnace gases, with the result that roasting is again uneven.

Furnaces. Revolving kilns and multiple-hearth furnaces of the McDougall type are ordinarily used. The latter type has had extensive use in the Wisconsin zinc district in roasting marcasite-blende concentrate to convert the marcasite into magnetic sulphide. CAPACITY of a 6- or 7-hearth, 22-ft. furnace in this service is 100 to 125 tons per day on material passing a 3/8-in. screen.

Cooling. Roasted material must be cooled before passing it through the separators, on account of the destructive effect on the machines and difficulty in handling. Cooling must be done out of the presence of air in order to prevent re-oxidation. Temperature of material leaving the cooler should be less than 100° C. Revolving cylinders, usually with water sprays on the outside of the shell are frequently used.

At TRAIL (*120 P 864*) it was found that the effect of a roast to increase the magnetic quality of pyrrhotite without complete conversion to Fe_3O_4 was lost if immediate quenching or slow cooling was practiced, but retained with rapid cooling in a rotary cooler.

Performance. Table 13 shows the results of a series of experiments made at the Minnesota School of Mines Experiment Station on roasting HEMATITE ore to the magnetic oxide. The work was done in a rotating cylindrical externally-heated gas-fired furnace, using illuminating gas as a reducing agent. PYRITE-BLENDE CONCENTRATE, Wisconsin. (*107 J 1107*). Self-roasting furnaces of the Wedge and Skinner types are used with rotary coolers. Characteristic roaster feeds range from 21.6 to 45.9 per cent. Zn, 12.8 to 27.4 per cent. Fe, 0.22 to 0.82 per cent. Pb, 1.50 to 2.15 per cent. CaO and 35.7 to 41.6 per cent. S. One plant uses an 8-hearth Wedge furnace, 22 ft. 6 in. diameter by 24 ft. high. Ore is heated gradually by the heat of its own combustion to a maximum temperature of 900 to

1000° F. on the lowest hearth, at which temperature marcasite is strongly oxidized but blende is unaffected. Gases contain 4 to 5 per cent. SO_2. Decrepitation and abrasion increase the percentage of −40-mesh material from 9 per cent. in the entering feed to 30 per cent. in the discharge. Four rotary coolers are used, 2 × 26-ft., 6 r.p.m., with outside spray (30 gal. per min. each). The magnetic quality of the roasted ore is greater when slightly warm than cold. Dings tray-type separators make rough concentrate assaying 56 to 58 per cent. Zn; this is raised to 61.5 per cent. Zn by a high-intensity cleaner, and a tailing containing 4 to 5 per cent. Zn and 25 per cent. S, which is suitable for sulphuric-acid manufacture. At another plant in the same district (*99 J 977*) the zinc-iron gravity concentrate is given a slight, positively-controlled roast in an oil-fired revolving kiln, cooled in a revolving cooler and separated on a Campbell separator (tray-type with cross belts for concentrate removal). The raw concentrate assays 21 to 34 per cent. Zn and finished concentrate 49 to 61 per cent. with recoveries of 92 to 95 per cent. reported. Shrinkage in weight during roasting runs from 50 to 70 per cent. The iron product is suitable for acid manufacture, if not over-roasted. CASSITERITE-PYRITE SEPARATION, Llallagua (*100 J 513*). The furnaces are of the McDougall type, 5-hearth; ore is self-roasting (no carbonaceous fuel added); feed is all −1-mm. and assays about 25 per cent. sulphur as pyrite and 15 per cent. Sn; furnace feed contains about 5 per cent. moisture. Best results are obtained on Stern-type wet separators. (A star-shaped pole piece revolving 10 to 20 r.p.m. around a horizontal axis in a tank of pulp picks up magnetic material and carries it above the surface of the pulp where it is washed off the pole arms and over the sides of the tank by a strong jet of water. Current draft is about 6 amp. at 110 volts. Capacity: 18 tons per 24 hr. was handled when the roasted product contained 10 to 12 per cent. S. Under these conditions the magnetic product contained 50 per cent. Fe and 22 per cent. S and the non-magnetic 2.5 per cent. Fe and 1.5 to 2 per cent. S.) Properly-roasted product was black with metallic luster; over-roasting was indicated by a reddish product on which the separators did poor work and discharged a tin product high in iron. Capacity of roasting furnace was about 0.04 ton per sq. ft. of hearth area per 24 hr. Amount of flue dust was less than 5 per cent. of the furnace feed and tin content of dust was about 5 per cent. on a 20 per cent. feed, due in part to the fact that cassiterite does not decrepitate. There was never more than 2 per cent. loss of tin in dust. COPPER-IRON, Calumet and Arizona smelter, Douglas, Ariz. (*Bul. 9, MSM 38*). Davis states that magnetic roasting is being incidentally performed at this plant in connection with drying and de-sulphurization prior to smelting. The ore, crushed to pass a 1-in. screen is roasted in a 6-hearth McDougall-type oil-fired furnace 21 ft. 6 in. diameter at the rate of 80 to 100 tons per 24 hr. with conversion of about 80 per cent. of the iron to magnetic oxide at a total operating cost in 1919–20 of $0.31 per ton.

SECTION 14

MISCELLANEOUS PROCESSES OF CONCENTRATION

1. Mechanical pickers

Anthracite pickers are built to take advantage of the difference in shape between particles of coal and of slate. The simplest and earliest form, typified by the ZIEGLER, consists of a sloping steel chute with a transverse slot in the bottom through which the flat, sliding, slow-traveling slate falls while the rounded, rapidly-rolling coal particles "jump" over and pass on to the end. The principal modification of this type is a slate-bottomed chute, which retards slate in the coal more than a steel bottom and causes more rolling of the coal. Another modification of the same device was introduced by shaking the separating chute, which, of course, makes it possible to set the separating surface on a flatter slope and thus save head room. Another modification is the roller picker, which has a series of transverse spaced rollers across the bottom of the separating chute, the spaces corresponding to the slots in the jump-type pickers. AYERS PICKER consists of a flat apron conveyor traveling up-slope at such an inclination that rounded coal particles roll down-hill while flat slate particles are carried up and over the head roller.

At PHOENIX COAL CO. (*18 CA 796*), treating culm, an Ayers chestnut picker runs 150 to 200 ft. per min.

Spiral picker is the most widely used of the mechanical picking devices. One form is illustrated in Fig. 1. In sliding down the spiral chutes the coal, being rounded, travels faster than the flat slate, works to the outer periphery, and falls off into the larger spirals, which discharge separately from the smaller. Spiral pickers will not work on wet coal. They are adjustable for temperature. Each type and size of coal requires a different setting. Spirals are of little value for fine coal. Certain types of coal are not amenable to spiral treatment. According to Sinnat and Mitton (*67 IME 491*) the coal must be sized between the following limits: $-6 +4$-in., $-4 + 2\frac{1}{2}$-in., $-2\frac{1}{2} +1\frac{1}{2}$-in., $-1\frac{1}{2} +\frac{3}{4}$-in., $-\frac{3}{4} +\frac{1}{4}$-in. Spirals have had their greatest success in treating anthracite, because the slaty impurities are tabular while the coal is rounded. Ashmead (*66 A 422*) gives the data in Table 1 as the results of a test. The usual CAPACITY is 8 to 12 tons per hr., depending upon the size of feed.

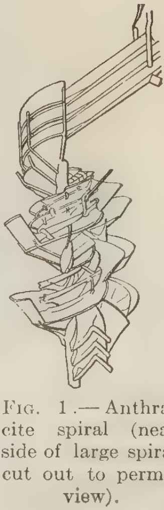

FIG. 1.—Anthracite spiral (near side of large spiral cut out to permit view).

Table 1. Performance of anthracite spiral

	Per cent. of coal	Per cent. of slate
Feed	84.60	15.40
Coal discharge	98.93	1.07
Slate discharge	5.88	94.12
Recovery	99	94

Disadvantage of mechanical pickers is the fact that the coal product carries considerable slate and *vice versa*. Therefore it is always necessary to concentrate the products further, either by hand-picking or by jigging. For this reason such pickers are being superseded by jigs except for grate-size coal, which is too coarse for efficient discharge from jigs The principal advantages of the pickers are their high capacity and low operating cost.

2. Pneumatic concentration

Pneumatic table for treating bituminous coal is a development of a table used for cleaning seeds, cereals, nuts, etc.; it has been tried spasmodically without much success in metal concentration. The usual form is shown in Fig. 2 (*19 CA 811*). It consists essentially of a reciprocating riffled deck (*a*),

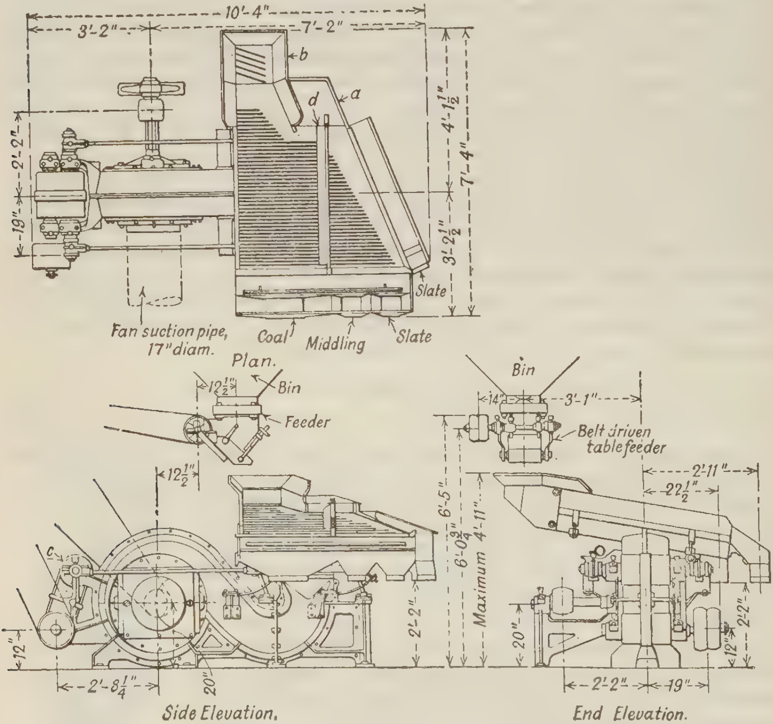

Fig. 2.—Pneumatic shaking table.

about 4 × 4 ft., driven by an eccentric but mounted like the Ferraris or rocker screen (Sec. 5, Art. 6). The deck has an adjustable inclination, averaging about 5° transversely to the riffles, away from feed box (*b*), and has a fixed inclination parallel to the riffles of about 1° upward from the mechanism end. It is driven at from 270 to 330 @ ⅝-in. strokes per min. through the cone

pulleys (*c*). The deck surface is made of cloth or woven wire. Riffles are spaced about 2 in. and taper from about ½ in. at the head end to nothing at the discharge end. For coarse material, the deck is covered with ⅜-in.-mesh wire cloth to keep the bed from sliding; for fine material, tapering paper strips terminating one-half to two-thirds of the distance to the slate-discharge end are pasted under the cover between the wood supporting strips (Fig. 3) to give a quiet space for fine impurity to travel in. (*22 CA 876.*) Air is supplied to a pressure box underneath by means of a 40-in. steel-plate centrifugal suction blower at 1600 r.p.m. An air gate is placed in the table base to regulate the amount of air admitted at just enough to produce stratification without boiling.

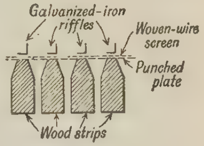

FIG. 3.—Cross-section of deck of pneumatic table.

Operation depends upon the fact that the heavier particles in a mixture of particles of different specific gravities on the deck of the table offer the greater resistance to lifting by the issuing air and that the combination of the lifting force of the air and the agitating effect of the table motion imparts sufficient fluidity to the mass to permit the lighter (coal) particles to rise to the surface of the mass, where they roll down slope, while the heavier (shale and pyrite) particles at the bottom are constrained by the riffles to move to the end away from the head motion. Bone and some slate also work to the lower edge and are collected as a middling product as indicated in the figure.

Bituminous coal as coarse as 3-in. is being treated. The feed should be closely sized. The usual screens for −3-in. material are 1½-, 1-, ½-, ¼-, ⅛- and ¹⁄₁₆-in. Coal finer than ¹⁄₁₆-in. cannot be economically treated on the regular table on account of the small capacity and the consequent high cost. A different form of table, known as the Y-TABLE, from the shape of the deck (Fig. 4), has been used at McCOMAS for ⅛-in. to 40-mesh material (*MCJ, Jan., 1926*). It showed a capacity about twice that of the older type.

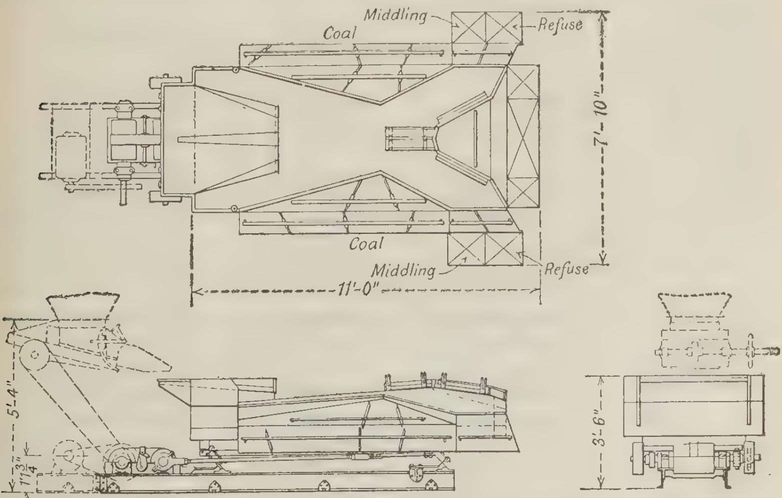

FIG. 4.—Pneumatic coal separator, Y-deck.

COARSE FEEDS require relatively large volumes of air at low velocity and are, therefore, treated on a deck with relatively coarse apertures (woven-wire screen cloth); fine material

a Pocahontas, No. 3-seam coal. *b* Weight (13 lb.) too small to treat. *c* Indiana, No. 5-seam coal. *d* − 26-mesh raw coal assayed 16.56 per cent. ash, 3.52 per cent. S and 0.008 per cent. P. It was not treated. *e* Illinois coal. *m* mesh.

requires a smaller volume at higher velocity. Skinner satin is a satisfactory material for the finest sizes.

Performances in three large-scale tests on −1½-in. Pocahontas coal (*20 CA 53*) are given in Table 2. The +1-in. material was thrown directly into the refuse and the −26-mesh material into clean coal.

At American Coal Co., McComas, W. Va. (*MCJ, Jan., 1926*; *22 CA 875*) the −3-in. screenings contain approximately 83 per cent. of coal (−1.35 sp. gr.) assaying 4.30 per cent. ash; 5 per cent. low-ash bone (1.35 to 1.50 sp. gr.) with 15 per cent. ash; 2 per cent. high-ash bone (1.50 to 1.70 sp. gr.) with 30 per cent. ash; and 10 per cent. of slate and fireclay with 86 per cent. ash, a total for the raw screenings of 13.5 per cent. ash. The bone is found principally in the +½-in. material, which contains 13 to 17 per cent. ash. The finer sizes contain 9 to 11 per cent. ash. The −1⁄16-in. material contains about 11 per cent. ash. The present dry-cleaning plant for treating 240 tons per hr. of −3-in. +1⁄16-in. bituminous coal contains 8 tables, one table for each of the sizes −3 +1½-in., −1½ +1-in., −1 +½-in., −½ +¼-in., and two each for the −¼ +⅛-in. and −⅛ +1⁄16-in. sizes. Tests have shown that on the coarser sizes the capacity of a machine is 25 tons per hr. while on the finer sizes it is 12 to 14 tons. The entire plant consisting of 8 tables, 36 Hum-mer screens and 3 fans (100,000 cu. ft. per min. of free air) with necessary elevators and conveyors requires about 2.35 kw.-hr. per ton of coal treated. Air consumption on coarse-feed tables is about twice that on fine-feed tables. The average labor force is 4½ men per shift. The cleaned product contains about 92 per cent. −1.35 sp. gr.; 5.5 per cent, 1.35–1.50; 1.2 per cent., 1.50–1.70, and 1.5 per cent. +1.70 sp. gr.; total ash, 6.4 per cent. The +½-in. cleaned coal averages 6.5 to 7 per cent. ash and the smaller sizes 4.5 to 5 per cent. (*25 CA 761*). The refuse is about 8 per cent. of the total feed and averages more than 80 per cent. ash. Average cost of cleaning (1924) was $0.20 per ton, including power, labor, supplies, repairs, depreciation and interest. At St. Louis, Rocky Mtn. and Pacific Co., Raton, N. M. (*23 CA 791*) the tables are run at about 350 @ ⅝-in. strokes per min. Fan speeds range from 900 r.p.m. on the finest size to 1040 r.p.m. on the coarsest. About 6000 cu. ft. of free air per min. comes up through the table deck. Capacity on different-sized feeds is shown in Table 3. From auxiliary tests it is shown that the tables

Table 3. Performance of S. S. and S. (American Coal Co.) pneumatic table on bituminous coal at St. L., R. M. and P. Co. (*After Young*)

Size of feed, inches	Tons of feed per hour	Analyses, per cent. ash			Recovery of combustible, per cent.

Totals........	....	16.8	11.1	64.6	95.5

a Ash in picked samples of clean coal runs 8 to 9 per cent.

remove about 72 per cent. of the free impurity. The waste rejected is about 10 per cent. of the raw coal by weight. At West Canadian Collieries, Ltd., Blairmore, Alberta, Canada (*MCJ, Jan., 1926*) the capacity on −¼ + ⅛-in. coal is 18 tons per hr.; −7⁄16 + ¼-in., 24 tons; −¾ + 7⁄16-in., 30 tons; −1⅝ + ¾-in., 38 tons per hr. Cost of plant to treat 110 tons per hr., using Hum-mer screens for sizing was $1360 per ton of hourly capacity.

Cost of a dry-cleaning plant for bituminous coal is estimated by Tams (*MCJ, Jan., 1926*) at from $500 to $660 per ton of hourly capacity, and the installed power from 1.33 to 1.67 kw.-hr. per ton. The power consumed will be less than this.

Advantages of dry cleaning are: (*a*) No water is required, which is an important consideration at many mines; (*b*) no moisture is added to the coal, on the contrary a certain amount of drying is effected. This latter fact is important when the coal is to be shipped

long distances or in cold weather; or when it is to be used for coking in which case common specifications call for less than 5 per cent. moisture as received; or when the coal is to be pulverized, when, unless it is dry, the drying equipment may be half of the total equipment and the drying cost more than half of the total cost.

Hooper pneumatic jig (Fig. 5) consists of a stationary adjustably-inclined deck (*a*) covered with broadcloth (or other porous material) supported on slats (*b*). Above the broadcloth are carried two sets of metal riffles (*c*), the lower set, ¼ in. high spaced 1 in. running toward one side while the upper set, 3½ in. high spaced ¾ in. run toward the other side. A leather diaphragm (*d*) with flap valves opening upward is actuated by eccentrics on the pulley-driven shaft (*e*), thus causing air to pulsate upward through the broadcloth. Feed is introduced into hopper (*f*), stratified according to the specific gravity of the particles by means of the pulsating air current and travels generally down slope toward the discharge chute the lower and upper strata being guided toward opposite sides by the riffles. Splitters are provided at the discharge end to separate concentrate, middling and tailing.

This machine was first developed to concentrate graphite, but has been displaced in that service by froth flotation. At the NORTH RIVER GARNET Co. (Sec. 2) it is used to separate garnet from feldspar and hornblende at 30- to 68-mesh sizes.

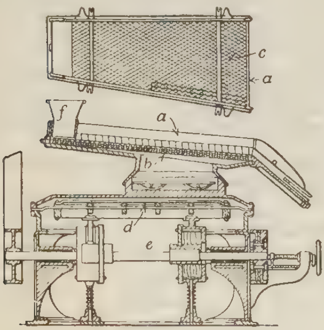

FIG. 5.—Hooper pneumatic jig.

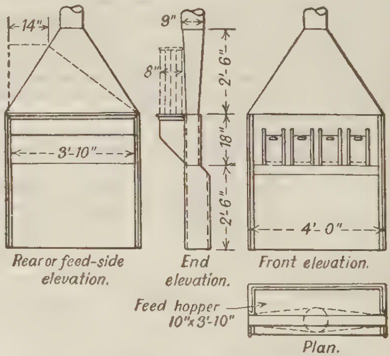

FIG. 6.—Sutton, Steele and Steele aspirator.

Air classification. ASPIRATOR (Fig. 6) (made by Sutton, Steele and Steele) used by ST. LOUIS ROCKY MOUNTAIN AND PACIFIC Co. (*23 CA 794*) to de-dust −1/16-in. bituminous coal consists of an enclosed chute, 1 in. deep by 30 in. wide, sloping 50° to the junction with a vertical chute which narrows down at the junction to the same dimensions but widens above to form a 10-in. circular pipe leading to a suction fan, and below to the discharge. The air velocity at the junction is about 7000 ft. per min. and nearly all dust smaller than 60-mesh is removed.

Gayco separator (Fig. 7) is fed at (*a*) onto the rotating plate (*b*) which distributes the solid in a thin roughly horizontal sheet across the annular space (*c*). A current of air, circulated by the fan (*d*) enters through the vanes (*e*) and rises through space (*c*) at such a rate that all but the coarsest material is lifted; the coarsest drops and passes out at (*f*). The rising current is given a definite swirling motion by the rotating vanes (*g*) and, due to centrifugal action, the coarser solids are thrown against the walls (*h*) and pass out through (*f*); the finer rise up into the main fan zone where a stronger whirl throws most of the solid against the walls (*i*), down which it settles and passes out

through (j). The usual speed of the spindle carrying (b), (d) and (g) is 160 r.p.m. Sizes run from 30-in. outside diameter (laboratory machine) to 14-ft. Power requirement (maker's rating) is ¼+ hp. for the 30-in. size; 6 hp. for the 8-ft., and 12 hp. for the 14-ft.

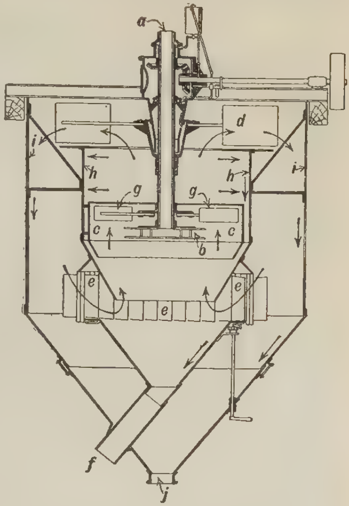

Fig. 7.—Gayco separator.

At Eastern Magnesia Talc Co. the capacity of a 14-ft. machine sizing tripoli is 1600 to 2000 lb. of feed per hr. when the fine product is 99.5 per cent. −325-mesh; 2000 to 2400 lb. for 97 per cent. −325-mesh; 2400 to 3000 for 90 to 92 per cent. −325-mesh; 4000 to 5200 for 99.7 per cent. −140-mesh and 80 to 85 per cent. −325-mesh. This machine had to be speeded up above the recommended speed in order to get the desired grade and capacity; the grade drops off with decreased speed and the product is non-uniform with light feeding. At W. H. Loomis Talc Corp., Gouverneur, N. Y., a 14-ft. machine produces about one ton per hr. of 99 per cent. −325-mesh short-fiber talc; feed runs upward of 50 per cent. of −325-mesh material; the performance is affected to some extent by the weather. The manufacturer's rating for limestone, cement, etc., separating at 85 per cent. −200-mesh is 15 to 20 tons per hr. on the 14-ft. machine; the 10-ft. machine has about half of the capacity of the 14-ft., and the 8-ft. about one-third.

Air-sand process for coal separation (U. S. pat. 1,534,846; *PP 1561-F A*) is a sink-and-float method of separation in which the separating medium is fine sand, supported on a porous medium and maintained in semi-fluid state by means of air forced through the bed. Using −20-mesh silicious river sand and sufficient air to make the mass fluid without "boiling," the density of the sand-mass is about 1.45, as tested by a spindle hydrometer. The air pressure required for this density is 1½ to 3 in. of mercury, according to the porosity of the permeable diaphragm and the thickness of the sand layer. A testing apparatus used by the Bureau of Mines is shown in Fig. 8. The small pneumatic tube (Sec. 22, Fig. 21) may be used for smaller tests. Fig. 9 shows diagrammatically a layout suggested for continuous operation. Table 4 shows results of a test on −3 + 2-in. Illinois bituminous

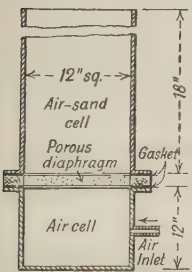

Fig. 8. — Laboratory apparatus for air-sand concentration (*after Fraser and Yancey*).

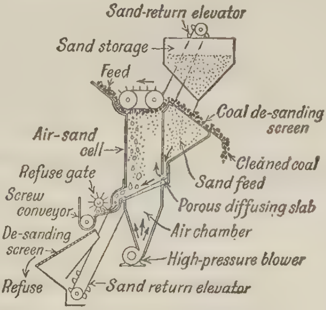

Fig. 9.—Proposed lay-out for continuous air-sand separation (*Fraser and Yancey*).

Table 4. Results of air-sand separation. (*After Fraser and Yancey*)

Product	Weight, pounds	Yield, per cent.	Ash, per cent.	Sulphur, per cent.

Cleaned coal....	54.4	87.3	9.9	4.57
Refuse.........	7.9	12.7	44.9	16.56

coal. A 2-compartment jig treating the same coal made a yield of 82.6 per cent. washed coal assaying 10.3 per cent. ash. The sink-and-float yield on the feed was 90.4 per cent. assaying 9.9 per cent. ash.

3. Greased-surface concentrators

Greased-surface concentrators apply the principle of selective wetting of metalliferous-mineral and gangue particles at greased surfaces, usually in the presence of water. The principle is similar to that of precious-metal amalgamation. (Sec. 15, Art. 6.) The important elements of such apparatus are the mechanical means of presentation of the ore pulp to and removal from the surface, and the character of the grease.

Elmore (703,905/1902) described flowing a thin pulp against an oiled-canvas belt to which oil globules and oiled particles were expected to adhere. The tailing launder was lined with blanket or matting and blanket or matting were floated on the pulp in the launder, the idea being that these would become oiled in time and thereafter catch oiled mineral particles that came in contact with them. Tar and heavy residuum oils and the like and acids were recommended. Foote (744,322/1903) described coating a fixed inclined surface with an oily soap or grease made by mixing petroleum and slaked lime or lime water, and then flowing pulp thereover. Schwarz (807,505/1905) suggested coating an inclined surface with a grease made by mixing a hydrocarbon and sulphur. The hydrocarbons named were paraffin, ozocerite, resin, pitch, asphaltum or any animal, vegetable or mineral oil. A specific mixture cited was paraffin, resin and sulphur. Alkaline, acid or neutral pulp was to be flowed over this surface. Wolf (899,149/1908; 899,478/1908) described coating an endless belt with a viscous mixture made by treating an oil or grease with chloride of sulphur. The same patentee (1,310,492/1919) described a special collecting belt of "woven-hard" duck, soaked with one oil, *e.g.*, a mineral oil, and lightly sprayed with another oil, *e.g.*, a vegetable drying oil, or *vice versa*. Luckenback (1,370,601/1921, 1,448,927; 1,448,928/1923) describes passing pulp over a belt and through a tangled mass of filamentous material coated with a mixture of oil or grease and a resin such as caoutchouc, mastic, shellac, congo, rosin, asphaltum, pitch, etc. Petroleum grease or liquid rubber or a mixture of the two is recommended as a covering compound. The same patentee (1,478,237/1923) recommends an oil or grease and an alkali for surface coating, *e.g.*, petroleum grease, an animal fat or oil and sodium silicate or a mixture of sodium silicate and sodium hydroxide. Addition of liquid rubber makes the coating more adhesive. Dolbear, (1,458,467/1923) suggests coating the mineral by rinsing with water and oil and then flowing the pulp over a metallic surface to collect the mineral. Tin and zinc are given as examples and 10 lb. per ton of pine-tar or coal-tar oil as suitable oils and quantities. Revolving drums are recommended as separating apparatus. Alston (1,534,481/1925), describes a revolving drum with inner surface coated with a fatty, oily or greasy collecting substance.

The only instance of successful commercial application of greased-surface concentrators is in diamond milling (see Sec. 2, Art. 15).

4. Granulation

This term describes a phenomenon that may be observed when certain finely-crushed minerals, *e.g.*, sulphides or coal, are stirred together with a relatively large amount of oil in the presence of water. Under such circumstances the minerals form with the oil a coherent mass or masses whose consistency depends upon the kind of oil, the relative quantities of oil and mineral, and the character of the stirring. The ordinary rock-forming minerals do not similarly granulate, hence if these are present, separation may be effected after granulation by screening or by ordinary gravity-concentration methods.

Tunbridge (228,004/1880) was the first to mention this property of metallic substances. He applied it to the separation of metals such as gold, silver and alloys in suspension in water, by means of soaps which were caused to coagulate and collect the metals, upon agitation and the addition of a salt such as sulphate of lime, or an acid. The coagulum was thereafter separated by filtration through wood shavings, sawdust, straw or the like. Everson, (348,157/1886) described dry mixing of sulphide (and oxide) ores with any one of a large variety of oils or compounds of oils or fats to form a mass of doughy consistency, and thereafter kneading or stirring this mass in acidulated water, as a result of which operation the

rocky minerals were expelled from the oily mass and a coherent mixture of oil and mineral remained. If the kneading has been slow, the oil-mineral substance is in relatively large masses readily separable from the dispersed rocky particles by screening or settling in water. If vigorous stirring has been used, the oil-mineral matter will have considerable air in it, and will either float or, on a Wilfley table, come off below the sands. CATTERMOLE (763,259; 763,260; 777,273; 777,274/1904), came nearer to success than either of his predecessors. His process consists essentially in violent agitation of a freely-flowing pulp of finely-pulverized sulphide ore to which has been added an amount of oil usually between 20 and 100 lb. per ton of solid. Acid in an amount equivalent to 0.2 to 1 per cent. on the water and heat both aid the operation. An ore containing upwards of 10 per cent. mineral is necessary for the best performance. Granulation ordinarily takes place in from 3 to 10 minutes and gentle rolling of the pulp thereafter causes increase in size and firmness of the granules. Under the best conditions these granules are 1/16- to 1/4-in. diameter and sufficiently firm and dry to be readily handled. Separation of granules from the gangue may be effected on a screen or shaking table or in a hydraulic classifier. The Cattermole process was tried for the treatment of zinciferous dump tailing at BROKEN HILL, Australia, but was discarded for the reason that in the attempt to cut down on oil consumption a practical method of operating the agitation-froth process was discovered.

The physical phenomena underlying granulation are the same as those acting in agitation-froth flotation, *viz.*: preferential coating of the mineral particles with oil followed by gas precipitation on the oiled particles. Subsequently excess oil meets and spreads on the mineral-coated bubbles, and when the oil coating becomes sufficiently thick, most of it, together with the mineral, which has been displaced to the oil-water interface, slips off the bubble like a sheath. This sheath is relatively viscous by reason of the solid coating and rolls up, under the swirling action of the pulp, into the characteristic granule. The loaded air bubbles and viscous sheaths may be observed readily by taking test-tube samples during the course of a Cattermole test and examining before a binocular microscope.

DARLING (763,859/1904) pointed out that carbonaceous materials mix with oil to "form a buttery and homogeneous mass, with which the earthy or other materials occurring in the mixture do not associate" and that separation may be made by mixing the oiled mass with water and screening. He described application of his process to a graphitic ore, using crude petroleum, and to finely-powdered coal, coke or charcoal. SCHWARZ (807,501 to 807,503; 807,505; 807,506/1905) described granulation of sulphides with normally-solid hydrocarbons, the mixing being effected with the hydrocarbon in melted condition and hardening brought about by cooling.

Trent (1,420,164/1922) describes the granulation process applied to coal. He recommends the use of liquid hydrocarbons, specifically fuel oil, crude oil (petroleum), gasoline and benzol in amounts up to 50 per cent. of the carbonaceous content of the solid feed. The feed should generally be ground to pass 100- to 200-mesh. This process differs from that of Darling in that mixing of the oil and carbonaceous material is done in the presence of water while Darling mixed dry.

A small amount of oleic acid greatly improves the operation of the Trent process.

Performance. Table 5 shows the results of an exhaustive series of tests made by the Bur. of Mines (*20 CA 172*).

Feed was crushed to 65-mesh, then ground in a 50-per cent. pulp in a laboratory ball mill for 6 hours and then agitated with the oil in a 25-per cent. pulp. The oil used was a Navy fuel oil (petroleum residuum), 0.875 sp. gr. (30° Bé.), running 125 sec. at 25° C. in a Saybolt viscosimeter. The table shows excellent recovery of combustible, and in most cases, a cleaned coal low in ash. In general the sulphur reduction is negligible. For the 17 tests it averages an actual reduction of 0.17 per cent. and a percentage reduction of only 8.8 per cent., although in three cases the percentage reduction lies between 30 and 48 per cent. Supplementary tests on a high-sulphur coal (*j*) to study the behavior of the sulphur showed that of the total sulphur in the coal, amounting to 4.75 per cent., 3.01 per cent. (on the coal) was pyritic, 0.36 per cent. sulphate and 1.37 per cent. organic. The cleaned coal contained

a Corrected per cent. ash $= 1.08A - \frac{21}{40}S$ where A and S are percentages of ash and sulphur respectively, as determined by proximate analysis. Parr (*5 IEC 523*) suggests:

$$\text{Corrected per cent. ash} = A_w - 3C + \frac{5S}{8} + 0.08\left[A_w - \left(\frac{34C}{3} + \frac{10S}{8}\right)\right],$$

where A_w = percentage of ash as weighed after ignition at 750° C. with addition of H_2SO_4; C = percentage of carbon appearing as carbonate in the unburned coal, and S = percentage of sulphur in unburned coal. *b* Anthracite culm. *c* Anthracite culm from Hudson Coal Co. *d* Anthracite, Rhode Island. *e* Pulverized bituminous coal. *f* Run-of-mine bituminous coal. Allegheny Steel Co., Avenue mine, Pa. *g* Bone-coal refuse from same washery. *h* Illinois bituminous, run-of-mine, Superior Coal Co. *i* Indiana bituminous, run-of-mine, Vandalia Coal Co. *j* Oklahoma bituminous, run-of-mine, Folsom Morris Coal Mining Co. *k* Washington bituminous, run-of-mine, Wilkeson Coal and Coke Co. *l* Bituminous-washery refuse, Phelps-Dodge Co., New Mex. *m* Bituminous-washery refuse, Durham Coal and Iron Co., Tenn. *n* Bituminous-washery refuse, Black Creek Coal Co., Ala. *o* Washington sub-bituminous, Pacific Coast Coal Co. *p* California lignite, McKissick Cattle Co. carbonized at 500° C. *q* Texas lignite, Bertetti Coal Co. carbonized at 500° C. *r* Brazil bituminous.

2.10 per cent. pyritic sulphur, representing 47 per cent. of that in the feed. Sulphate sulphur in the cleaned coal was 0.15 per cent. while organic sulphur increased to 1.50 per cent. Similar tests on coal (*c*) showed only 5.5 per cent. of the original pyritic sulphur in the cleaned coal, but the sulphate sulphur as well as the organic sulphur in this product increased. The normal tendency is, of course, for pyritic sulphur to go with the oil. If it does not do so, it is probably because it is too coarse or because it is tarnished. Sulphate sulphur should ordinarily decrease and organic sulphur, being, probably, molecularly mingled with the coal structure, naturally goes with the coal. Some tests on artificial mixtures of coal and pyrite indicate maximum sulphur reduction at 200-mesh maximum size with smaller reduction on − 100-mesh and on − 600-mesh feeds.

Oils. A series of tests with carbon disulphide, benzine, carbon tetrachloride, gas oil, fuel oil, and two cylinder oils indicated that the results with the first four oils, whose viscosity was 40 sec. Saybolt and less, were cleaner coal and better ash reduction than with the oils of higher viscosity, but more combustible is lost with the former oils, and considerably more oil is necessary. Details of the results of tests on several coals with residuum and gasoline are given in Table 6 (*22 CA 913*). Table 7 shows comparative results with several oils on the same coal.

Table 6. Comparative results of Trent process with viscous and mobile oils. (*f*)

Table 7. Performance of Trent process with several oils. (*After Ralston*)

Oil	Relative viscosity	Ash, per cent.		Coal recovery, per cent.
		Feed	Granules	
Gasoline	0.95	25.9	8.0	91.8
Crude benzol	0.97	25.9	9.4	90.9
Kerosene	1.0	25.9	9.5	93.1
Stove oil (30°)	1.3	25.9	9.6	95.9
Crude oil (25°)	5.0	25.9	11.8	96.7
Residuum (18°)	50.0	25.9	12.2	97.4
Asphaltum (10°)	Very high	25.9	13.5	98.2

The best amount of oil to be used was found by Perrott and Kinney to be from 0.3 to 0.4 lb. per pound of clean dry coal, the higher figure corresponding to the finest feeds. The amount necessary to effect good granulation can be reduced to between 3 and 5 per cent. on the feed by adding a small amount of oleic acid or pine oil to the petroleum.

Moisture in cleaned coal. According to Perrott and Kinney a cleaned coal consisting of ⅛-in. granules will retain 10 to 15 per cent. of moisture after draining; if the granules are very fine, the moisture content will run up to 30 or 40 per cent.

Size of granules depends upon the amount and kind of oil, the size of feed, the intensity and duration of agitation and the kind of coal. It can also be controlled to some extent by varying the acidity of the pulp water and by rolling or slow stirring after the granules have first formed.

Time of agitation was found to be proportional to moisture content. The time necessary for initial segregation and granulation of the coal varied from 0.5 to 30 min. with variations in moisture content of raw coal from 1.50 to 10.93 (see Table 5) while the lignites with

15 and 27 per cent. moisture could not be granulated until after carbonization; drying at 110° C. was ineffective. In general, coals containing more than 3 or 4 per cent. of hygroscopic moisture were difficult to treat.

Size of feed. An exhaustive series of tests with feeds ground to 65-, 200- and 600-mesh indicated that the percentage of ash reduction was, in general, greatest with the finest grinding and that with low-ash bituminous feeds it was necessary to grind to 600-mesh to affect any useful ash reduction. With high-ash bituminous feeds 65-mesh was fine enough in some cases, while with others and with the anthracites it was necessary to grind to 200-mesh but not to 600-mesh. Table 8 shows incidentally the effect of difference in feed size on ash content of granules.

Table 8. Comparison of performances of Trent process and agitation-froth flotation on Pacific Northwest coals.(*f*) (*After Ralston*)

Coal	Trent process, per cent.				Flotation, per cent.	
	−300-mesh feed(*f*)		−65-mesh feed(*f*)		−65-mesh feed(*f*)	
	Granules, ash	Coal recovery	Granules, ash	Coal recovery	Froth, ash	Coal recovery
a	9.0	99.5	13.5	99.0	13.8	90.4
b	10.6	98.0	13.5	98.0	15.5	80.0
c	12.2	98.0	16.3	96.0	18.4	90.0
d	15.8	99.5	18.0	98.5	18.8	96.0
e	7.7	99.5	10.8	99.0	10.7	97.0

a, b, c, d, e See same letters, Sec. 12, Table 45. *f* For analyses of feed, see Sec. 12, Table 45.

Trent process *vs.* agitation-froth flotation. Table 8 shows comparative results of a series of tests by different investigators by the two processes on the same coals. At 65-mesh, which was as fine feed as the agitation-froth process could successfully treat, the ash contents of the concentrates from the two processes were not greatly different, but when the feed was ground down to 300-mesh and more ash was freed, the Trent process rejected it and obtained better concentrate. Neither process is, as yet, worked out generally with respect to coal washing. The fact that Trent granules may be substantially dewatered by simple screening and draining while flotation concentrate requires thickening, filtering and partial drying or else granulation similar to the Trent treatment is, of course, in favor of the former. On the other hand, the Trent product is not easy to store, ship or handle under boilers when cheap oil is used and left with the coal and, if expensive oil is used, it must be removed by low-temperature distillation, which is, of course, a charge against the process. Direct comparisons are not available.

Trent (1,421,862/1922) suggests using pulverized coal and hydrocarbon liquid together in treating ores by granulation, claiming thereby to get cleaner concentrate than is possible by froth flotation and further that the fuel for smelting will be incorporated in the concentration process. He suggests, also, using the process to clean flotation concentrate and for the separation of the metallic content of iron- and steel-mill flue dusts.

5. Electrostatic concentration

Electrostatic concentration employs the difference in electrical conductivity of minerals to effect separation. Fig. 10 illustrates two methods of application; in (*a*) the good conductors immediately upon making contact with the roll take on like charges and are repelled, the poor conductors require a longer time to become charged and therefore, in the short time that they are

in the electrical field, are substantially unaffected and fall directly downward. In (*b*) a stream of charged air particles goes from the charged wire toward the grounded roll and charges particles on the face of the roll. In the case of conducting particles the charge is transmitted immediately to the roll and ground; they are therefore unaffected and fall normally; poor conductors become charged by the stream on the face toward the wire, this charge induces a charge of unlike sign on the adjacent face of the roll, the particle is attracted and held until the charges dissipate by conduction or until the clinging particles are mechanically swept away. Fig. 10 (*a*) shows the principle of the early Blake-Morscher machines which were impractical and unreliable; the Huff machines utilize the principle shown in (*b*). All sulphides except pure blende, all native metals and most metallic oxides class as good conductors; all other common minerals as poor conductors. The forces acting are those between electrical charges, and their magnitude is a function of the surface expanse of the individual particles, hence surface must be large in proportion to weight, *i.e.*, the particles must be small, say, −10-mesh; close sizing is necessary for clean separation.

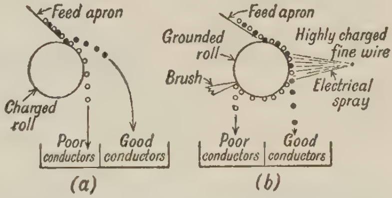

Fig. 10.—Principles of electrostatic separation.

Application. The process has found but little use in the mills. The best known installation was that at the Midvale plant of U. S. S. R. & M. Co. (see p. 177) for separating pyrite from blende; it has now been replaced by differential flotation.

Dielectric separation is proposed by Hatfield. The underlying principle is that particles whose dilectric constant (specific inductive capacity) is greater than that of the medium by which they are surrounded are attracted toward electrically charged points in the medium and *vice versa*, in a way entirely analogous to the action of paramagnetic and diamagnetic particles respectively in a magnetic field (Sec. 13, Art. 1). The dielectric constant of good conductors *e.g.*, the ordinary metallic minerals, is high and that of poor conductors, such as the ordinary gangues, is generally less than 10; by using a medium such as a mixture of nitro-benzene (dielectric constant, 36.4) and kerosene (2.4) any desired dielectric constant between the two can be obtained (in proportion to the respective parts of each in the mixture) so that with a given mixture of minerals such a medium can usually be made with an intermediate dielectric constant in which finely pulverized particles can be separated, the particles with high constant collecting on charged points. Single-phase alternating current of about 200 volts and 100 frequency is suitable for charging the collecting plates.

The process is at present nothing more than a laboratory expedient; it gives little practical promise on account of the high expense of the medium. For details of laboratory procedure see *33 IMM 335 and 343.*

SECTION 15

HYDROMETALLURGY

BY

R. C. CANBY, CONSULTING METALLURGIST, WALLINGFORD, CONN.

1. Introduction

Hydrometallurgy is the art of recovering metals from ores by first effecting solution of the metal or metals in the form of a salt, separating the solution from the impoverished solid, then decomposing the metallic salt in such a way as to cause precipitation of the metal in a state of comparative purity. The solvent is usually regenerated in the precipitating reaction. The LIXIVIANT (leaching solution) is invariably an aqueous solution.

Hydrometallurgy is substantially never an economic alternative to either concentration or smelting; rather it is applicable to ores of too low grade to be smelted economically and of too small metal content or with the metal in such mineralogical combination as to render it not amenable to concentration.

Gold, silver and copper are the metals whose ores are most commonly treated; zinc concentrate is treated in fairly large amounts at two plants; lead has been the subject of much experimentation but of little or no economically successful operation. This is due, not to lack of amenability of lead ores but rather to the fact that lead ore has peculiar value in smelting other ores, and hence gets favorable rates from the smelters, while gold or copper ores of the types suitable for hydrometallurgical treatment are costly to smelt.

In substantially all cases it is necessary that the metal before dissolving be in an oxidized or metallic state, either naturally, or so rendered by roasting or the use of oxidizing solutions, the possible exceptions being precious-metal tellurides and selenides and silver sulphides. The ores usually treated are those containing metallic gold and silver; carbonate, oxide or metallic copper and, less frequently, copper sulphide or copper silicate; zinc sulphide (this must first be roasted); lead carbonate, chloride and oxide.

The fundamental operations are the same in all hydrometallurgical processes, irrespective of the metal or solvent used, and may be classified as (1) PREPARATION for solution, including crushing and, if necessary, oxidation or reduction to a soluble state; (2) solution in a suitable, generally dilute, lixiviant (LIXIVIATION); (3) separation of pregnant solution from leached solid (WASHING); (4) PRECIPITATION of the metal; this may require preliminary PURIFICATION of the solution.

2. Preparation

Crushing is necessary in order to permit access of leaching solution to the metallic-mineral particles, and, in the case of ores requiring roasting, to facilitate this operation. The SIZE necessary for successful leaching varies with different ores; caved copper ore in the mine is leached at OHIO COPPER Co. and few copper ores are crushed smaller than ⅛-in.; gold and silver ores must, on the other hand, substantially always be crushed to 40- to 60-mesh and in many cases to 200-mesh. In most cases recovery increases with increased fineness of grinding and the rate of solution likewise increases. Decision as to proper size is, therefore, a balance between increased crushing cost on the one hand and increased recovery and saving in leaching-plant equipment and operation on the other.

Crushing and grinding machinery is described in Secs. 3 and 4.

Cost of crushing to ¼-in. should not exceed \$0.06 to \$0.10 per ton in large plants nor double these amounts in smaller plants. Crushing and grinding to, say, 48-mesh costs from \$0.30 to \$0.50 per ton in large plants and \$0.40 to \$0.75 in small; to 200-mesh the costs will exceed these by 50 to 100 per cent.

Roasting is rarely practiced except on zinc ores, in which case a high-temperature oxidizing roast is employed. Certain high-grade sulphide and sulpho-telluride gold ores (CRIPPLE CREEK) are roasted but the same extraction would be possible with finer grinding *(14 CME 205)*. An oxidizing roast for copper sulphides and a reducing roast for silicates is promising theoretically but, in general, is not commercially practicable on account of the large bulk of barren rock that must be heated. Chloriziding roasting has a limited application to lead-silver ores prior to brine leaching.

Oxidizing roast. The reaction starts at about 350° C. with pyrite according to the following simplified equation: $2FeS_2 + 11\ O = Fe_2O_3 + 4SO_2$. Lead, copper and zinc oxidize, with increasing temperatures, in the order named, thus: $PbS + 4\ O = PbSO_4$ or $6\ PbS + 23\ O = 6PbO + 5\ SO_3 + SO_2$; $CuS_2 + 2\ O = CuS + SO_2$; $CuS + 3\ O = CuO + SO_2$; $ZnS + 3\ O = ZnO + SO_2$. The final temperature for a zinc roast should run up to from 700 to 780° C.; for copper about 590° C. should be the maximum.

Whether the end product is a metallic oxide or sulphate depends to some extent on the concentration of SO_2 in the interstices of the charge; high concentration with gentle rabbling produces more sulphate, vigorous rabbling and strong draft, more oxide.

Chloridizing roast is carried on at moderate temperature in a neutral atmosphere in the presence of a chloride, usually of an alkali or an alkaline earth. The end sought is conversion of sulphides of copper, lead and silver into chlorides; at the same time the metal of the original chloride is changed into sulphate. Loss of lead and precious metals by volatilization is serious unless the temperature is kept low. Experiments are at present under way on low-grade oxidized lead ore at CERRO DE PASCO involving low-temperature batch roasting in Holt-Dern furnaces with a chloride and recovery of the lead by electrolytic precipitation. This process aims to eliminate volatilization losses by low temperature in the initial roast and elimination of smelting.

Reducing roast is one performed at low to moderate temperatures in an atmosphere of carbon monoxide. The object is to reduce the desired metal (copper, in so far as present hydrometallurgical processes go) to the metallic state. The reducing roast has a most important application at present in the preparation of oxidized and copper-silicate ores for ammonium carbonate leaching. At the BWANA M'KUBWA pre-heated ore is treated in a gas-locked cylindrical reducing furnace, fitted with an internal spiral to regulate time of contact *(119 J 838)*. Producer gas flows counter-current to the ore and is not ignited. The ore enters the furnace at a temperature of 540° C. *(120 J 852)*.

Roasting furnaces. For descriptions of various furnaces see: *The metallurgy of non-ferrous metals*, Wm. Gowland, Griffin, Lond., 1921. *General metallurgy*, H. O. Hofman, McGraw-Hill, 1921. Multiple-hearth furnaces of the MacDougall type, *e.g.*, the Herreshoff, Wedge and Skinner, are the principal ones used for hydrometallurgical work in North America. CAPACITY of roasting furnaces in hydrometallurgical practice is not yet generally established but known capacities correspond sufficiently with those in roasting for smelting, to justify use of the latter standards, which follow *(92 J 1271)*:

Method of roasting	Lb. per sq. ft. of hearth area per 24 hr.
Roast heaps and stalls	5 to 20
Reverberatory roasters:	
(1) Hand rabbled	24 to 35
(2) Mechanical, average	33 to 75
(3) Mechanical, special conditions	150
(4) Revolving cylinders	128
Blast-roasting pots	500 to 900
Average	600
Blast roast in layers:	
(1) Intermittent down draft	1000 to 2000
(2) Continuous	2200 to 3000
McDougall (7-hearth, 20-ft.) average	60
At Great Falls	37

Removal of impurities prior to leaching is rarely practiced; such practice as exists has been in cyanidation. Substances which consume cyanide (CYANICIDES), particularly oxidized copper minerals; partly oxidized sulphides of zinc, iron and copper; tellurides, arsenides and antimonides; mineral acids and their basic salts and organic material will, if present in any considerable quantity, render an ore unamenable economically to cyanidation. Sulphides can be removed by concentration; small quantities of free or latent acid can be neutralized by lime; larger amounts of acid may require a preliminary wash with water or alkaline solution; oxidized copper minerals require an acid wash. Graphite causes re-precipitation of gold; it has been successfully removed by flotation.

3. Lixiviation

Lixiviation is the operation of effecting contact between the ore to be leached and the leaching solution. Two general methods are used, *viz.*: (1) circulation of solution through a stationary ore mass (PERCOLATION); (2) stirring of a mixture of ore and solution (AGITATION). The second method is clearly applicable only to ores in finely-pulverized state; the first may be practiced on either coarse or fine ore, according to the method employed.

Percolation is applied to caved ore standing in the mine (LEACHING IN PLACE; OHIO COPPER CO.), or to run-of-mine ore piled in heaps at the surface (HEAP LEACHING; RIO TINTO; ARIZONA COPPER CO.) or to crushed granular ore ranging in maximum size from 3/8-in. (NEW CORNELIA) to 80-mesh for oxidized ore and 100-mesh for unoxidized ore at HOMESTAKE (TANK OR SAND LEACHING). When the nature of the ore is such that percolation is applicable, *i.e.*, when an economic amount of valuable mineral is exposed and soluble at sizes permitting relatively free circulation of leach liquor and air through the standing mass, this is the cheapest method of operation, since it eliminates the cost of fine grinding and the power required for agitation.

Rate of percolation. Two and one-half to 3 in. per hour is good; 1½ to 2 in. is fair; ¾ to ½ in. indicates a condition unsuitable for percolation. Vacuum may be used to hasten the rate.

Filter leaching is a form of percolation applicable either when the ore is very readily leachable or when pressure in excess of atmospheric is desirable for solution. A cake of finely pulverized ore is formed on a filter leaf (see Sec. 17) and leach solution is passed through (usually alternating with air or steam) until the desired solution is effected.

Agitation is the usual method of leaching finely-pulverized ore. The purposes of pulp movement are: (1) to effect continuously changing contact of mineral and solution and (2) to entrain oxygen. Agitation in crushing and in the flow of pulp through launders, pumps, elevators and the like is highly

effective, hence leach solution is frequently added to the grinding mills. Special agitating devices include mechanical and pneumatic means.

Mechanical agitators include tanks with reciprocating or rotary stirring mechanisms, revolving drums containing a multitude of small tumbling bodies, centrifugal pumps and mechanical classifiers. The important feature of such devices from the solution standpoint is that they cause thorough and continuous splashing of the pulp, which effects aeration. PNEUMATIC AGITATORS have been most widely used. The PACHUCA TANK is typical. It consists essentially of a vertical cylindrical tank with cone bottom, 35 to 55 ft. high, 7½ to 13 ft. diameter, with an air-lift (see Sec. 20, Art. 15) about one-tenth the diameter of the tank, extending from about 18 in. above the bottom of the cone to within 18 in. of the top of the tank. The lift itself aerates the pulp and the lifted pulp splashes against an umbrella above the lift pipe and falls back onto the pulp surface outside, thus entraining more air. Common operating limits are: 4 to 88 cu. ft. of free air per min., 22 to 33 lb. pressure, ⅛ to 1¾ hp. and 15 to 110 tons daily capacity. (*97 P 424*.) The PARRAL TANK is a flat-bottomed tank with a plurality of air-lift columns which may be readily installed in any flat-bottom tank (*42 A 819*). Combined mechanical and pneumatic agitators are typified by the DORR. Diagonally-placed slow-moving ploughs on horizontal rotating arms move settled slime to an axial conduit which acts as an air-lift column, and delivers the pulp onto rotating distributing launders. In the HENDRIX agitator the pulp is raised through a central column by propeller blades, assisted by an air-lift.

Leaching solution depends, of course, on the metal (or mineral) to be dissolved. CYANIDE of potassium or sodium is used for gold and silver (other solvents such as CHLORINE for gold and SODIUM HYPOCHLORITE for silver have had some little vogue but are not used at present); SULPHURIC ACID is used for copper carbonates, sulphates, oxides and the like and for roasted zinc concentrate; FERRIC SULPHATE, for copper sulphides and oxides; AMMONIA (actually ammoniacal cupric carbonate) for native copper; and brine (usually acidified) for lead and silver.

Strength of solution is dependent upon the ore and solvent chemical and is also related to the time available, fineness of grinding, temperature, and a number of other minor elements of plant operation. It was early thought that very weak CYANIDE solutions dissolved gold and silver selectively. While this is not actually so, there is lessened efficiency in solutions exceeding 0.25 per cent. KCN and marked increase in cyanide consumption. MacFarren (*Practical stamp milling and amalgamation*, Min. and Sci. Pr., San Francisco, 1914) points out that the normal oxygen content of cyanide solution decreases as the strength increases, but that if oxygen is supplied, strong solutions dissolve faster than weak. At HOMESTAKE the essential factor seems to be the passage of a definite volume of solution through the slime cake, rather than treatment with a solution of definite strength or for definite time (*52 A 15*). With SULPHURIC ACID increase in solution strength causes increase in rate of solution but the gain may be more than offset by increased solution of alumina, iron, etc., which do not regenerate in precipitation and therefore waste acid. These dissolved metals may also affect electrodeposition unfavorably, as in the case of copper. In the high-acid process for roasted ZINC ores, the increased solution of silica and iron facilitates filtration and keeps the anode free from incrustation during electrodeposition. With acid ferric sulphate much excess of ferric iron over 1 per cent. decreases current efficiency in electrodeposition.

Strength is expressed in per cent. or in pounds per ton of lixiviant. Usual strengths of various lixiviants are as follows: CYANIDE (generally expressed in terms of KCN): for gold, sand leach, 0.1 per cent.; agitation leach, 0.05 per cent.; for silver, sand leach, 0.1 to 0.3 per cent.; agitation leach, 0.05 to 0.15 per cent. In certain cases much greater strength is used, *e.g.*, REAL DEL MONTE (0.45 per cent.) and in ONTARIO. Leaching concentrate requires solutions up to 0.75 per cent.

SULPHURIC ACID for copper ores, 2 to 10 per cent.; for zinc, 5 to 15 per cent. Tainton (*U. S. Pat.* 1,891,498) proposes 28 to 30 per cent. for zinc. ACID FERRIC SULPHATE: On

INSPIRATION ORES; copper sulphate, 2.5 to 3.5 per cent.; total iron, 1.5 to 2.5 per cent. (ferric up to and somewhat higher than 1.0 per cent.); free (sulphuric) acid, 3.5 to 7.5 per cent. (*73 A 58*).

AMMONIA (NH_3) for copper, sand leaching, 1.25 to 5.0 per cent. with about the same amount of CO_2 (*70 A 395*; *120 J 849*). In the ammonia process constant strength is maintained by removal of copper (*70 A 602*).

The necessary time of contact with lixiviant is affected by a number of factors; principally the degree of pulverization, strength of lixiviant, degree of solubility of the mineral or the form in which it occurs, and the effectiveness of contact. In any given case it must be determined by experiment.

In CYANIDING from four hours to six days is required; the majority of cases are between 36 and 72 hours. Dilute SULPHURIC ACID with copper ores: CHILE COPPER CO., 24 hours; AJO, 7 days (*40 A 30*); these are both tank leaching. ACID FERRIC SULPHATE, tank leaching, INSPIRATION, probably 9 days maximum. In heap leaching and leaching IN SITU acid ferric sulphate leach extends over many months or even into years. In the AMMONIA process a solution of proper strength becomes practically saturated in one passage through fresh sand (*70 A 595*).

Heating is unusual with sulphuric acid or cyanide solutions. Tainton recommends heating to 60° C. in leaching zinc calcines with strong acid solution. He estimates coal consumption at 1 ton per 20 tons of zinc produced, if the return electrolyte is at 30° C. (*PP 1301-M A*). The rate of solution of metals in cyanide solutions increases with rise of temperature. Heated solutions are used on silver ores at TONOPAH, but in most cases the increased cyanide consumption more than offsets the increased rate of extraction. Ferric sulphate and ferric chloride solutions are usually applied hot but at the INSPIRATION experimental plant commercial results have been obtained at atmospheric temperature. Brine for lead leaching is heated to at least 75° C., when precipitating on dense iron, but 30° C. is sufficient for precipitation on sponge iron (*PP 1281-M A*).

Aeration is an essential element in leaching precious-metal ores with cyanide or copper-sulphide ores with ferric salts. In percolation it is most effectively performed by forcing air through the charge; in agitation it is a concomitant of the splash, as previously stated. In cyanidation, oxygen, although not actually entering into the solution reaction, is essential to its consummation; in copper-sulphide leaching the oxygen is an essential part of the reaction, $Cu_2S + 5\ O + H_2O = CuSO_4 + Cu(OH)_2$, which precedes solution of the copper.

Addition agents have been used principally in cyanidation. LIME is used to "protect" the cyanide by neutralizing free or latent acid, consumption ranges from two to about six pounds per ton; sodium peroxide and bromocyanogen have been used as oxidizers in treating telluride ores and ores containing mispickel; lead acetate or litharge is frequently used with silver ores containing sulphides.

Regeneration of solutions. See Art. 5.

4. Washing

After the economic degree of solution is effected it is necessary to separate the pregnant solution from the leached solid in order that the metal, subsequently precipitated, may be collected in a state of comparative purity. Simple draining off in percolation, or filtering or decantation, following agitation, is insufficient separation on account of the valuable liquid that remains with the solid. This liquid must be displaced and collected or so diluted as to constitute a reasonable loss. The operation is called WASHING. The method of accomplishment differs according to the method of lixiviation.

In percolation a succession of batches of solutions of decreasing metal content and eventually barren water are passed through the batch of leached ore. These washes displace and dilute the interstitial remnant from the preceding liquid so that eventually the interstices are filled with a solution containing little more metal than the barren water. If regular advance of solutions through the charge were effected, then in the most unfavorable case, where diffusion and convection kept pace with the advancing wash, the value of the liquor remaining after washing would be $(ab + cd)/(b + d)$ where a and c are the assays of the remnant liquor after the preceding drain and of the wash liquor respectively and b and d are the respective volumes. (Interstitial volume is readily estimated by determining the dry weight of a given volume of drained material and the mean specific gravity of the solid.) If diffusion and convection do not keep pace with the advancing wash, the assay of the interstitial solution after washing will be less than that given by the equation. Usually the advance of solution is uneven and the wash remnant assays higher than calculation indicates.

The volume of barren-water wash is usually limited to the amount of water lost by leakage and evaporation plus that discharged with tailing; otherwise solution accumulates until the tank capacity of the plant is exceeded. In certain cases, *e.g.*, where acid (Chile Copper Co.) or ferric salts build up excessively, a certain amount of solution is discarded periodically after precipitation, in which case, of course, more wash water can be added.

Decantation is the method of washing usually applied to slimes, following lixiviation by agitation. It consists of a succession of the operations of dilution and thickening of the pulp, each successive dilution with a solution of lower metal content, finishing with barren water. The underlying principle is the same as that in washing following percolation, but thorough mixture of solutions is assured. On the other hand a greater proportion of solution to solid is finally discarded unless the tailing is filtered.

Counter-current decantation is a method of continuous operation of decantation washing. It is performed in a plurality of continuous thickeners so arranged that thickened pulp moves in order from the first to the last, while overflowing solution progresses in the opposite direction. The feed to the first thickener is a pulp of strong, rich solution and finely pulverized ore that has been thoroughly leached in the preceding operations; the overflow is pregnant solution ready for precipitation; the underflow is solid plus rich solution; it goes to the second tank. Here it meets and is mixed with solution that has overflowed from the third tank, and which is much lower in metal content than that contained in the thickened pulp. The overflow of the second tank goes to the first and the underflow to the third. Fresh water is added to the last tank, thus effecting the maximum possible dilution of solution discharged with the tailing and furnishing the progressive washes in the preceding tanks.

5. Precipitation

Metal is recovered from pregnant solutions by precipitation. The principal methods are chemical reaction and electrolysis; decomposition by heat is used in the ammonia process, ammonia and carbon dioxide being driven off in a special still and re-absorbed for further use. With one or two important exceptions, the leaching chemical is regenerated by the precipitating reaction.

Chemical precipitation without regeneration is typified by precipitation of copper from sulphuric-acid solutions by means of metallic iron. The reaction

is: $CuSO_4 + Fe = FeSO_4 + Cu$. Theoretically 0.875 lb. of iron is consumed per pound of copper precipitated; actually the consumption is about pound per pound. Subsequent oxidation of ferrous to ferric sulphate produces a copper solvent but not, of course, the original acid. The earliest practice was to use SCRAP IRON, but the consumption would exceed the supply for large-scale operations. PIG IRON may be used. GRANULATED IRON gives a larger surface but is not completely consumed, which is wasteful and contaminates the product. SPONGE IRON, made by reducing oxidized iron compounds (magnetite, hematite, calcined pyrite) with 15 to 50 per cent. of coal, coke, charcoal or other reducing agent in special reverberatory, muffle or retort furnaces at about 1700° F., has been much experimented with. About 1.5 to 1.75 lb. is consumed per pound of copper.

Precipitation on scrap iron is usually done in launders; tanks are more efficient in terms of pounds precipitated per unit volume of container. Precipitated copper is usually loosened by shaking or washing off the scrap; At AJO precipitation is performed in a long rectangular tank and precipitated copper is loosened by agitation of the liquid in the tank by compressed air.

The important factors in iron precipitation are strength of solution in copper and acid, temperature, contact time and velocity of flow of the solution. RATE OF PRECIPITATION decreases with decrease in copper content but at OHIO COPPER CO. solution containing only 0.204 per cent. copper yields 97 per cent. in 40 min. contact. HEAT and HIGH ACID CONTENT prevent precipitation of insoluble salts on the iron with consequent interference with copper precipitation, but since both are costly (the acid is consumed by the iron) it is cheaper to reject foul solution from time to time. The VELOCITY of flow of the solution should be sufficient to prevent precipitation of foreign material on the surface of the iron.

Cost of precipitation of copper on iron ranges from 2½ to 4½ cents per lb. of copper.

Iron is used to precipitate lead from brine solutions. Sponge iron is the best, since it will precipitate at 20 to 35° C. while with dense iron the solution temperature must be at least 75° C.

Chemical precipitation with regeneration. Precipitation of gold and silver from cyanide solution by means of zinc or aluminum results in regeneration of cyanide, probably not in the form of alkali cyanide as originally added, but in a form in which an equivalent amount of effective cyanide ion is present. The metal is added in the form of shavings of the general structure of excelsior, or as dust; the latter is the modern development. When solutions contain the usual amount of dissolved air (oxygen) it is necessary that the cyanide strength be high in order to prevent formation of "white precipitate" (a mixture principally of oxide and ferrocyanide of zinc) on the zinc, which stops the action. The CROWE PROCESS involves de-aeration of the solution before precipitation; this prevents formation of "white precipitate," makes it unnecessary to add cyanide, and greatly increases the efficiency of the zinc. Metal dust is the more convenient form for use in the Crowe process.

Precipitation with zinc shavings is performed in compartmented boxes; the shavings, after dipping in lead acetate (and being thus coated with lead) are packed into alternate compartments and solution is circulated so that it rises through the zinc-filled compartments and flows downward in the others. The boxes are 12 to 24 ft. long, 1½ to 3 ft. wide and 1½ to 3 ft. deep; the zinc compartments are substantially square, the intermediate compartments narrow. CAPACITY is 5 to 15 tons of solution per cubic foot of zinc-compartment space per 24 hr. ZINC CONSUMPTION on the RAND is 0.12 to 0.26 lb. per ton of ore milled.

Metal dust (90 per cent. − 200-mesh, containing, in the case of zinc, upward of 95 per cent. free metal) is mixed with solution in a plunger pump and forced into a plate-and-frame filter press. A small amount of lead acetate aids precipitation. ZINC CONSUMPTION on the Rand is 0.10 to 0.14 lb. per ton milled. In the Crowe process the consumption of metal is about half the above figures (*111 J 624*).

Recovery of cyanide from foul solutions by liberating hydrocyanic acid and re-absorbing the gas in fresh alkaline solution is an old idea. Some recent patents (*U.S.* 1,387,289; 1,486,137) promise successful operation. Both patents specify an acid stronger than hydrocyanic for decomposition of cyanides and both use sulphurous acid; the first (MILLS-CROWE) recommends blowing air through the acidified solution at normal temperature to remove hydrocyanic acid; the second (HALVORSEN), boiling under high vacuum. With such recovery possible much stronger cyanide solutions can be used than formerly with consequent economy and the harmful effect of cyanicides is distinctly minimized.

Sodium sulphide (Fig. 3) and **charcoal** have been used in cyanide precipitation but in isolated cases only.

Precipitation of copper from sulphate solutions by means of iron generates ferrous sulphate which oxidizes to ferric sulphate and thus regenerates the solution.

Electrolytic deposition is the standard method in copper and zinc precipitation; it is used for lead at BUNKER HILL AND SULLIVAN and is being tried for the same metal at CERRO DE PASCO; it has been many times proposed and experimented with for cyanide, and this latter application is the subject of a recent patent of much promise (*121 J 113*). Electrolytic precipitation is invariably regenerative.

Typical general procedure is to clarify the solution, usually by sedimentation; condition it, if necessary, which is usually the case for zinc, so that it is of the proper chemical composition; then flow it through electrolytic cells, between the poles of which suitable current is passing. The desired metal precipitates, and is collected either as an adherent deposit on the cathode (copper and zinc) or as a collection of flakes or crystals (lead and precious metals).

The important elements in operation are current strength and voltage, temperature, concentration of the desired metal and of other substances in the solution, rate of solution flow and the character of anodes and cathodes.

Current. The fundamental consideration is the fact that a given amount of current passing through a solution of a given metal will precipitate a definite amount of that metal. The theoretical maximum amount of a given metal that it is possible to deposit with a given current, at 100 per cent. current efficiency, is $W = 0.0104Aw/v$ mg. where A = the current in amperes, w = the atomic weight of the metal to be deposited and v is the valence of the metal. CURRENT EFFICIENCY is the ratio of the weight of metal deposited to this theoretical maximum, usually expressed in percentage. The lack of effectiveness that such a statement of efficiency may indicate does not reside in the current itself but arises from the solvent action of the electrolyte upon the cathode metal; this dissolving action may counteract the precipitating action of the current to any extent. CURRENT DENSITY is limited, in copper and zinc deposition, by the fact that a smooth, adherent deposit of metal is desired and that excessive current density causes flocculent, spongy or tree-like deposits. (For other factors influencing character of deposit see p. 958.) In copper deposition with the usual solutions a current density of 8 to 10 amp. per sq. ft. of cathode surface has proved best; in zinc cells, with 3.5 to 7.5 per cent. acid content, 20 to 31 amp. According to a recent patent (Tainton, 1,491,498), with 22 to 27 per cent. sulphuric acid present in zinc sulphate solution, and a temperature of 60° C., it is advantageous to use a current density as great as 100 amp. per sq. ft.

Voltage is determined by the composition of the solution and the spacing and

composition of anodes and cathodes. In copper cells with solutions containing about 2 per cent. copper as sulphate, 0.5 to 2 per cent. ferrous iron and about 3 per cent. free acid, which may be looked upon as an average condition, with lead anodes and copper cathodes spaced about 2 in. face-to-face, and with temperatures not exceeding 60° C., the normal voltage drop from anode to succeeding anode is two volts. At TRAIL in zinc cells with 6 to 8 per cent. zinc-sulphate solution at 60° C. and lead anode and aluminum cathode spaced about 2 in. face-to-face, the normal current density for a smooth, adherent deposit is 20 to 31 amp. per sq. ft. and the voltage 3.9.

Cell. The transverse section is determined by the convenient size of cathode; length by the reasonable size of the bus bars. Table 2 shows some recent practice.

Table 2. Size of electrolytic cells

Plant	Length		Width		Depth		Number of	
	ft.	in.	ft.	in.	ft.	in.	Anodes	Cathodes
Katanga	55	7	3	2½	4	3	115*a*	110*a*
New Cornelia	29	7	4	9	4	3	84	83
Chile Copper Co.	18	8	3	5	5	10	56	55
Anaconda	10	3	2	10	5	0	28	27
Cons. Min. and Sm. Co.	6	8	2	3	3	6	17	16

a In five groups.

Cells are usually made of wood lined with sheet lead; reinforced concrete lined with a mixture of sand and sulphur is used at TRAIL (*34 IMM 2*); reinforced concrete and asphalt lining at Chuquicamata (*45 AES 381*).

Anodes are insoluble. Carbon is theoretically ideal but practically, in a non-diaphragm cell with sulphate electrolyte, when the cell becomes polarized and the voltage rises oxidation of iron decreases, gas collects, and the anode disintegrates.

Van Arsdale (U. S. Pat. 1,553,415) proposes a composite anode with exactly the proportion of carbon area, in conjunction with lead or other suitable insoluble anode material, required to oxidize a certain definite amount of ferrous sulphate and leave no destructive excess of anodic oxygen. Lead anodes are satisfactory in sulphate electrolytes free from chlorides and nitrates (*115 J 20*) and are used at NEW CORNELIA, ANACONDA and CONS. MIN. AND SM. CO., but cannot be used at CHILE COPPER CO., owing to the presence of chlorides. Hollow cast magnetite anodes proved too brittle at the latter plant; DURIRON and many other alloys were tried; "CHILEX," essentially an alloy of copper, silicon, iron and lead with a small amount of tin and about 4 per cent. manganese is now used (*45 AES 381*).

Cathodes for copper are copper sheets; for zinc, aluminum, from which the zinc deposit is subsequently peeled off.

Anodes and cathodes are usually hung transversely in the cell, but are placed longitudinally at NEW CORNELIA. (This arrangement was first used by the writer in the KEYSTONE experimental plant in 1913.) SPACING must not be so close that short circuiting can occur because of "trees" or buckling. Glazed porcelain insulators are used at AJO (*114 J 188*). Spacing depends upon the thickness of anode and cathode; with ½-in. anodes, spacing ranges from 5 in. to 4 in. or less. POWER and CAPACITY are affected by the spacing. At CHILE COPPER CO., with ferro-silicon anodes, current efficiency decreased with reduction in spacing from 5- to 4-in.; with CHILEX anodes, increased capacity and proportionately increased power efficiency followed reduction in spacing (*45 AES 381*).

Character of solution. Certain impurities (substances other than the desired salts of the sought-for metal and, in most cases, a residue of the leaching

chemical) have decidedly harmful effect in electrodeposition; *e.g.*, ferric sulphate causes re-solution of precipitated copper; arsenic (one part in 100,000), antimony and cobalt lower current efficiency in zinc deposition (*26 CME 596*); excess of iron prevents smooth deposition of copper; and iron, vanadium, cobalt, nickel, arsenic and antimony must be practically excluded from zinc cells for the same reason; any metal of lower decomposition voltage than the metal to be deposited will deposit and in addition to its effect on purity (which may be negligible), decrease current efficiency and may harmfully affect the character of the deposit; solid particles in suspension cause irregular and non-adherent deposition. Certain other impurities are helpful; thus in copper deposition ferrous salts combine with anodic oxygen and prevent voltage increase from polarization; sulphur dioxide acts similarly and likewise prevents formation of ferric sulphate, which would re-dissolve copper; manganese prevents attack on the anodes in zinc cells; certain colloids, *e.g.*, glue, retard or overcome the harmful effect on deposition of certain impurities (*26 CME 601*) and Tainton (*PP 1301 A*) says that glue, about 3 lb. per ton of zinc precipitated, or some similar colloid, is essential for smooth zinc deposits with high current density.

Removal of impurities. A neutral wash is used for ZINC. It consists in neutralizing the acid in the pregnant solution by addition of roasted ore with either calcium carbonate, zinc oxide or zinc powder, in the presence of manganese dioxide or other oxidizing agent, ferric sulphate and copper sulphate. This operation is usually carried out in a series of Pachuca tanks at 40 to 60° C. The precipitate is separated by decantation and filtration (see Fig. 7). COPPER SOLUTIONS are usually purified by discarding a portion of the solution over scrap iron, as necessary. If the amount of such discard is great, the cost of the operation is seriously increased on account of the expense of refining the cement copper produced.

Oxidized copper agitated with heated cupric sulphate solution at 75 to 80° C. will precipitate salts of iron, arsenic, antimony, bismuth, cobalt, nickel, etc. (*8 MI 192*). Chlorine is reduced to less than 0.5 gm. per liter at CHILE COPPER CO. by agitation of the copper-bearing solution with cement copper; this reduces cupric chloride to cuprous chloride, which is insoluble and is separated by decantation. The cuprous chloride is then dissolved in ferrous chloride and cement copper is recovered by passing the solution over scrap iron (M. D. Thompson, *Applied electrochemistry*, Macmillan, 1914).

Precipitation is the most difficult part of hydrometallurgy; the foregoing text is meant only to give a general idea of the art. For details see *Principles and applications of electrochemistry*, Creighton & Fink, Vol. II, and the recent files of Amer. Inst. of Min. and Met. Engineers, Amer. Electrochem. Soc., and Chem. and Met. Eng.

6. Amalgamation

Amalgamation is the process of collecting metallic gold and silver with metallic mercury. The mixture formed, called AMALGAM, is not completely understood, it is variously called an alloy or compound. Practically the phenomenon of amalgamation may be looked upon as wetting of metals by mercury, as a result of which the metals are drawn into the body of the mercury. The latter can be driven off by heat. Most gold ores yield a certain recovery readily; the tellurides are an exception. If high recovery is obtainable by amalgamation the ore is called FREE-MILLING.

Plates. Amalgamation is usually performed in broad, shallow, sloping troughs in the bottom of which AMALGAMATED (mercury-coated) copper

plates are placed. These are called APRON PLATES. They are usually but not necessarily placed directly after the fine-grinding machines. BATTERY PLATES are those within a stamp mortar. They are rarely used on account of the scour of the pulp and the fact that they necessitate wide mortars with consequent reduction of capacity.

Apron plates are usually 1/8 in. thick; thin plates buckle and cause uneven flow of pulp; if there is much scour, as on battery plates, 1/4-in. plates are used. Usual WIDTHS are 4 to 5 ft. (corresponding to the length of a battery mortar); LENGTH, 8 to 12 ft. The AREA ALLOWANCE, when amalgamation is principally relied upon for recovery, is 3 to 4 sq. ft. per ton of ore per 24 hr. SLOPE is 1½ to 2 in. per ft.

Surfacing plates. Copper is usually plated with silver (1½ to 3 oz. per sq. ft.) and then dressed with mercury or, better, an amalgam of mercury with silver. Sodium amalgam (3 parts sodium to 97 parts mercury) and certain other amalgams such as zinc and cadmium resist surface contamination and are sometimes used for this purpose. Amalgam does not penetrate the plates, hence the kind of copper used makes no difference (*A. J. Clark*, *PC*).

Fundamental requirements in plate amalgamation are: (1) that the precious metals shall be free and have clean metallic surfaces; (2) that they shall be flowed over the plate in a pulp sufficiently fluid to permit metallic particles to sink readily; (3) that the velocity of flow be sufficiently low that the precious-metal particles can sink to the plate surface and yet high enough that other constituents of the pulp cannot remain permanently at rest thereon; (4) that the plate surface be clean and bright; and (5) that the amalgam be sufficiently soft (fluid) to permit it to spread over the metal particles. Bright metallic surfaces are usually obtained in grinding. Pulps normally contain 10 to 20 per cent solids; any higher solid content decreases the mobility of fine particles materially. The velocity and thickness of the pulp stream should be such that the pulp progresses in a series of waves; contact of solid particles with the plate may be increased by drops of an inch or more; amalgam builds up at each such drop. Plate surfaces are best kept bright by keeping grease away, preventing banking, and by brushing, scraping with a rubber, wood or steel scraper, and by scrubbing. If these expedients are insufficient it may be necessary to use special amalgams or chemicals to counteract the particular coating influence. Soluble sulphates, such as zinc and iron, cause crusting on the plate surface with consequent lowering of extraction. Certain minerals such as pyrolusite, sulph-arsenides, and sulph-antimonides, and grease or oil prevent coalescence of mercury globules; the mercury is said to be SICKENED or FLOURED; it is no longer a good collector nor will it remain on the plates, but passes on and must be caught by some method of gravity concentration, *e.g.*, an amalgam trap (settler) or a shaking table or vanner.

Amalgam on plates hardens with loading up of the mercury with precious or other metals and then fails to catch and hold further metal. This condition is overcome by adding more mercury, or by scraping, in case the hardening is a surface effect only.

Clean-up to recover metal is made periodically. The procedure is to first wash off all ore, then heat the plates, preferably by live steam under a covering of planks, and then to remove all amalgam that comes off readily with a wood or steel scraper. The plates are then dressed again with mercury or dilute amalgam. The period between clean-ups is determined principally by the metal content of the ore. The collected amalgam is squeezed in chamois skin to express as much free mercury as possible, then retorted (see Art. 7).

Loss of mercury averages 0.07 to 0.15 troy oz. per ton crushed (*116 P 483*).

Intensive amalgamation consists in the use of aids to contact or union of the precious metals and the mercury, *e.g.*, passing a small low-voltage electric current through the plate; placing iron bars on the plates and milling in salt water (sea water); placing plates on the walls of a centrifugal machine; grinding in the presence of mercury, etc. Except for the last expedient, the results do not justify the expense.

Blankets are sometimes used when very coarse gold or an excess of sulphides is present. See Sec. 2, Art. 19.

Amalgamation vs. cyanidation. Amalgamation is cheaper, less complicated and recovers coarse metal more readily; on the other hand it is rarely that the recovery is sufficiently high to justify the use of amalgamation alone, so that the practical choice always is between amalgamation plus cyanidation and cyanidation alone. This question is ordinarily resolved by the coarseness of the precious metal; if coarse and amalgamable, use amalgamation on account of the reduced time required for cyanide leaching after removal of the larger metal particles, and the probable greater recovery; if the precious metal is readily amenable to cyanidation, then introduction of amalgamation must be justified on the basis that it makes part of the metal more quickly available; that, due to the cheaper recovery of a part of the metal by amalgamation an overall saving is accomplished; or that sending impoverished feed to the cyanide plant permits less careful and therefore sufficiently cheaper operation there to more than make up for the added expense and complexity of milling with amalgamation in the flow-sheet. Amalgamation, on the other hand, precludes milling in cyanide solution and has indirectly been a most potent factor in the complacent use of the stamp battery.

7. Melting precipitate

Precipitate and sponge gold or silver from amalgamation are melted down into bars, slabs or ingots for marketing. Ordinarily some refining is done at the same time. The scale of the work varies, according to the quantity treated, from an assay-office operation to large-scale copper refining.

Amalgam. Free mercury is first squeezed out of the amalgam, the residue is charged into a cast-iron retort and the latter is gradually brought up to bright red heat, when the last traces of mercury are driven off. The remaining SPONGE is melted with borax or other suitable flux in graphite crucibles, and poured into heated cast-iron moulds, coated with graphite and usually also with paraffin or tallow.

Cyanide precipitate. If from zinc boxes, the precipitate is washed and screened on 20- to 60-mesh screens, to remove undecomposed metallic zinc, which is returned to the zinc-boxes. Undersize is collected under water in settling tanks and dried in flat pans. Sometimes a hot dilute sulphuric acid wash is given to remove fine zinc. Dried precipitate is melted in graphite crucibles with suitable flux, *e.g.*, borax, or a mixture such as 15 parts borax, 8 parts soda and 4 parts silica sand. With zinc-dust precipitation in filter presses, the precipitate is washed and dried by a current of air in the filter press, then melted in large crucibles (400-lb. charges), or special carborundum-lined, egg-shaped furnaces heated by oil through the trunnion; or in small blast or cupola furnaces with litharge and a flux, usually borax. The resulting bullion is cupelled.

Copper cathodes are not treated locally. For melting and refining practice see *Copper refining*, L. Addicks (McGraw-Hill, 1921). Cathodes from chloride solutions are subject to large refining losses.

Zinc. An ordinary coal-fired reverberatory is used. On account of rapid oxidation, the cathodes must be got beneath the surface of a molten bath of

zinc as quickly as possible. Fortunately the demand for zinc oxide in neutralization of solutions before precipitation will care for any reasonable amount of oxide produced. The dross and oxide may represent 20 per cent. of the weight melted.

At Cons. Min. and Sm. Co. a melting temperature of 1250° F. is maintained by pyrometric control. Only large slabs are charged into the reverberatory; scrap zinc is melted down in graphite crucibles protected from oxidation.

8. Flow-sheets

Homestake Mining Co., Fig. 1. (*114 J 757; 52 A 3; 23 IMM 68; A. J. Clark, P. C.*)

Location: Lead, S. D.
Ore: Gold and silver with a small amount of pyrite in quartz.
Assays: Feed, $3.50 to $4.00 per ton.
Capacity: 4500 tons per 24 hr.
Extraction: 72 per cent. by amalgamation; 22 per cent. by cyanidation; 94 per cent. total.
Cost: $0.22 per ton (1925).

Summary. Amalgamation and cyanidation.

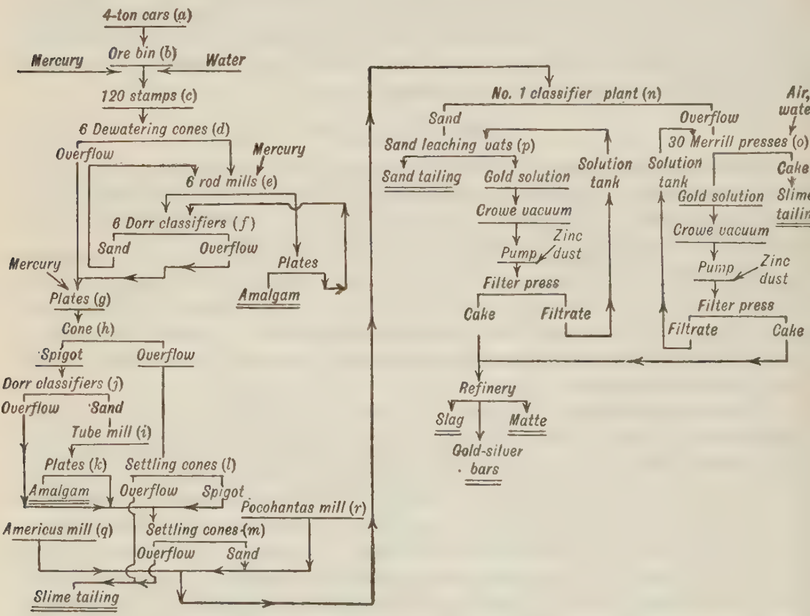

Fig. 1.—Homestake Mining Co.

a, Ore crushed at mine to 2-in. (see Sec. 3, Fig. 16). 4-ton cars, mine to mill. *b,* V-shaped, 7200-ton capacity. *c,* 1550-lb. stamps, 100 @ 8-in. drops per min.; order, 1–3–5–2–4; ½-in. screen; battery amalgamation; Challenge feeder; short trommel ahead of stamps to by pass fines. *d,* 6 @ 7 ft. (diam.) × 7 ft. *e,* 6 @ 5 × 10-ft. 22 r.p.m.; 100 hp., 29,000-lb. charge; 200 tons per day each. *f,* 6 @ 4-ft. 6-in. × 21-ft. 4-in. Dorr duplex classifiers; 2¼-in. per ft. slope; 26 strokes per min.; overflow, −80-mesh. *g,* 24 @ 9 × 12-ft. amalgamated copper plates, ⅛ in. thick. 2 oz. silver per sq. ft.; 21.6 sq. ft. of plate per stamp; each stream flows over two plates. *h,* 4 @ 7-ft. dewatering cones. *i,* One 5 × 14-ft. tube

mill. *j*, Dorr classifier. *k*, Two 9 × 12-ft. amalgamating plates. *l*, Eight 10-ft. settling cones. *m*, Eight 7-ft. settling cones. *n*, No. 1 dewatering plant; eight 10-ft. and eight 7-ft. cones; three 32-ft. Dorr double-tray thickeners; plant preceded by two banks of cones. *o*, 30 Merrill filter presses; each with 90 frames, 4 ft. × 6 ft. 4 in. One press holds 26 tons of slime. Daily capacity, 70 tons; 33 lb. pressure. (Increased from 16-lb. pressure.) Treatment time about 15 min. *p*, 24 sand-leaching vats, 44 ft. (diam.) × 9 ft. 610 tons sand capacity. Canvas-covered false bottom. Ore drained and air forced through the charge at a pressure that will not disturb the bed. About 75 cu. ft. of oxygen absorbed per ton of ore. *q*, Amicus mill. 240 @ 1000-lb. stamps, 5-tube mills, 5200 sq. ft. of amalgamating plates, 8 cones. *r*, Pocahontas mill. 160 @ 900-lb. stamps, 2900 sq. ft. amalgamating plates, 4 cones.

United Eastern Mining Co. Fig. 2. (*119 J 436, Q.*)

Location: Oatman, Ariz.

Ore: Gold and silver in very finely divided state in quartz-calcite gangue with some andesite.

Assay of feed: $19.80 per ton (aver. 1917–1924, incl.).

Capacity: 325 tons per 24 hr.

Extraction: 96.6 per cent.

Cost: 1917–1924 incl., average. See adjacent table.

Cyanide consumption: Aero brand, 0.713 lb. per ton.

Item	$ per ton
General expense	0.161

Summary. All-slime cyanide.

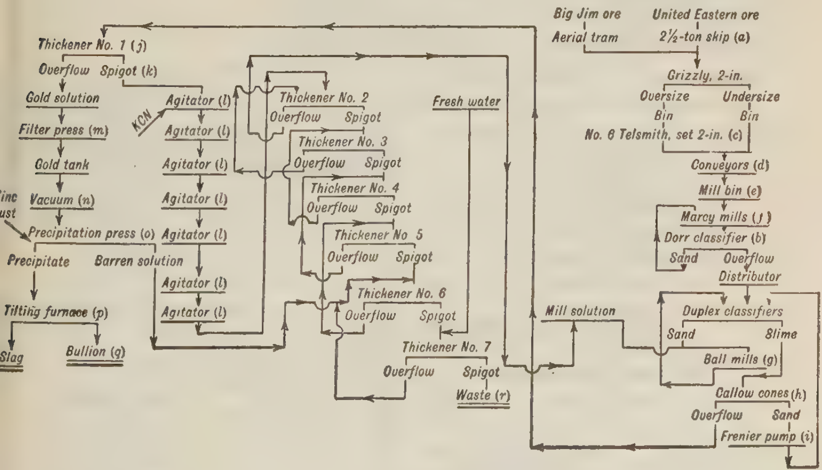

Fig. 2.—United Eastern mill.

a, Mill at collar of United Eastern shaft. Big Jim ore brought in by Riblet aerial tram. *b*, Simplex: slope, 3-in. per ft., 34 strokes per min. *c*, 35 tons per hr. *d*, 18-in. + 20°, 250 ft. per min. 50 tons per hr. Merrick weightometer on conveyor. *e*, 24 × 24-ft. flat-bottom tank, feeding onto 18-in. pan conveyor. *f*, Two 6 × 4½-ft. Marcy ball mills, 26 r.p.m., 67 kw.; in closed circuit. *g*, Three 5 × 6-ft. ball mills, 28 r.p.m., 48 kw., lined with 35-lb. T-rails. Each in circuit with one 54-in. duplex Dorr classifier. Slope 2½ in. per ft., 18 strokes per min., overflow maintained at 5 solution to 1 of solid. *h*, Two 8 ft. Overflow: United Eastern ore, 85 per cent. −200-mesh; Big Jim, 92 per cent. −200-mesh. *i*, Two No. 3 Abbe-Frenier pumps. *j*, One 40 × 12-ft. Dorr thickener. Spigot, 50 per cent.

solids. 3.87 sq. ft. per ton of solid. *k*, Duplex, Campbell-Kelly, No. 4 diaphragm pump. *l*, Seven 24-ft. (diam.) × 14- and 16-ft. (deep) Dorr agitators. Duration, 52 hr.; total contact, 146 hr. *m*, Merrill central-sluicing clarifying filter, with 28 frames 42 in. square. Sluiced once or twice every 8-hr. shift; acid treated with 1-per cent. hydrochloric acid every 3 days; sluicing time, 10 min.; acid treatment, about 1 hr. *n*, Crowe vacuum. 4 × 10-ft. receiver, 6-in. inlet at center of top. 23.4 ft. above the solution level in the steady-head tank. Solution poured down over perforated trays. Depth in receiver, 30 in.; regulated by float butterfly valve in intake pipe. Solution drawn from bottom of receiver by 7 × 8-in. triplex pump, glands 32.8 ft. below solution level in receiver; the column is under vacuum, insuring slight pressure at the pump glands, thus preventing admission of air. Zinc dust is fed by a screw feeder directly to a cone from which it is drawn by the precipitation pump, and mixed with vacuum-treated solution, then pumped to the precipitation press. Strength of solution 1.8 lb. KCN per ton, 1.0 lb. CaO, 0.27 to 0.44 oz. gold; silver, ½ oz. per oz. gold. *o*, Two Merrill presses each with 32 triangular 36-in. plates, dressed with four thicknesses of sheeting; inner sheet is burned on removal. Precipitate contains 45 per cent. water. *p*, Flux: 12 per cent. borax glass, 12 per cent. sodium bicarbonate, 6 per cent. manganese dioxide, 3 per cent. bottle glass, 10 per cent. or more of slag from previous melts; put in No. 8 paper bags. The charge is fed into a No. 150 Case tilting furnace, using No. 125 long-lipped graphite crucibles containing 600 to 1000 oz. bullion and 40 to 50 lb. slag each. *q*, Bullion buttons re-melted and cast into bars; average weight, 1800 oz. Ground slag is concentrated on a small Deister table. *r*, Tailing is distributed to various ponds through 6-in. slip-joint pipes; minimum grade of 3°. Tailing is deposited in benches 8 to 12 ft. high. After standing for several months, the accumulated layer of surface salts is of sufficient value to gather. Three "crops" of salts are collected and fed to the re-grinding mills.

Nipissing Mining Co. Fig. 3. (*31 Ont. Dep. Mines 280.*)

Location: Cobalt, Ont.
Ore: Native silver and arsenides of cobalt and nickel in calcite gangue.
Assay of feed: 44.78 oz. Ag (1923).
Capacity: 230 tons per 24 hr.
Extraction: 94 per cent.
Cost: \$4.60 to \$5.39 per ton (1923).

Summary. Concentration and all-slime cyanidation.

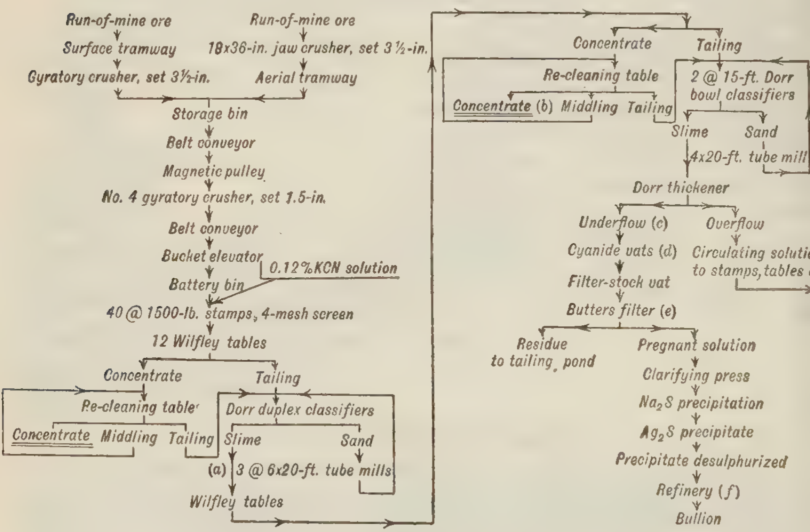

FIG. 3.—Nipissing low-grade mill.

a, 6 to 10 per cent. + 200-mesh. *b*, Treated further in high-grade mill. *c*, 29 per cent. solids. *d*, Cyanided by charge system. Agitated mechanically for 50 hr. in solution main-

tained at 0.25 per cent. KCN. Aerated by 6-in. air lift during agitation. Pulp then settled 8 hr., pregnant solution decanted, and the residue again agitated with new solution. *e,* 72 leaves, 40 tons solid per 3¾ hr. *f,* Sulphide precipitate reduced to 999-fine silver by treating in solution of caustic soda with aluminum ingots.

New Cornelia Copper Co., Fig. 4. (*60 A 22; 6 MMt 524; 119 J 285.*)

Location: Ajo, Ariz.

Ore: Malachite and chrysocolla in silicified monzonite porphyry. Some chalcopyrite and bornite.

Assay of feed: 1.5 to 1.6 per cent. Cu.

Capacity: 5000 tons per 24 hr.

Extraction: 78 per cent.

Cost: Crushing, \$0.157; leaching, \$0.275; precipitation, \$0.0217 per ton of ore (Power, \$0.0075 per kw.-hr.)

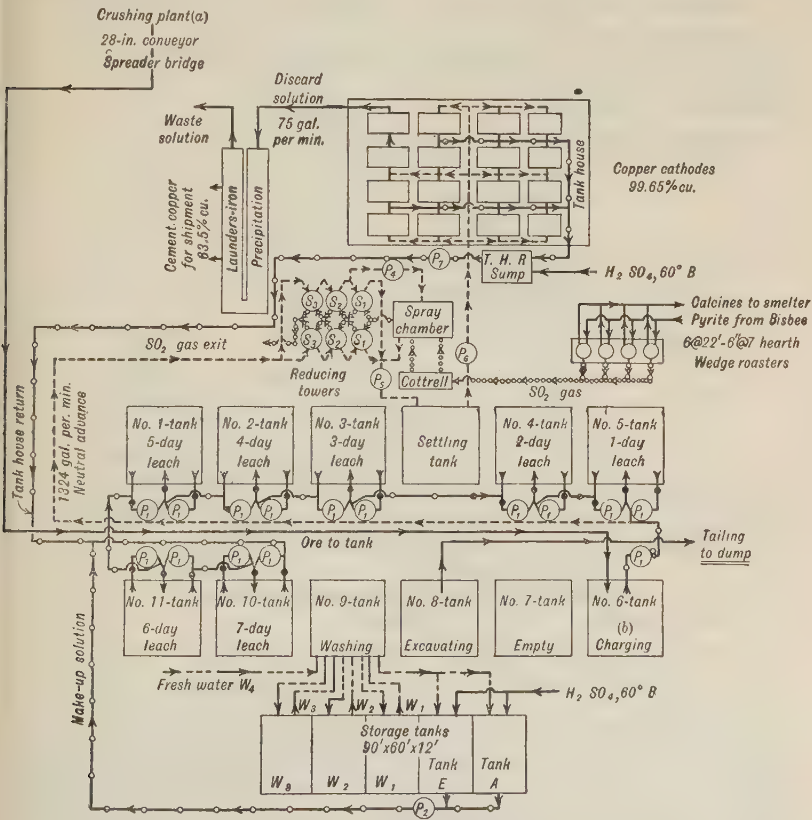

FIG. 4.—New Cornelia Copper Co.

a, See Sec. 3, Fig. 5. *b,* The flow lines with respect to the variously-numbered tanks are representative of the status on any given day. On the day following the one represented, tank No. 7 would be charging; No. 9, excavating; No. 8, empty; No. 10, washing; No. 6, 1-day leach, No. 5, 2-day leach, etc.

Summary. Sulphuric-acid leaching. The operation consists of five steps: (1) Crushing from steam-shovel size to $-\frac{3}{8}$-in.

(2) Charging the lixiviation tanks with dry ore. This step includes submerging the ore with solution, and circulating solution until it is clear.

(3) Leaching proper, which, although the ore remains fixed, is, in effect, a counter-current operation in which the newest ore has the weakest acid (0.3 per cent H_2SO_4 on first day increasing up to 2.3 per cent. on the eighth day).

(4) Washing, fresh water being added as the final wash; each preceding wash stepped up until that richest in copper advances to the stock-solution tank.

(5) Discard of tailing.

Inspiration Cons. Copper Co., Fig. 5. *(73 A 58)*.

Location: Miami, Ariz.
Ore: Oxidized copper minerals in silicified schist and decomposed granite.
Assay of feed: 1.23 per cent. Cu.
Capacity: 4500 tons per 24 hr.
Extraction: 85 per cent. (est.).

Summary. Ferric-sulphate leaching.

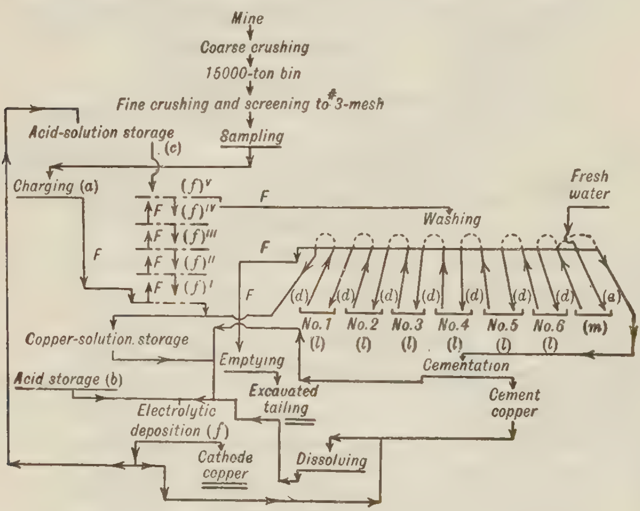

Fig. 5.—Inspiration Copper Co., leaching plant.

a, Charging by conveyor belt and spreader bridge requires two days for 9000 tons. *b,* Acid solution, 25.6 lb. 60° Bé. acid per ton of solution. *c,* 2250 gal. per min. *d,* Washed 3 days; 6 unit washes of 40 gal. per ton of ore; each wash advanced after each cycle, the strongest going to the tank house for electrodeposition. A circulating wash is finally pumped through until sufficient soluble copper is removed. A portion is then advanced to No. 6 wash-storage tank and is replaced by the same volume of fresh water, which may, if necessary, be passed through the leached ore to recover iron as needed. There is no discard of solution. *e,* Advance from fresh water. *f,* Anodes have exactly that proportion of carbon area in conjunction with lead or other suitable insoluble anode as is necessary to oxidize a certain definite amount of ferrous sulphate and leave no destructive excess of anodic oxygen. Solution, 2.5 to 3 per cent. Cu; 1.5 to 2.5 per cent. total Fe with ferric iron up to 1 per cent.; acid 3.5 to 7.5 per cent. Current density is sufficiently high to counteract, to a commercial degree, the solvent action of ferric iron upon the cathode; about 15 amp. per sq. ft. Current efficiency is about 60 per cent. or ⅔ lb. copper per kw.-hr. $F, f^{I}, f^{II}, f^{III}, f^{IV}, f^{V}$: The flow lines marked F from the tank being charged to the leaching circuit (f^{I}, etc.) and to the wash-

ing circuit and to "emptying" do not represent actual "flow" of ore, but merely indicate sequence of steps. The lines marked f^1, etc. represent different stages of leach solution. *l* Advancing-wash storage tanks, cap. 500,000 gal. each. *m* Circulating wash storage tank, cap. 500,000 gal.

Calumet and Hecla, Fig. 6. (*117 J 277; 70 A 595.*)

Location: Torch Lake, Mich.
Ore: Current mill tailing. See Sec. 2, Fig. 44.
Assays: Feed, 0.51 per cent. Cu; tailing, 0.10 per cent. Cu.
Extraction: 79.7 per cent. Cu.
Cost: \$0.32 per ton of feed; \$0.04 per lb. of copper.

Summary. Ammonia leaching.

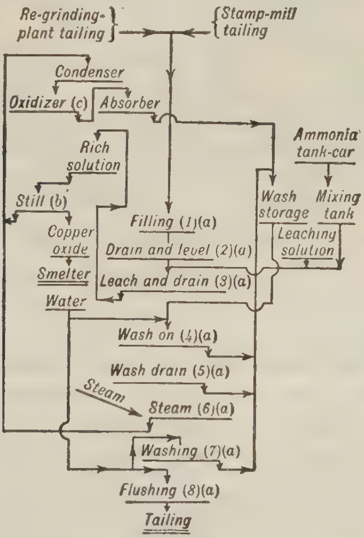

Fig. 6.—Calumet and Hecla leaching plant.

a, 16 steel leaching tanks, 54 ft. (diam.) × 12 ft. Water-sealed during leaching. Filled by portable distributor, Butters and Mein type. Numbers 1 to 8 represent successive operations in the same leaching vat as follows:

1. Filling vat: requires about 6 hr. 2. Draining and leveling, 1 hr. 3. Leaching, 10 to 12 hr. Leaching solution 30 gm. Cu, 60 gm. NH_3, and 40 gm. CO_2 per liter. Ammonia-copper ratio, 3 : 1. 622 cu. meters of solution per hour. 4. Wash 5 to 6 hr. with ammonia water to remove all copper. About 200 cu. meters of solution followed by 75 cu. meters of fresh water. 5. Draining, about 5 hr. 6. Steaming. A partial vacuum is maintained beneath the filter bottom of the tank; steam and ammonia pass downward as the charge becomes heated. Steam is admitted at atmospheric pressure, 12 to 13 kg. per hr., decreasing to about 4 kg. per hr. at the end of the 5-hr. period. 7. Washing with fresh water. 8. Flushing tailing with water, about 6 hr.

b, Solution distilled contains 35 gm. Cu, 35 gm. NH_3 and 30 gm. CO_2 per liter. *c*, Copper changed from cuprous to cupric. This is essential to maintain the dissolving power of the solution.

Consolidated Mining and Smelting Co. of Canada, Trail electrolytic zinc plant, Fig. 7. (*34 IMM 2; 23 CME 227.*)

Location: Trail, B. C.
Ore: Zinc concentrate.
Assays: Feed after roasting: Ag, 2 oz. per ton; Pb, 11 per cent.; Zn, 27 per cent; Fe, 25.8 per cent.

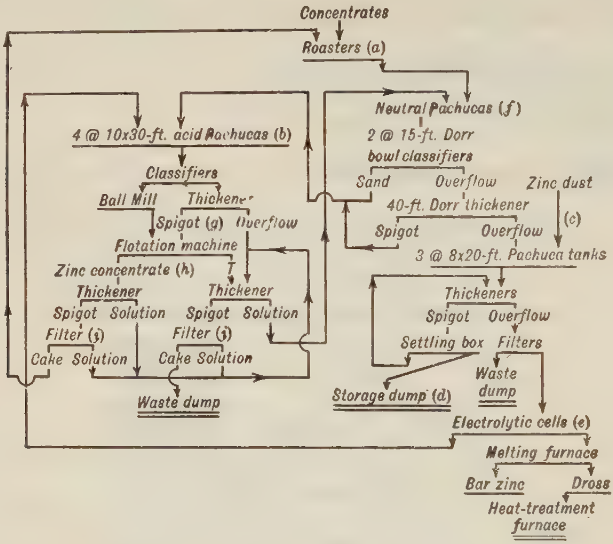

FIG. 7.—Consolidated Mining and Smelting Co. of Canada, Trail electrolytic plant.

a, 13 @ 25-ft. Wedge roasters. Temperature on sixth hearth, 1350° F. Calcine about 2.5 per cent. sulphate sulphur and 0.7 per cent. sulphide sulphur. *b,* 0.5 to 1 per cent. H_2SO_4. *c,* An amount sufficient to precipitate copper and cadmium and the remaining traces of arsenic and antimony. *d,* Contains cadmium and zinc. *e,* Two plants 12 and 14 electrical units each. Each unit 18 double-cell tanks of reinforced concrete, ¾- to 1½-in. lining of sand and sulphur; inside dimensions 27 × 80 × 42 in. (deep). 17 cast electrolytic-lead anodes and 16 sheet-aluminum cathodes. Cathodes 24 × 36 in., spaced 4 in.; anodes, 23½ × 35 in. Cathodes 1/10 in. thick, supported by 1-in. copper rod at one side and ½ × 1-in. strap iron on the other side. *f,* Solution alkaline. *g,* 40 per cent. solids. *h,* About 35 tons per day, 41 per cent. Zn. *i,* American, 8 @ 6-ft. disks.

SECTION 16

DEWATERING

DEWATERING

Dewatering consists in separating a mixture of solid and water into two parts, one of which is relatively solid-free, the other liquid-free, with respect to the original mixture. Substantially complete separation is attainable only by evaporating the water (drying). A solid-free liquid fraction and a solid fraction containing considerably less than 20 per cent. water can be obtained by bringing the mixture of solid and water to one side of a porous membrane at a pressure greater than that existing on the other side of the membrane (filtration). When less complete separation is sufficient, two methods are available. If the solid matter is in such coarse particles that solid and liquid are visually distinct, draining is effective. If the solid matter is so fine that slight movement maintains it in suspension in the water, separation is effected by bringing the water substantially to rest and allowing the solid to settle under the influence of gravity (thickening).

1. Draining

Draining is a crude form of filtration. The simplest case is that of a pile of wet material on a floor; the liquid settles to the lowest layers of the heap and, if the supporting surface is inclined slightly, runs away. Some residual liquid is held by adhesion at the surface of the solid particles and by capillarity between adjacent solid surfaces. The volume of water thus retained depends primarily on the size of the particles of solid; the finer the grains, the greater the particle area and hence the greater the volume of retained water. The moisture content of the drained solid is higher the lower the specific gravity of the solid, all other things being equal. Bins may replace floors. In some cases a screen forms the draining surface, permitting continuous as opposed to batch operation. Rectangular or circular tanks are frequently used for dewatering fine table concentrate.

At Santa Barbara (*112 J 1056*) lead-carbonate concentrate at the rate of 74 tons per 24 hr. is sent alternately to two concrete tanks 10 ft. wide by 60 ft. long by 4 ft. deep. The moisture content is reduced from 84 per cent. to 14 per cent. At Le Roi No. 2 mill (*114 J 1121*) about 30 tons per day of flotation concentrate is fed at one end of a series of two tanks each 1 ft. deep, 2 ft. wide and 22 ft. long with baffles 6 in. high at intervals along the bottom and double burlap screens at the outflow end. As concentrate accumulates it is tamped down for two or three minutes every hour or so. The material shoveled out when the tank is full contains only 10 to 15 per cent. moisture. The froth is efficiently broken down by flowing across the semi-dry surface of the settled solid. This method is not so cheap as thickener-filter operation but is immeasurably cheaper in first cost.

2. Scraper dewaterers

Scraper dewaterers are used principally for dewatering coarse sand products, and, less frequently, to effect a rough sand-slime separation.

Shovel wheel used at Tigre Milling Co. (*97 J 227*) is shown in Fig. 1. Feed enters through a chute, sand settles to the apex of the V-shaped trough, is scraped up-slope by the wheel, revolving counter-clockwise, and discharged through a slot, water or slime overflows a lip on the opposite side of the box at a level about 4 in. below the sand discharge. The V-box in Fig. 1 is 42 in. long and 52 in. wide, the wheel revolves 8 r.p.m. and treats 125 to 135 lb. solid per min. Performance is affected by the speed and inclinaton of the shaft and the character of the feed pulp. At the Santa Barbara mill of the Amer. Smelters Securities Co. (*112 J 1055*) two 48-in. wheels, revolving in opposite directions so as to raise sand along the transverse center-line of the box are set in a V-box 9 ft. 6 in. long by 4 ft. wide. The feed is the oversize from a 0.5-in. trommel fed at the rate of 430 tons per 24 hr.; it contains 42.5 per cent. solids; the sand discharge, 70 per cent. solids.

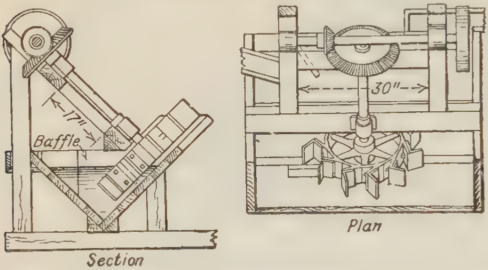

Fig. 1.—Shovel wheel.

Sand wheel (Fig. 2) consists of a wheel (*A*) carrying convex, perforated

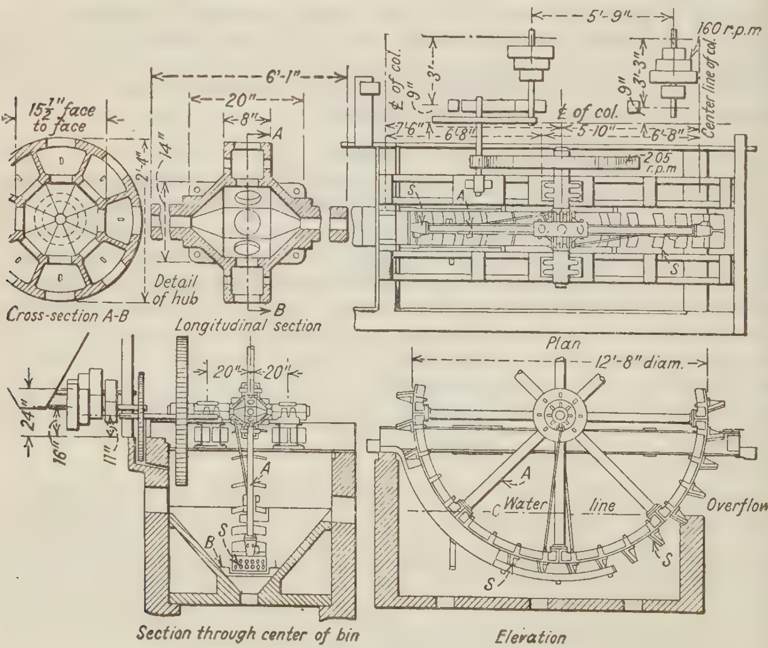

Fig. 2.—Sand wheel.

scrapers (S) at the periphery, revolving in a narrow trough (B) supported in a V-box. The wheel in Fig. 2 is 14-ft. diameter to the tips of the scraper blades.

The most efficient speed for dewatering combined jig and table tailing (−9-mm.) at Doe Run Lead Co. was 2 r.p.m. The 14-ft. machine handled 1500 tons of such material per 24 hr. The sand discharge carried about 15 per cent. moisture. The power requirement was less than 2 hp. A more elaborate form lifts the sand in buckets carried on a large wheel dipping into the pulp, decants water as the wheel revolves and finally discharges dewatered sand at the top of the revolution by automatically tilting the buckets. (*111 J 291.*)

Mechanical classifiers. For use in de-sliming see Sec. 6, Art. 6. For use in dewatering concentrate see Sec. 2, Fig. 60. Table 1 shows the performance of Dorr classifiers dewatering de-slimed coal.

Table 1. Performance of Dorr hydro-separator (26-ft. diam.) and three Dorr classifiers treating separator-spigot discharge at Loree anthracite breaker (*20 CA 608*)

Material	Feed	Separator		Classifier	
		Spigot	Overflow	Rake	Overflow
Total solids, tons per hour	49.8			22.7	
Plus 60-mesh, cumulative per cent	44.5			89.0	
Plus 100-mesh, cumulative per cent	57.6			97.0	
Plus 200-mesh, cumulative per cent	72.1			99.5	
Ash, per cent	32.9			24.8	
Total solids, per cent	100.0	60.9	39.1	45.6	15.3
Total + 60-mesh material recovered, per cent				91.0	
Total +100-mesh material recovered, per cent				76.7	
Total +200-mesh material recovered, per cent				62.9	
Total combustible, per cent				51.2	
Total water eliminated, per cent				98.4	

Cost (1921) was $0.053 per ton of recovered material for labor, power, supplies and repairs and $0.088 for interest, insurance, taxes and depreciation, being 20 per cent. on an investment of $17,500 for building and equipment.

Drag conveyors and elevators of various forms (see Sec. 20) are used to dewater coarse and fine granular coal. The conveyor runs in a tight or in a perforated trough. In metal concentrators drags, when used, are ordinarily applied to jig and table concentrate.

At Britannia (*113 P 696*) flotation concentrate is sent to a drag elevator and thence to bins. The drag discharge contains 20 per cent. moisture and the bin discharge 8 per cent. moisture. This method of treatment is applicable only to a very quick-settling concentrate.

A drag dewaterer for fine anthracite is described by Griffen (*61 A 514*). The tank was 2 ft. 8 in. wide, a flight conveyor with 6 × 18-in. flights, spaced 18 in. apart, dragged 60 ft. horizontally, then raised on a short incline to discharge the sand. Speed was 50 ft. per min. Feed rate was 800 gal. per min. of a pulp containing 13.5 per cent. solids, all through 1/16-in. round hole. Overflow contained 1.2 per cent. solids, which was 91 per cent. of the feed. Pulp was fed near the tail pulley and overflow was at the sides of the tank near the solid-discharge end. The dewatered material usually contained all of the +100-mesh coal.

The cost (1920-21) of a machine with 4 × 4 × 100-ft. tank and 8 × 18-in. flights together with a 65-ft. stacking conveyor was $10,250. Another machine to dewater 2000 gal. per min. and stack the dewatered product cost $9000.

THICKENING

THICKENING is the process of concentrating a relatively dilute slime pulp into a THICK PULP, *i.e.*, one containing a low percentage of moisture, by rejecting liquid that is substantially solid-free. SETTLING is another name for the same operation.

3. Principles

Slime, is the term used in milling practice to describe a suspension, in water, of the finely-divided fraction of pulverized ore.

The terminology is not precise, *e.g.*, the overflow of a mechanical classifier or cone guarding the discharge of a grinding mill is called slime as distinguished from the coarser SAND, even though the separation be made at upwards of 0.5-mm. size; the overflow of a hydraulic classifier is called slime, more or less irrespective of the size of the coarsest grains. Some writers (*41 A 398*, *42 A 752*) define slime as crushed rock in water when the rock is of such fineness that it will pass a 150- or 200-mesh (0.1- to 0.075-mm.) screen.

The solid particles in mill slimes are rock or mineral fragments formed by crushing operations, and secondary minerals such as steatite, talc, and clayey substances that have been disintegrated and dispersed by wetting. These latter substances are often called TRUE SLIMES.

A slime product separated in the early stages of reduction, which contains, therefore, an exceptionally high percentage of true slime, is called PRIMARY SLIME. The product formed by fine-grinding the crystalline part of the ore contains but little true slime.

Every slime consists initially of individual solid particles separated from other solid particles by a layer of water. Irrespective of whether the largest particles are 0.5-mm. (20-mesh) or 0.07-mm. (200-mesh) diameter, they are enormously larger than the smallest particles, large numbers of which are in the size range below 0.001-mm. The difference in settling behavior of these two classes is much greater than that between the coarse and fine particles met in hydraulic classification. The granular particles settle slowly under the influence of gravity, at definite rates approximated by Stokes' equation (Sec. 6, Art. 1). The fine particles may not settle at all, or they settle at a rate so slow as to be of no practical benefit in thickening. The viscosity term in Stokes' equation is relatively very large for these fine particles, and molecular effects such as Brownian movement and electrical repulsion between particles may effectively counterbalance any residual tendency toward downward motion due to gravity. These particles are in colloidal or semi-colloidal state.

Colloids. The word COLLOIDAL describes a state of matter. A COLLOID is not a certain specific kind of matter but any matter in a certain specific state. The COLLOIDAL STATE is sub-division into molecular aggregates of such minuteness that the aggregates are capable of maintaining their state of uniform dispersion in a given medium, without the necessity for expenditure of power on the mixture. The dispersed substance, the COLLOID, may be in gaseous, liquid or solid form and the dispersing medium may, likewise, be in any of these three states except that gas is never at the same time the disperse and dispersing phase. The mixture is a COLLOIDAL SOLUTION. Such solutions differ from the more familiar types of solution in all of the known solution characteristics except that of maintaining uniformity without requiring work to be done; they are not ionized, their boiling and freezing points do not differ from those of the dispersing medium, they do not dialyze nor exhibit osmotic pressure; finally, the dispersed particles are visible, with ultramicroscopic equipment, and separable by means of filters. SEMI-COLLOIDAL particles have, in a con-

siderable degree, colloidal properties. The dispersed particles in a colloidal solution are said to be PEPTIZED or DE-FLOCCULATED. The converse condition, resulting from aggregation of the dispersed particles, is called FLOCCULATION, and the aggregates are called FLOCCULES or FLOCS.

The effective mechanism underlying colloidal solution (DISPERSION) is adsorption of ions by the dispersed particles, resulting in electrical charges at the particle surfaces. The charges cause the particles to mutually repel each other, thus preventing coalescence and settlement. Ion adsorption is preferential and specific to the particular colloidal substance. Thus certain colloidal substances will adsorb negative ions from solutions of certain electrolytes and positive ions from solutions of other electrolytes and may, therefore, be negatively charged in one instance and positively charged in another. Beans and Eastlack (*37 ACS 2667*) show that only those ions are adsorbed that will, under proper conditions, enter into chemical combinations with the dispersed substance, and that the amount or intensity of adsorption is greatest for those ions that form with the substance chemical compounds of greatest stability.

Colloidal solutions are destroyed and the colloidal substance is precipitated by any means that will neutralize the charges on the dispersed particles or separate the adsorbed ions. The commonest means of destruction is to add an electrolyte from which the colloidal particles will adsorb ions of opposite sign to those that produced stabilization. An amount of electrolyte just sufficient to neutralize the charged particles produces maximum flocculation; a small excess will usually reverse the sign of the charge and tend to again produce and stabilize dispersion. (Burton, *Physical properties of colloidal solutions*, 1916.) Further excess decreases peptization until finally a point of absolute excess is reached beyond which peptization cannot be effected.

Coalescence of uncharged particles with formation of floccules is movement in accord with the second law of thermodynamics. The potential energy of a colloidal system is relatively large on account of the large area of INTERNAL SURFACE, *i.e.*, interface between the dispersed particles and the dispersing medium. Coalescence decreases this surface and thereby lessens the potential energy of the system.

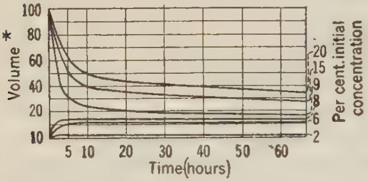
Primary slime. Most ores and rocks as mined contain both earthy secondary minerals that disintegrate in water to colloidal sizes, and suitable electrolytes to furnish the ions necessary to stabilize dispersion of the fine particles. The viscosity and density of this disperse system are such that coarser particles, which would settle in water, are suspended, if any turbulence at all exists. Thus primary slime is formed. Its satisfactory settlement is one of the difficult problems of milling.

Sedimentation. When a de-flocculated slime pulp is brought to rest there is gradual clearing of the upper part of the liquid, accompanied by collection of the coarser particles in the bottom of the container. This is called SUBSIDENCE SETTLING (Free, *101 J 681*) or SEDIMENTATION. If an actual colloidal suspension exists, complete settlement cannot be effected, but the overlying liquid will remain turbid.

The particles that deposit by sedimentation settle more rapidly the more dilute the suspension, because particles in a dilute suspension are more widely spaced and the effects of their electrical charges on their neighbors are least. Dilution also lessens both the viscosity and density of the colloidal solution and these changes likewise aid settling, as may be seen from Stokes' equation. Shellshear (*8 Aa 5*) and Nichols (*17 IMM 328*) confirm this conclusion experimentally.

Heating increases the settling rate in de-flocculated suspensions containing semi-colloidal material, probably by decreasing the viscosity of the suspending medium.

Economy forbids attempts to thicken de-flocculated pulps, even when there is a considerable amount of semi-colloidal and granular material present, both on account of the retardation of the settlement of the coarser material by the colloid and on account of the loss or inconvenience due to the colloidal solid in the liquid fraction.



* Ordinate is the height of the upper surface of the settling material, divided by the total height of the water surface, expressed as percentage.

Fig. 3.—Relation between settling rate and percentage of solids in a colloidal clay suspension (*after Free*).

Consolidation settling is the name suggested by Free for settlement of flocculated pulps. When such pulps settle the solids fall *en masse*, clear liquid appears at the surface immediately, and the liquid layer increases in thickness through addition of water displaced upward by consolidation of the settling solids. In Fig. 3, the three lower curves illustrate sedimentation, the three upper, consolidation settling. The slopes of the curves, irrespective of sign, measure settling rates.

Stokes' equation cannot be practically applied to the settling of flocculated pulps, because the flocs, which consist of unstable aggregates of solid particles holding considerable water, have indeterminate specific gravities; their surface is highly irregular and their shape nonuniform; finally they are in contact with their neighbors at many points, at least in all but the earlier stages of settling, and this condition violates one of the hypotheses upon which the equation was founded.

Compacting settling. Ralston (101 *J* 768), working with short (10-in.) settling columns, noted that when free-settling slimes reached a consistency by consolidation settling of about 40 per cent. solids the settling rate fell off markedly (see Fig. 4). This phenomenon was not noticeable in 36-in. columns. He describes such settling a compacting settling. It may be important in shallow-tray or baffle thickeners (Art. 7), but is not in thickeners of usual dimensions.

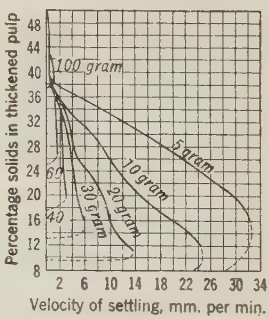


Fig. 4.—Effect of dilution on consolidation of slimes.

4. Flocculation

Consolidation settling yields clear overflow and a thickened product substantially as dense as that obtained by sedimentation. Since clear overflow is practically a *sine qua non* of pulp thickening and flocculation is essential to its accomplishment, means of flocculating slime pulps are of prime importance. Four means are known, *viz.:* (1) by addition of suitable electrolytes, (2) by addition of suitable colloids, (3) by guarding against production of too dilute feed pulps, (4) by heat. In so far as each of these methods is

effective, it must act by affecting the adsorbed ions that stabilize the slime colloid.

Flocculation by electrolytes is the most effective way to produce consolidation settling. Fig. 5, compared with Fig. 3, shows the effect of adding 0.25 gm. of NaCl per 100 cc. of water to clay suspensions. The point of change from sedimentation to consolidation settling comes between 2 and 3 per cent. initial solid concentration when the electrolyte is present, instead of between 8 and 9 per cent. without the added electrolyte, and the rate of settling is increased even at those concentrations at which flocculation already existed.

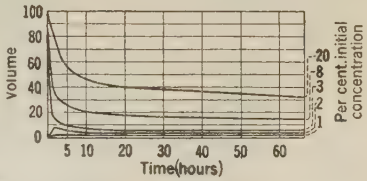

Fig. 5.—Settling curves of kaolin suspensions flocculated with sodium chloride (*after Free*).

The explanation of the effect of electrolytes is two-fold. Beans and Eastlack (*loc. cit.*) found that in making colloidal gold by the Bredig arc method, the amount of gold suspended varied with the quantity of electrolyte after the fashion of Fig. 6. If it is assumed that in a given slime the amount of colloid dispersed corresponds for that slime to the peak of the curve and that the sign of the colloid (*i.e.*, sign of the adsorbed ion) is negative, then when a suitable electrolyte is added *i.e.*, one of which the positive ion is adsorbed, the effect is to move down the left leg of the curve until, when substantially all of the initial ion charge is neutralized, complete flocculation exists. Ellis (*9 Trans. Faraday Soc. 14*), working with positive hydrate-of-iron colloid and negative cylinder-oil emulsions found that the resultant of the charges on the particles varied from negative through zero to positive with increasing addition of the iron hydroxide and that maximum instability occurred when the voltages were between -0.04 and $+0.035$ volt. Addition of further quantities of electrolyte may again produce dispersion. This means that the system is moving back to the right along the curve, this time with opposite sign. Large excess of added electrolyte again produces complete flocculation, corresponding to the field to the right of the point where the right leg of the curve cuts the X-axis.

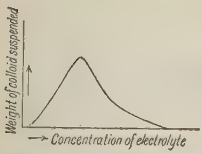

Fig. 6.—Relation between colloid dispersion and concentration of electrolyte.

Electrolytes containing polyvalent ions are, when the polyvalent ion is adsorbed, more effective both in flocculating and dispersing than those containing monovalent ions.

Ralston (*101 J 894*) states that a negatively-charged quartz colloid was equally flocculated by sodium, calcium and aluminum chlorides in amounts that varied as $1 : \frac{1}{40} : \frac{1}{1600}$. This is a well-recognized phenomenon of colloid behavior (Taylor, *General properties of colloids, p. 98*). It indicates that the amounts of different ions adsorbed from a solution of given concentration, as well as the neutralizing power of the individual ions, increases with the valence of the ion and that the resultant increase in effect is of the general order $1 : x : x^2$. (Whetham, *Theory of solution, 396.*) The generally accepted ratio for metallic ions is 1 : 35 : 1023. Ralston (*101 J 894*) also cites an experiment in which a given slime was equally flocculated by 1 per cent. of NaCl, 0.1 per cent. of H_2SO_4 and 0.01 per cent. of $Fe_2^{III}(SO4)_3$. As between the sodium chloride and ferric sulphate, this may be looked upon as another instance of the greater potency of the polyvalent ion, if the colloid was negative, but this assumption does not explain the position of the sulphuric acid. On the other hand, if the colloid was positive, the sodium chloride and sulphuric acid are in line, but the effect of the ferric sulphate is not explained. The probability is that the colloid was negative and the greater potency of the sulphuric acid was due to the commonly observed fact that hydrogen and hydroxyl ions are much more readily adsorbed than the other univalent ions (Taylor, *loc. cit. p. 102*).

Cataphoresis is the migration of colloidal particles in an electric field. The direction of migration is dependent upon the sign of the electrical charge on the particle. Taylor summarizes the behavior of SUSPENSOID (solid-particle) COLLOIDS in the statement that most such are negatively charged, *e.g.*, the metals, metallic sulphides, and most other

a Undetermined.

With the ores tested the organic acids were strong de-flocculants as were also the inorganic acids in low concentrations. The reversal in the action of sulphuric acid on Horn Silver ore with increasing concentration is in accord with Fig. 6. The powerful flocculating effect of the inorganic bases indicates that the general statement, frequently made, that ore slimes are usually negatively charged is not to be accepted without question. The experiments with sodium hydroxide indicate that the two sulphide-ore slimes, Horn Silver and Ophir Hill, were positively charged while the remaining two, which were oxidized ores, were negatively charged. The action of the inorganic salts indicates that the metallic ions were strongly adsorbed on the Horn Silver slime while the acid ions were rather feebly adsorbed on the Grand Central. The tri-valent Al ion is shown to have been much more effective than the bi-valent Fe.

Shellshear (*8 Aa 12*), working with 2-per cent. suspensions of extreme fineness and of many minerals (see Table 3) found that sulphuric acid increased the settling rate of all

Table 3. Settling rates of various mineral powders. (*After Shellshear*)

classes; calcium chloride was particularly effective on silicious material; lime was not so potent as calcium chloride but, like it, was most effective with silicious material; sodium hydroxide in small quantities dispersed silicious material, but accelerated settlement in greater concentrations; alum and sodium bicarbonate, added together, produced a gelatinous precipitate that swept down the suspension; potassium permanganate accelerated settlement greatly. Bruhl (*107 J 1089*) notes that slaked lime is 30 per cent. more soluble than unslaked and produces a more marked settling effect. Sulman (*17 IMM 312*) says that ammonium chloride and other ammonia salts have marked coagulative effect on slimes.

Nichols (*17 IMM 322*) found no marked difference in effect between $BaCl_2$ (83 mg. per 200 cc.), H_2SO_4 (17 mg. per 200 cc.), lime (56 mg. per 200 cc.) and NaCl (167 mg. per 200 cc.) in a 2-per cent. pulp, but on the basis of weights of electrolyte added, H_2SO_4 is the most potent. At ANACONDA (*49 A 478*), settling a 2.5-per cent. slime pulp to 10 per cent. in Callow cones, 1 lb. per ton of ferrous sulphate increased settling rate (capacity) 30 per cent.; 2 lb., 40 per cent.; and 5 lb., 50 per cent. Sodium chloride, 0.25, 0.5 and 1 lb. per ton, respectively, increased the rate 3 per cent. to 4 per cent. only. A mixture of glue and ferrous sulphate, 0.25 lb. of each per ton, was remarkably effective; it increased the capacity of a 28 × 10-ft. Dorr thickener from 195,000 to 311,000 gal. of slime pulp per 24 hr., and on round-table concentrate caused the same settlement in 1.25 min. that required 11 min. with untreated pulp. Nicolai (*103 J 1064*) found that $MgCl_2$ in the end liquor from German potash plants, added in the proportion of 1 cc. of solution per liter of slime, increased settling 67 to 95 per cent.

The effect of electrolytes on settling rate is greater, the more dilute the feed pulp.

Table 4 (*101 J 991*) shows that with 5 per cent. solids in the feed an increase of 35 per cent. in settling velocity is effected by addition of 0.025 per cent. lime while with 20 per cent. solids the same lime addition produced only 4 per cent. increase in velocity over that with no lime. Addition of lime also caused the change from sedimentation to consolidation settling to take place much earlier in dilute pulps than it occurs without lime, while no such change occurred with thick feed pulps.

Table 4. Effect of electrolytes on pulps of different densities. (*After Ralston*)

Flocculation by colloids is a special case of flocculation by electrolytes. The difference is that the neutralizing ion is added attached to a colloidal particle. The principal use of colloids as flocculators involves varieties that form jelly-like precipitates. Their usefulness lies probably as much in their sweeping action, when they themselves are flocculated by the other colloid, as in their neutralizing function.

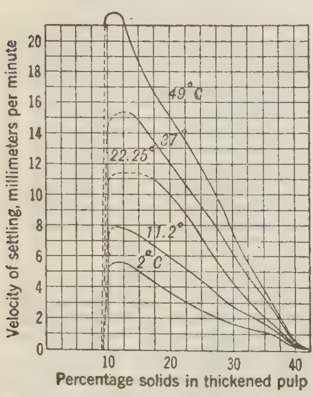

FIG. 7.—Effect of dilution on settling rate (*after Ralston*).

The effect of several organic colloids on ore slimes is shown in Table 2. Some of these, notably gelatin, exhibit both positive and negative charges in the same solution (Taylor, p. 83), which may explain the apparent anomaly of the equal effectiveness of gelatine as a flocculant on both the positively-charged HORN SILVER and the negatively-charged GRAND CENTRAL ores.

Flocculation by increase in solid concentration is illustrated by Fig. 7.

Pulps containing 8 per cent. or less of clay were so little flocculated that they could not be

cleared by settling, those containing 9 per cent. or more were flocculated and settled readily. The essential point here, however, is not fundamentally the concentration of solid but the concentration of electrolyte which was unintentionally introduced with and by the solid. Its presence is proven by the fact that dispersion was effected when solid concentration was low, since electrolyte is necessary to peptization. The behavior with an excess is that to be expected from Fig. 6.

This method of increasing flocculation is important in mill practice, since to reduce the amount of water added to a slime pulp before it reaches the thickeners means a saving due to lower water consumption or less return water to be handled. It is not always a possible solution, but the possibilities should always be closely investigated. Removal of primary slime ahead of hydraulic classifiers or jigs and sending it directly to the thickener will frequently accomplish the desired result.

Dilution of feed has an important effect on settling rate apart from its effect on flocculation.

Fig. 8 (*94 J 646*), presenting the results of laboratory experiment, shows roughly direct increase in settling rate with increase in feed-pulp dilution. Table 5 (*ibid.*) shows that the same relation holds in the mill and that laboratory settling rates are substantially the same as mill performances. Fig. 4 (*101 J 893*) shows that the difference in settling rate is not merely the one to be expected by reason of the greater freedom of the falling particles in dilute pulps, but that at any given pulp density in the consolidating layer the settling rate (velocity of subsidence of the surface of the consolidating layer) is greater the more dilute the feed pulp.

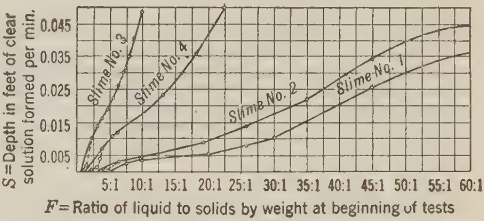

FIG. 8.—Effect of dilution on settling rate (*after Mishler*).

Table 5. Effect of feed-pulp dilution on settling rates in laboratory and mill. (*After Mishler*)

F Liquid : solid ratio in feed, by weight. *D* Liquid : solid ratio in discharge, by weight. *T* Tons dry slime per 24 hr. $S = 0.00004912\ T(F\text{-}D)$. Mill data are results of daily samples over 49-day period from a 24 × 12-ft. Dorr thickener. Laboratory tests were of 10-min. duration and were made in glass cylinders 0.1 ft. diam. and 2 ft. high.

Flocculation by heating. This phenomenon is quite different from that involved in the common practice of employing heat as a temporary expedient

to increase capacity of thickening tanks. Heating may increase flocculation, if the electrolyte that is stabilizing peptization is less soluble in cold than in warm water, and is present in excess of its soluble proportions. Under such circumstances heating will increase the amount of electrolyte dissolved and ionized and flocculation will result from excess of electrolyte according to Fig. 6.

This is undoubtedly the explanation of the case cited by Ralston (*101 J 891*) of a Mexican cyanide plant at which the slimes suddenly ceased to settle during a cold spell and normal working was restored by a few steam jets introduced into the solution.

Heating, however, does not always produce flocculation or aid settlement but may actually increase dispersion.

Nichols (*17 IMM 293*) reports a case in which high temperature (200° F.) with accompanying violent agitation resulted in de-flocculating a pulp and thereby markedly decreasing its settling rate. If initial flocculation was due to a position for the system to the left of the peak in Fig. 6, yet undissolved electrolyte was present, heating, if it caused more electrolyte to dissolve, would cause further peptization. If, on the other hand, initial flocculation indicated a state for the system to the right of the peak in Fig. 6, then unless there was an absolute excess of electrolyte present, the increased activity of the water molecules caused by heating would, by increasing the molecular bombardment producing Brownian movement, increase dispersion.

Effect of heat on slime settlement is ordinarily to increase the rate. Richards (*2 OD 1147*) calls attention to this fact and Dorr (*49 A 224*) states that heating may prove an economical method of adding 10 to 20 per cent. to the capacity of a thickener.

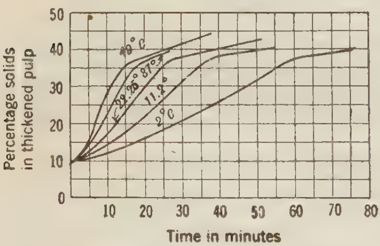

FIG. 9.—Effect of heat on slime settlement (*after Ralston*).

Nicolai (*103 J 1064*) states that the thickener overflow of a German lead-zinc mill carried from 0.02 to 0.1 gm. solid per liter on warm summer days and 0.2 to 0.4 gm. on cloudy or windy days.

The effect may be due to increase in flocculation but is more frequently due to decrease in the viscosity of the water. (See Sec. 25, Table 2.)

Figs. 7 and 9 summarize experiments by Ralston (*101 J 890*) on the effect of heat on settlement. He assigns all of the increase in settling rate with increased temperature to decrease in viscosity and shows that, for the data represented, the quotient obtained by dividing the time of settling to a given pulp thickness by the absolute viscosity is a constant, which confirms his conclusion for this particular set of data. Nichols (*17 IMM 321*) found that the rate of settlement of a 2.33-per cent. slime increased on heating from 60° F. to 190° F. and decreased at the same rate on cooling, which is substantially conclusive that the effect was due to change in viscosity.

Results of tests at ANACONDA (*49 A 479*) are given in Table 6. Laist and Wiggin call attention to the fact, as a matter of practical design, that while the average settling rate at the average summer pulp temperature of 50° is greater

Table 6. Effect of pulp temperature on settling rate of Anaconda slime. (*After Laist and Wiggin*)

Pulp temperature, degrees F.	Time to settle from depth of 17.5 in. to 3.5 in., minutes		
	Average	Maximum	Minimum
35	41.7	57.0	29.5
40	38.0	50.7	27.3
45	35.0	45.2	25.0
50	31.7	40.2	23.0

60	26.0	33.0	18.3
65	23.3	29.8	16.0
70	21.2	26.7	13.8
75	19.5	25.0	12.0

than that at the average winter temperature of 38°, yet other factors may enter to make the minimum rate at 50° less than the maximum, or even the average rate at 38°, and they conclude that pulp temperature is, therefore, a relatively unimportant factor in thickener-plant design.

Flocculation is a reversible phenomenon. Reversion may occur on account of changes in solid concentration when effective electrolytes are brought in with the solid, if the total amount of electrolyte present constitutes only a slight excess. When flocculation is effected by an added electrolyte, small variations either side of the iso-electric point, due to small deficiency or excess of electrolyte, will cause reversion. Changes in temperature may also be effective. Change in character of ore is another possible cause of reversion. Agitation will not usually cause reversion and even when such is the apparent effect, it is probable that some change in electrolyte concentration is the real cause. Any reversion in mill practice is likely to produce cloudy overflow from thickeners and decrease their capacity.

Depth of settling tank has no effect on settling rate with dilute feeds, *i.e.*, the rate of subsidence of the surface of the consolidating solids is the same irrespective of the depth of the tank, for any given pulp density, provided that the initial feed pulps are of the same density.

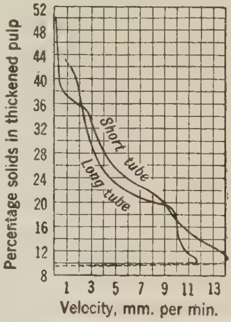

FIG. 10.—Effect of depth of tank on pulp thickening (*after Ralston*).

Fig. 10 presents a summary of Ralston's results (*101 J 892*) and Table 7 gives Mishler's data (*94 J 643*).

Table 7. Effect of depth of tank on rate of settlement in dilute feed pulps.(*a*)
(*After Mishler*)

a Quiet settling in glass cylinder 2.3 ft. high by 0.1 ft. diameter. *L* Liquid. *S* Solid.

When the feed pulp is thick, and the tank shallow, the settling rate increases with the depth of tank, as is shown by Table 8. This table shows also that the transition between "thick" and "dilute" feed pulps comes at different densities, according to the depth of the tank; the greater the tank depth the thicker the pulp that settles at the dilute-pulp rate. Mishler points out, how-

ever, that the tanks used in practice are all "deep" compared to those investigated, and that in such deep tanks the settling rate for thick pulps, also, is independent of the depth of the tank.

Table 8. Effect of depth of tank on rate of settlement in thick feed pulps.(*a*)
(*After Mishler*)

a Quiet settling in glass cylinder 0.1 ft. diam. Each test made by noting time required to form a volume of clear solution equal to 1/20 part of the original volume of pulp. Below the broken lines the slime begins to follow the principles of settling for thin slime. *L* Liquid. *S* Solid.

For the effect of tank depth on density of discharge see p. 992.

Effect of kind of mineral on settling rate is not, apparently, related to the specific gravity.

Shellshear (*8 Aa 7*) has tested various minerals in 2-per cent. suspensions in pure water with the results shown in Table 3. He found that mixing rapid-settling and slow-settling pulps resulted in flocculation and great increase in settling rates. The extent of flocculation depended upon the proportions of the mixture.

5. Thickeners

Thickeners are tanks of such capacity that the time required to fill them at the rate of flow of the stream to be thickened is sufficient to permit the upper surface of the solid matter to settle a safe distance below the overflow level and the lower stratum of settled solid to consolidate to the desired consistency. They are provided with an overflow weir and one or more bottom-discharge openings so located as to draw off the settled solids uniformly. They are built either for intermittent or for continuous operation. The latter type may be discharged by gravity or mechanically. Intermittent thickeners have found their greatest use in the Rand gold mills; continuous thickeners, first of the gravity-discharge type but latterly of the mechanical type, are almost universal in the United States.

Intermittent thickeners are usually rectangular tanks or elongated ponds fed at one end and overflowed at substantially the same level at the other end,

Feeding continues until the overflow contains more than an allowable load of solid, when the feed stream is diverted to another tank. After the solids have settled the supernatant clear liquid is drawn off through pipes variously arranged for adjusting the draw-off level. The thickened solid is finally flowed or pumped out from a sump and the tank is ready for another charge. The draw-off level for liquid is varied by means of pipes placed at various heights in the walls, or by means of a jointed stand-pipe from the top of which short lengths are easily removed; most frequently by means of an inclined pipe joined, by means of a 90° ell, with a horizontal pipe in the bottom of the tank. (See Fig. 11.)

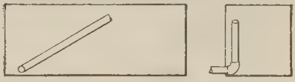

Fig. 11.—Adjustable draw-off for intermittent settling tank.

The horizontal cross-section of intermittent settling tanks should be such that the rate of rise of liquid therein is less than the settling rate of the surface of the solids in consolidation settling.

Thomas and Osterloh (*17 JCM 214*) state that two slime ponds with a total circumference of 6000 to 7000 yd. are sufficient to handle 30,000 tons of thick Rand slime per month.

Continuous thickeners of the gravity-discharge type are typified by the cone; the Dorr thickener is typical of the mechanically-discharged type. In these machines there is continuous feed of pulp, usually at the center of the tank, continuous peripheral overflow of substantially solid-free liquid and continuous discharge of thickened pulp from the bottom.

Cones are typified by the Callow cone (see Sec. 6, Art. 5).

At the Great Falls plant of Anaconda Copper Co. (*49 A 423*) 8-ft. cones treating −0.074-mm. slime were fed with slime pulp carrying 1.5 to 2 per cent. solids at the rate of 25 to 30 gal. per min. or 0.582 to 0.698 gal. per min. per sq. ft. of settling area. The overflow contained about 2 to 2.5 per cent. of the total solids fed and 90 per cent. of the total water. The spigot product ran about 8.75 per cent. solids and was discharged through a ⅜-in. gooseneck spigot under 24-in. head. Thirty 8-ft. tanks handled 1,000,000 gal. of slime per 24 hr. carrying 80 tons solid. At the Anaconda plant (*49 A 473*), the capacity of an 8-ft tank treating −0.074-mm. slime from a different ore, was only 12.3 gal. per tank per min. or 0.286 gal. per sq. ft. of settling area per min. The spigot discharge contained 9 to 14 per cent. solids representing 90 to 95 per cent. of the total solids fed (*46 A 253*).

Table 9. Effect of overfeeding a cone thickener

Rate of feed, gallons per minute per square foot	Solids recovered, per cent. of total feed
0.194	100.0
0.213	95.0
0.233	90.0
0.272	85.0
0.301	80.0
0.330	75.0
0.369	70.0

The effect of overfeeding is shown in Table 9, presenting results of a test on a rectangular settling tank 10 ft. by 9 ft. 6 in. by 8 ft. (deep), center fed, treating Anaconda slime with 2.5 per cent solids.

Lead ores have been treated at the rate of 30 to 35 gal. per min. of feed containing 1 per cent. solids, giving a spigot product with 25 to 40 per cent. solids and an overflow carrying 5 gm. per gal.

At Alaska-Gastineau 8-ft. 6-in. tanks were used for dewatering a feed containing 88.5 per cent. −200-mesh at the rate of 20 tons solid per 24 hr. in a pulp containing 96 per cent. moisture. The spigot product contained 91.2 per cent. moisture and 88.4 per cent. −200-mesh, the overflow, 98.3 per cent. moisture.

At Homestake (*99 J 412*) 26-ft. conical-bottom tanks, 23 ft. 9 in. deep, treated 406 tons of slime pulp (sp. gr. 1.036) per 24 hr. making 84 tons underflow containing 33 tons solid and 322 tons clear overflow. This pulp contained no reagent and water was at winter temperature. Increase in the feed rate to 505 tons pulp per 24 hr. increased the density of discharge to 33 tons solid in 86 tons pulp, but caused cloudy overflow.

Intermittent discharge lessens the difficulty in maintaining thick spigot

product from gravity cones. Fig. 12 shows a typical form. Speed depends upon amount of solids fed to the cone, the greater the amount the greater the number of openings necessary per unit of time.

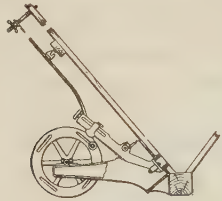

FIG. 12.—Ayton intermittent pulp-discharge valve.

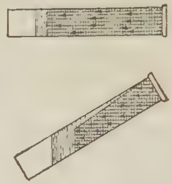

FIG. 13.—Effect of baffles on slime settlement (*after Dorfman*).

Baffles set at an incline in a thickening tank increase the settling capacity. Fig. 13 illustrates the action. The thickness of the layer of consolidating solid through which water must be expelled is lessened by inclining the container, and the number of surface pores available for egress of water is increased, both of which changes make for an increased rate of expulsion. Table 10 is a summary of the results of tests in a rectangular tank 3 ft. wide by 3 ft. deep by 9 ft. long at ANACONDA (*46 A 250*), with baffles of corrugated iron set at 45°, tops 4 to 6 in. below the overflow level and the lower ends about 9 in. from the tank bottom. The tank was fed at one end and overflowed the other; baffles were arranged in various positions without causing marked differences in result.

When high removal of solids is desired, there is little to choose between the open and baffled tanks, but with less complete solid removal the capacity of the baffled tank is markedly greater than that of the open tank.

Table 10. Comparison of baffled and open settling tanks at Anaconda. (*After Hayden*)

Feed rate, gallons per foot of width per 24 hr.	Per cent. of solids settled	
	In baffle tank	In open tank
1883*a*	100.0	100.0
2000*a*	99.9	94.8
3000	97.5	67.8

8000	75.9	28.0
9000	67.8	23.8

a Extrapolated.

6. Dorr thickener

Description. The Dorr thickener (Fig. 14) consists of a relatively shallow tank (*a*) of large horizontal area and with flat or slightly conical bottom, a central feed well (*b*), a peripheral overflow launder (*c*), finally, a slow-moving mechanism (*d*), suitably supported, carrying rake arms near the bottom of the tanks that serve, by their revolution, to move settled solids to a central bottom-discharge opening. Thickened pulp may be discharged by gravity alone through a suitable pipe-and-plug spigot, but is best handled by means of a diaphragm pump set slightly above the overflow level. Tanks are made of wood staves, sheet steel or concrete; in rare cases they are merely pits dug in the ground. Rake arms are set on a slope. When the feed is

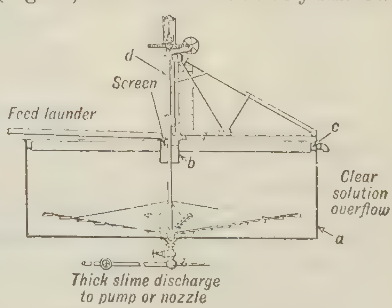

FIG. 14.—Dorr thickener.

low-grade, the solid is allowed to build up in flat-bottomed tanks to the slope of the rakes, but if the feed pulp contains much value, as for instance, flotation concentrate, the bottom is frequently filled in with cement concrete by pouring in a relatively stiff slow-setting mixture of sand and cement with rakes operating in the lowest position. When concrete tanks or concrete bottoms are used these are built to the desired slope initially.

The driving mechanism (Fig. 15) is fitted with a power screw (*a*) for changing the vertical position of shaft and rakes while operating, and a resistance indicator and overload alarm to call attention to the necessity for such change. Block (*b*) abuts against the end of shaft (*c*) which carries the driving worm. If the resistance of the rakes, transmitted through the worm gear, is great, block (*b*) is pushed back against the pressure of spring (*d*) and pointer (*e*) is moved toward the left. Dangerous resistance causes the pointer to move over until a copper plate (*f*) closes an electrical circuit and an alarm bell is rung. The remedy is to raise the rakes by means of (*a*) and to decrease the feed rate or increase the discharge rate or both. Increasing the speed of the arms will, in many cases, lessen resistance by decreasing the thickness of the layer of solid in motion toward the center.

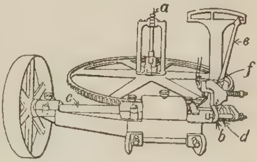

Fig. 15.—Driving mechanism and overload alarm for Dorr thickener.

Discharging thickened pulp. The old method was by means of a pipe-and-plug spigot. To discharge at some distance from this fitting, 4-in. pipe was extended to the discharge point and then bushed. With this arrangement thick discharges cause trouble due to deposition of solid in the 4-in. line.

Hanson (*109 J 853*) recommends replacing the 4-in. line by 1½-in. line to increase pulp velocity and prevent sedimentation.

The Dorr Co. now recommends a diaphragm pump mounted at or a few feet above overflow level with the suction pipe attached to the tank-discharge opening. The pump prevents clogging and permits close and positive regulation of rate and density of discharge by means of a pet-cock tapped into the pump chamber below the diaphragm, which regulates pump suction.

Cole (*100 J 131*) installed eight mechanically-operated 3-in. ball valves, on the 130-ft. thickener at Arizona Copper Co., and reports satisfactory operation. At Bunker Hill and Sullivan (*100 J 639*) a rotating cock, opened 15 to 25 times per min. eliminated clogging of a gravity discharge.

Performance at various mills is shown in Tables 11, 12, 13, 14 and 17.

Table 11. Performance of Dorr thickener on cyanide pulps

a Estimated. 96.1 per cent. through 240-mesh. *b* 7 tanks as follows: 1 @ 30 × 10.25, 1 @ 34.75 × 8.6, 1 @ 34.75 × 10.25, 4 @ 60 × 13. *c* Substantially clear. *d* Maximum. *e* 80 sq. ft. per ton required to thicken to 50 per cent. solids (*69 A 178*).

Speed of rake arms depends to some extent on the character of the feed, *e.g.*, sandy feeds and those containing solids of high specific gravity require higher speeds than ordinary slime pulps. The usual peripheral speed of rake-arm tips on slime pulps is 10 to 15 ft. per min.; on flotation concentrate, 15 to 20 ft. per min.. Speed should not be sufficient to stir up the solid. With flocculent material slow speed, with consequent high resistance, gives thicker discharge, apparently because of consolidation under the rake pressure.

Table 14. Performance of Dorr thickener at Middlefork washery of U. S. Fuel Co.
(*After Campbell, 63 A 686*)

	Feed	Overflow	Spigot
Water, per cent.	98	99.7	47.2
Specific gravity	1.0052	1.0008	1.1580
Tons of pulp per hour(*a*)	500	485	15

a This represents the wash water from about 1200 tons of washed coal per 8 hr. Two @ 70-ft. tanks are used.

Power consumption is very small, probably not over 0.1 hp. for thickeners under 50 ft. diameter, but practice is to install larger motors, particularly with individual drive, in order to save stalling when, for any reason, the load of solid builds up, and also to furnish excess power in starting up after a shut-down.

Labor is a negligible item in operation. Except where an exceptionally large number of tanks is in use, operators on adjacent machines can take care of the tanks. At ANACONDA 1 man, full time, takes care of 40 @ 28-ft. tanks. At CHINO COPPER CO. 1 man attends 21 tanks of 20 to 75-ft. diameter.

Repairs are substantially *nil*, barring accidents due to attempts to start after a shut-down when the rakes are imbedded in solid. Such accidents may be avoided by raising the rakes before shutting down and lowering them slowly on starting. Wooden tanks rot in course of time and should not be used, if long life is desired, except where metal cannot be used on account of the chemical character of the liquid and concrete is not justified.

Capacity depends upon the kind of feed and the density of discharge pulp desired. It is usually reckoned in terms of square feet of tank area per ton of solid per 24 hr. or per gallon of liquid overflowed per minute. With relatively dense feed pulps the tonnage of solid is the limiting factor while with dilute pulps the volume of overflow governs. On cyanide pulps running 75 to 90 per cent. through 200-mesh and containing from 10 to 20 per cent. solids the usual allowance is 4.5 to 5 sq. ft. of settling area per ton of solid per 24 hr., up to 15 or 20 sq. ft. when considerable clayey matter is present. The area allowed with cyanide pulps per gallon of overflow per minute ranges from 2.4 to 19.2 sq. ft., average 9.7 sq. ft., but this is not the determining factor in this service. The rising velocity in tanks fed with the more dilute pulps was as high as 0.25 mm. per sec. Velocities with thicker feeds were far below this, which indicates that considerably more water could have been added to these feeds without making it necessary to reduce the solid tonnage.

In thickening flotation-feed pulps the area allowance ranged from 1 to 20 sq. ft. per ton of solid feed per 24 hr., average 8.4 sq. ft.; and from 1.5 to 9.0 sq. ft. per gal. of water overflowed per min., average 3.2. These feeds contained, in general, less than 5 per cent. solid and volume of overflow was the determining factor.

Ramsey (*57 A 412*) recommends 6 to 7 sq. ft. per ton to discharge at 20 per cent. solids. At TUL MI CHUNG mill (*114 P 362*) addition of 2 lb. caustic soda per ton (calcitic ore, 40 per cent. limestone) decreased settling rate to such an extent that where formerly the allowance was 6 sq. ft. per ton per 24 hr. for clear overflow, 36 sq. ft. was necessary after the addition, the feed containing 25 per cent. solids.

Rising velocities with flotation-feed pulps ranged from 0.10 to 0.41 mm. per sec., average 0.19 mm.

In thickening flotation concentrate before filtering, the area allowance ranged from 8.8 to 39.8 sq. ft. per ton of solid per 24 hr., average 18.4; and from 1.6 to 24.2 sq. ft. per gal. of overflow per minute, average 12.0.

Ramsay (*56 A 715*) states that INSPIRATION, ANACONDA, RAY and CHINO are thickening copper concentrate to about 60 per cent. solids on a tank allowance averaging 40 sq. ft. per ton of solid feed and that UTAH COPPER thickens to the same consistency in a 75-ft. tank at

the rate of 200 tons per day, or 22 sq. ft. of tank area per ton. Zinc concentrate is easier to settle. TIMBER BUTTE, BUTTE AND SUPERIOR and ANACONDA allow 12 to 15 sq. ft. per ton per 24 hr. when thickening to 60 to 70 per cent. solids. At AFTERTHOUGHT (*119 J 154*) by taking an overflow containing 2 per cent. solid, a mixed copper-zinc concentrate was thickened from 25 per cent. to 75 per cent. solids at the rate of 150 tons per 24 hr. in two 21-ft. tanks, or 1.6 sq. ft. per ton per 24 hr. Area requirement for lead concentrate is about the same as for zinc.

This is the most difficult service on account of the extreme fineness of the solid, lack of flocculation, difficulty of breaking up the gas-mineral aggregates, and thick spigot discharge required. Rising velocities allowed in most cases were of the order of 0.05 mm. per sec.

Breaking flotation froth is one of the principal difficulties in thickening this class of material. It is necessary either (*a*) to subject bubble walls to exterior mechanical strains sufficient to cause rupture or (*b*) to so disturb the surface-tension equilibrium that they rupture by reason of the disturbance.

Water jets and sprays of various kinds are the commonest of the mechanical methods of breaking. It is necessary to strike practically every bubble that is to be broken, hence the water must be projected at the froth as a multitude of small masses (spray) or as a number of small streams (multiple jet) or as a sheet. The water must be under some pressure in order to be moving with sufficient velocity to break the bubbles, but the velocity should not be so high as to produce froth by cascade action. (See Sec. 12, Art. 11.) The sprays or water jets are applied in the launders leaving the flotation machines or are directed at the stream as it enters the thickener.

Pumps and bucket elevators have been used at several plants but neither is particularly satisfactory. If the froth is persistent and voluminous it will not enter these machines, but overflows the sumps and water must be used to break it down. The cascade action at the discharge will cause considerable froth to form.

At CIA COROCORO DE BOLIVIA (*112 J 983*) a very tough froth was broken by running it into the intake of a 4-ft. × 6-in. ventilating fan running at 250 r.p.m. The fan handled more than 50 tons of froth per 24 hr. Blades lasted 4 to 6 months. Only the foam was sent to the fan.

Soluble reagents that lower surface tension greatly in relatively low concentrations, such as pine oil, wood creosotes and the like have been mixed with the spray water at some plants. Water containing such reagents lowers the surface tension of the bubble films that it strikes to such an extent and so suddenly that the adjacent film contracts sufficiently to break the bubble wall at the point of low tension.

The use of Wilfley tables as froth breakers is an application of the method of surface-tension change.

When the reagent that is added is suitable for flotation in the plant, thickener overflows and clear water from the filter plant pumped back to the flotation machines carry much of the oil value with them.

Lime has been added at Cœur d'Alene plants to break down froth (*105 J 716*) but the probability is rather that it promotes settling, since it has not sufficient effect on surface tension to act from that angle.

Frequently small-bubble persistent froth collects on the surface of concentrate thickeners and, if not confined, overflows. If it can be confined by a ring placed a few feet in from the overflow rim and extending down for several feet into the tank and up a foot or more above the overflow rim, it gradually dries out and compacts and equilibrium is reached with settlement of the densest portion from the bottom near the periphery balancing accession at the center. At MIAMI this end was attained by using several tanks more or less intermittently and thus allowing sufficient time in each for the necessary compacting. At GOLD HUNTER (*107 J 839*) floating froth was scraped off into a special launder by arms connected to the revolving mechanism, and joined with the thickened product ahead of the filter plant.

Density of discharge pulp depends primarily upon the specific gravity of solids and the size of particles. In thickening flotation feed a spigot discharge containing from 20 to 30 per cent. solids is usually all that is desired. On the other hand, in thickening concentrate a spigot discharge containing 50 to 70 per cent. solids is wanted and capacity is correspondingly reduced. In cyanide work, also, a thick spigot discharge is sought, but capacity is high on account of the flocculating effect of the electrolytes present. In general, silicious ores can be thickened to greater density, with a given feed rate, than can clayey and highly oxidized feeds.

Dorfman (*20 CMI 103*) reports, as the results of experiments on four different varieties of PORCUPINE ore, that a quartz pulp will settle to 35 per cent. moisture in 3½ hr.; a gray schist,

in the same time, to 51 per cent.; quartz porphyry to 60 per cent. and sericite schist to 64 per cent. The latter still contains 47 per cent. moisture after 18 hr. settling.

Coarse feed yields thicker discharge than fine, with a given feed rate. The limit of economical thickening of fine-ground clayey material, even with flocculating agents present, is probably between 40 and 50 per cent. solids while clean silicious ore, equally ground, can be readily thickened to 60 or, in some cases, 70 per cent. solids. Thick feed produces thicker discharge than dilute feed.

Ralston (*101 J 991*) notes that when flocculation is produced by electrolytes, the discharge is increasingly moist with increased flocculation of the pulp. He states that heating to accelerate settlement does not have the same bad effect.

Distribution of material in an operating thickener is shown by Figs. 16 to 18 incl. The deep clear-water layer in Fig. 16 leaves a safe working margin for feed fluctuation while the shallow layer in Fig. 17 will quickly disappear with slight increase in solid content of the feed or decrease in settling rate. The segregation of sizes shown in Fig. 18 is to be expected, the larger and heavier solids settling near the center. The act of raking to the central dis-

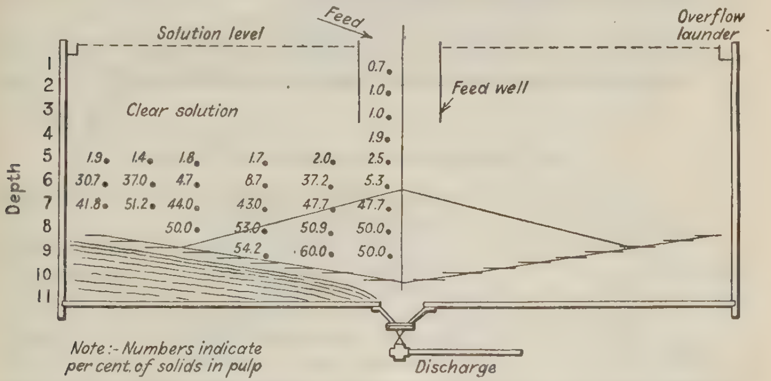

FIG. 16.—Pulp densities in a Dorr thickener, normal feed rate (*after Dorfman*).

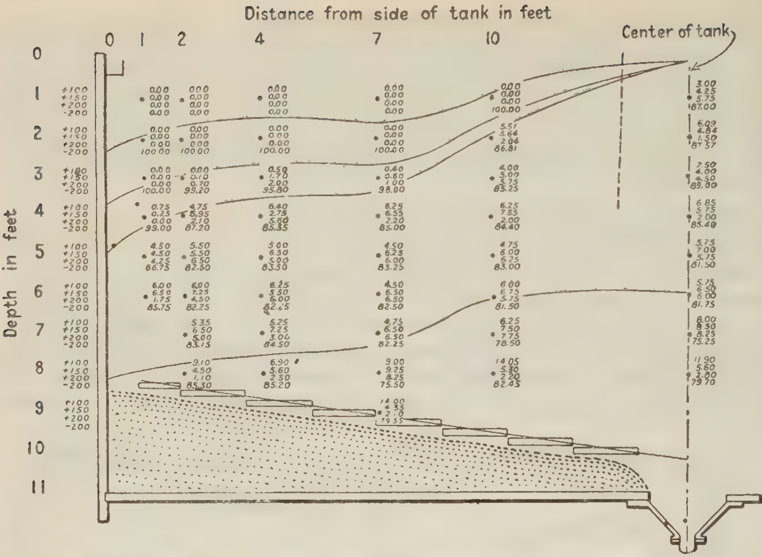

FIG. 18.—Size distribution in a Dorr thickener (*after Dorfman*).

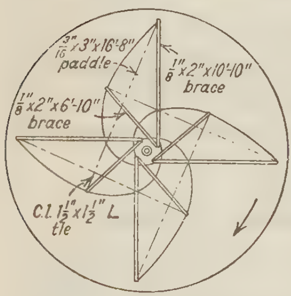

FIG. 19.—Rake for El Tigre thickener.

charge, of course, restores the size distribution to that of the original feed.

Effect of depth of tank on density of spigot discharge is small. The time during which consolidated pulp is compacting is the important element in determining discharge density. Shallow tanks ordinarily show slightly thicker discharges for a given time of settling, on account of the fact that compacting starts earlier therein. Table 15 is typical.

El Tigre thickener (*92 J 691*) is a Dorr tank with spiral paddles (see Fig. 19) replacing the rakes. The face of the spiral blade is approximately 45° to the tangent to its circular path at any point. The object of this form of rake is to prevent eddying.

7. Tray thickeners

Description. These are essentially shallow thickeners superimposed, with a common shaft carrying independent rakes for each tank. Fig. 20 shows the type in use at ANACONDA with separate tanks, known as the SUPERPOSED TYPE; Fig. 21 shows the SUBMERGED TYPE with one or more trays in the same deep tank. The first type is more accessible, the second more compact and has all overflows at the same level.

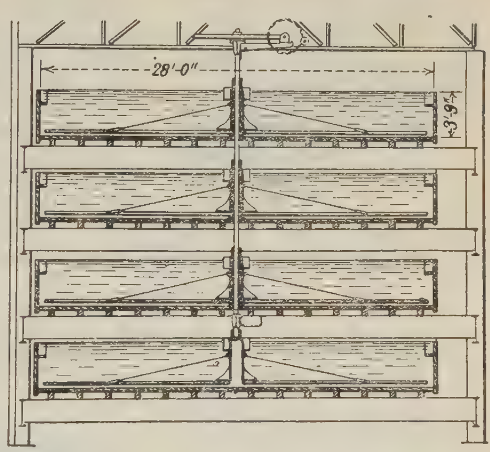

FIG. 20.—Dorr tray thickener, superposed type.

The principle of the tray thickener is illustrated by an experiment reported by C. H. Jakin (*94 J 872*) and analyzed by Mishler (*94 J 1114*). Jakin found that one slime with which he worked settled from 59 per cent. to 46 per cent. moisture, yielding clear overflow, in 45 min. in a tank 1.25 ft deep and required 420 min. to attain the same thickness in a tank 12 ft. deep. With another slime, thickening from 90 per cent. to 81 per cent. moisture, 120 min. was required in a tank 1.25 ft. deep and 1020 min. in a tank 10 ft. deep. Mishler shows that the settling rates were 0.0092 and 0.0089 ft. per min. in the deep and shallow tanks respectively in the first experiment and 0.0050 and 0.0052 ft. per min. in the second, *i.e.*, substantially the same, as his previous experiments had shown to be the case, and since there was sufficient time to produce thick pulps of the desired consistency in the shallow tanks, both shallow and deep thickened at the same rates. Actually, the time required to effect the desired compacting of discharge pulp is the essential factor in determining minimum depth of tank, while, since the settling rate is independent of depth, the amount of clear overflow produced is dependent only upon tank area.

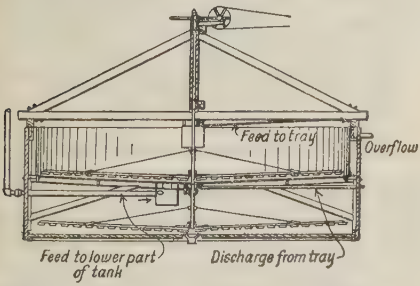

FIG. 21.—Dorr tray thickener, submerged type.

Performance. Laist and Wiggin (*49 A 474*) report that 28 × 3-ft. tanks at ANACONDA had 85 per cent. of the capacity in thickening flotation feed, of 28 × 9-ft. tanks and that the capacity of 28 × 2-ft. tanks was 85 per cent. that of the 3-ft. tanks. At LIBERTY BELL (*49 A 221*) a tray in a 33 × 10-ft. tank doubled capacity. At TONOPAH BELMONT addition of trays to 30 × 12-ft. tanks increased capacity about 75 per cent. (*52 A 104*). In general, with quick-settling ores, when discharging relatively thin pulps, trays will increase capacity upwards of 90 per cent., somewhat less with clayey ores or thicker discharges. OLD DOMINION (*56 A 715*) is using a 40-ft. single-tray thickener for 600 tons per day of flotation concentrate in a pulp containing 8 per cent. solids. The spigot product contains 63 per cent. solids and the overflow is clear.

Trays are not suitable when there are great changes in character or quantity of feed; the excess volume of a deep tank is then necessary to take care of the fluctuations in depth of clear-water layer dependent on the feed changes.

Hydrotator thickener (Fig. 22) may be used either as a dewaterer or a de-slimer. The machine superimposes on the ordinary continuous-thickener principle the further operation of taking suspended solid matter from the top of the settling tank, as at (*D*) or (*E*) and pumping it, by pump (*G*) into the rotating sprinkler mechanism (*B*) thereby placing such solid nearer the discharge point. Settled solid is drawn off from any of the pipes (*F*), as desired.

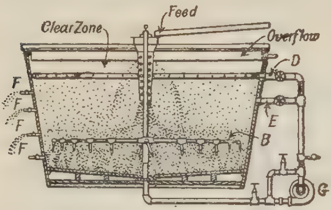

FIG. 22.—Hydrotator thickener.

The machine is new; it has been tested principally on fine coal. In one test – 3/32-in. anthracite slush (15 per cent. + 20-mesh; 35 per cent. – 100-mesh) yielded clear overflow at the rate of 1.3 gal. per sq. ft. per min. and overflow containing 1 per cent. solids (all – 100-mesh) at the rate of 2.2 gal. per sq. ft. per min. A shallower machine is used as a de-sliming classifier. Another form has been used for froth flotation (see p. 805).

8. Filter thickeners

Hardinge super-thickener (Fig. 23) is a combination of the usual settling-type dewaterer with mechanical removal of settled solids (Dorr thickener), and a sand filter. Its underlying principle is to increase the rate and extent of compacting (see p. 974) of settled solid by making the direction of the currents of expelled water downward instead of upward. It does this by maintaining a head of solution on the sand-filter bottom, either by suitable difference in elevation between the level of overflow and filtrate discharge or, if this is insufficient, by discharging filtrate by means of a vacuum pump. In Fig. 23 (*a*) is the thickener tank with overflow launder (*b*), spigot discharge (*c*) through a diaphragm pump, scraping mechanism (*d*) for moving settled solids toward the discharge spigot, a sand bed (*e*) through which filtrate is to be drawn, supported on the usual framework of studs, slats, cocoa-matting and burlap (*f*) (see Sec. 17). A pipe (*g*), connected to the space under the filter bottom, discharges filtrate either into the atmosphere or into a vacuum tank, according to the filtering duty required. The essential element of successful operation is the continuous removal of a thin skin from the top surface of the filter bed, thus maintaining this at full filtering efficiency (see p. 1000). This is effected by means of a thread (*h*) on the upper end of the drive shaft and a ratchet-driven feed mechanism (*i*) which lowers the scraping mechanism at the rate of 1/64 in. to as much as 8 in. per 24 hr., depending upon the amount of material present that tends to clog the filter. The thread (*h*) is 5 ft. long. The sand should be fine, granular and of such a mixture of sizes as will give maximum porosity and yet permit minimum penetration of solid, as in Table

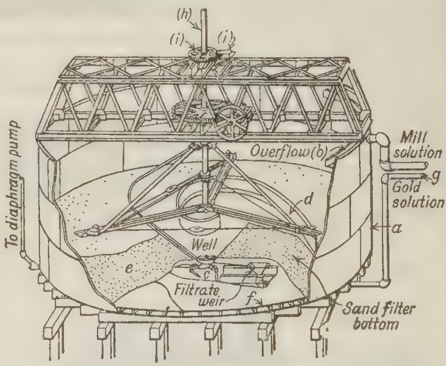

FIG. 23.—Hardinge super-thickener.

16. Power requirement for the scraper and diaphragm pump is about the same as in the Dorr thickener. If suction is used, more power, in accord with the suction requirement, will be needed.

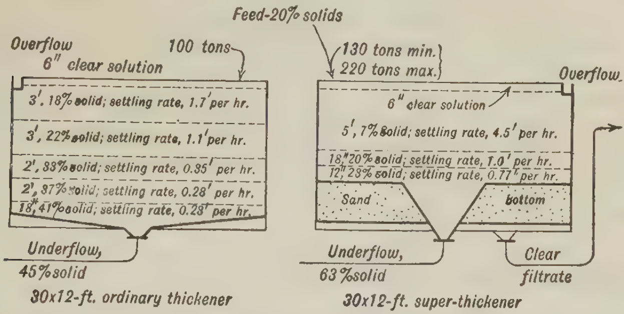

FIG. 24.—Comparison of densities and settling rates in super-thickener and ordinary thickener at Golden Cycle.

The effect of the filter bottom on density of pulp at various depths in the tank and consequently on settling rate of the solids is shown in Fig. 24.

The underflow of the super-thickener at GOLDEN CYCLE could be maintained at a much higher density than was possible in the usual type. When feeding cyanide pulp containing 20 per cent. solids, ground so that 95 to 98 per cent. was − 200-mesh, the super-thickener would discharge at 70 per cent. solids, working under a static head of 20 in. of water, but the diaphragm pump could not handle pulp of this thickness, so that density was lowered to 64 per cent. solids. This is to be compared with maximum operating thickness of 45 per cent. solids on the same pulp in the ordinary machine. (*Hardinge Co.*)

Applicability. The super-thickener is particularly adapted to clarification and to production of exceptionally thick spigot products. For thickening service that is within the capacity of the ordinary Dorr thickener the latter is simpler to operate and probably cheaper, notwithstanding a somewhat lower capacity.

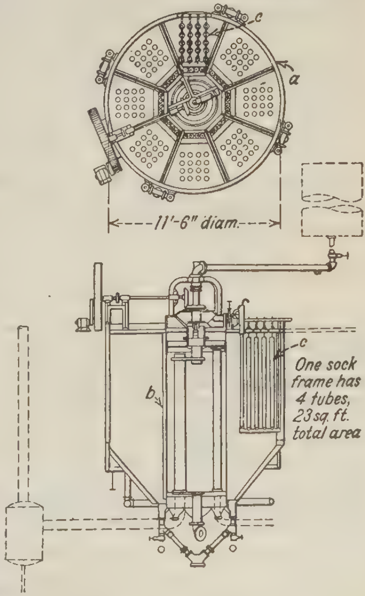

FIG. 25.—Genter thickener.

Genter thickener (Fig. 25) is essentially a vacuum filter, useful for dilute, difficult slimes. It consists of a compartmented annular tank (*a*) for receiving feed pulp, a central vacuum chamber (*b*) and a series of tubular filtering elements (*c*) suspended in the compartmented tank. Clear liquor is drawn to the interior of the filtering elements and a layer of thickened slime is deposited on the outside. This slime is dropped off by reversing the flow of liquid through the filter cloth momentarily. The thickened slime falls to the bottom and is discharged by means of a diaphragm pump. The filtering tubes have 5.75 sq. ft. filtering area each.

9. Centrifugal dewaterers

These have been extensively developed and widely used in the chemical industry. They consist essentially of a feed container rapidly rotated on a vertical axis whereby centrifugal force amounting, in some cases, to as much as 40,000 times the force of gravity is applied. The basket or EXTRACTOR TYPE

has a rotating member with porous walls which retain solid matter but pass the suspending liquid. This is substantially pressure filtration (see Sec. 17). Usual sizes of basket are 30 to 72 in. diam. and 24 in. or less in depth. They develop centrifugal force 200 to 600 times as great as gravity. Operation is intermittent. The machine is charged while running at low speed, extracted at full speed, then stopped and the basket cleaned of extracted solid. Use is limited to solid-liquid separation. For best operation the solids should be granular, with little variation in size and free of gelatinous matter. The percentage of solids in feed should be high (40 to 50 per cent. or more) on account of the necessity for discharging all liquid through the bed of solids. The BULK CENTRIFUGAL has a solid basket or cup and discharges liquid by overflow. The basket of the Gee machine is 36 in. diam. by 54 in. deep and is driven at 1000 r.p.m. Solid is deposited on plates hung on the inner surface of the basket. The Resine machine has horizontal baffles in the basket to lessen flow of solids to the liquid discharge. Most bulk centrifugals must be stopped to discharge solid. This type is suitable for treating mixtures containing low percentages of solid, but yields a cloudy liquid and a solid fraction containing much more water than is obtained from the extractor type. The bulk centrifugal has been used for purifying and grading clays and for recovery of coal from waste waters. The HIGH-SPEED CENTRIFUGAL and SUPER-CENTRIFUGE are of the solid-basket type with baskets of small diameter to withstand the great forces developed. The high-speed machines are run at 5000 to 15,000 r.p.m. and the super-centrifuge up to 40,000. Capacity is so small and power consumption so high that the high-speed machines can be used economically only for treating valuable products of small bulk.

A successful centrifugal thickener for ore-dressing must discharge both clear liquor and thickened solids continuously and must have sufficiently high capacity to overcome its relatively great capital and power costs. Many machines have been developed in the attempt to fulfill these conditions, but none has as yet been successful commercially.

ADVANTAGES of a successful machine will be small floor space and positive control of spigot density. DISADVANTAGES of the present machines are high repair and power costs, dirty overflow, and, with most, intermittent operation.

COMPARISON OF THICKENERS

Continuous thickeners have greater capacity per square foot of settling surface than intermittent because the settling rate in the latter is slowed down, when they are nearly full, by the approach of thick pulp to the surface. Convenience in operation is, of course, all in favor of the continuous machines. Gravity-discharge continuous thickeners have the same capacity per square foot of settling area as the mechanically-discharged machines, so far as settling alone is concerned, but on account of the difficulties in maintaining uniform discharge of thickened material by gravity, the practical effect is to cut down the capacity. Boss (*103 P 326*) says that slow rotary motion of a settling pulp aids settlement, but there is no conclusive evidence on this score in favor of the mechanical thickeners. It does appear, however, that the slow raking of the thick-pulp layer to the discharge opening aids and accelerates final compacting. Filter thickeners are superior to gravity thickeners for clarification, for treating very dilute pulps, and for making very thick spigot products. Centrifugal thickeners are not yet practical in ore dressing.

10. Design of settling tanks

Coe and Clevenger (*55 A 356*) describe a method based on laboratory tests made in glass cylinders 2 in. or more in diameter and 12 in. to 18 in. deep. Two series of tests should be made made, the first to determine the area required to obtain clear overflow, the second to determine the tank volume necessary to obtain a spigot discharge of the required density. In both series all conditions must be the same as will be encountered in practice, *e.g.*, the time that the ore has been in contact with water or solution; the kind and quantity of electrolyte or other dispersing agent present, if any; the method of grinding and the temperature must be watched particularly.

Tests for area require from six to a dozen samples of pulp of varying consistency ranging from that of the original feed pulp to that of the thickest free-settling pulp (normally between 20 and 30 per cent. solids). The samples are best taken from a large batch which has been thickened to the desired consistency by decantation, then thoroughly stirred and sampled. Each sample, diluted to the desired consistency with decanted liquor, is allowed to stand until the upper surface of the solids has settled about ⅛ in., then a reading is taken and the rate of subsidence for a period ranging from 2 or 3 min. for thin pulps to from 6 to 10 min. for thick pulps determined. With thick pulps intermediate readings should be taken to insure that the rate of subsidence is uniform. A decrease in rate indicates departure from free-settling conditions. The observed rates should be converted into feet per hour and tabulated as shown in the first three columns of Table 19. Column No. 4 of the table is computed from the equation

$$A = \frac{2000}{24\left(\dfrac{62.35R}{F - D}\right)},$$

in which A = area required per ton of solid feed per 24 hr. in sq. ft.; R = rate of subsidence of top of solids in feet per hour; F = the parts of fluid per part of solids in the feed pulp, and D = parts of fluid per part of solids in the pulp to be discharged from the projected settling tank. This is taken as 1.12 in the computations for this table. If D is unknown from other sources spigot-density tests must precede the calculation of column 4.

Table 19. Results of tests to determine area of settling tank. (*After Coe and Clevenger*)

Test number	Feed consistency, parts fluid to one part of solid	Rate of subsidence of surface of settling solids, feet per hour	Area required per ton of solid feed per 24 hr., square feet
1	6.00	2.180	3.00
2	4.94	1.190	4.29
3	4.00	0.893	4.31
4	3.51	0.758	4.22
5	3.00	0.600	4.05

Table 20. Results of spigot-density test. (*After Coe and Clevenger*)

Time of settling, hours	Parts of fluid per part of solid in settled mass
2	1.70
4	1.59
9	1.35
14	1.20
19	1.12

Spigot-density test is made on the thickest free-settling pulp by reading the level of the surface of th subsiding pulp in the same cylinder as above used a intervals of several hours until subsidence ceases or unti the required pulp consistency is reached. The overlyin clear liquor should be removed often enough to keep th water surface near that of the subsiding solid. Table 2 shows the results of such a test.

From Table 19 it appears that the maximum are required to be provided per ton of solids per 24 hr. i 4.31 sq. ft. If less area is provided the layer of pulp o this density will increase in thickness and solid matte will eventually overflow. Table 20 shows that pulp mus be retained in the thickening zone 19 hr. in order t attain the required discharge density of 1.12 : 1 Tank volume must, therefore, be provided fo

$\frac{19}{24} \times \frac{2000}{4.31} = 367$ lb. of solid per sq. ft. That part of the solids that has been in the tank for 14 to 19 hr. will have settled to an average density of 1.16 : 1. The weight of solids in this volume will be $5/19 \times 367 = 96.6$ lb. which is 5 hr. supply to 1 sq. ft. If the sp. gr. of the solid is 3.5, each cu. ft. of pulp whose consistency is 1.16 : 1 will contain 43.2 lb. of solid ($W = 62.4S/(1 + CS)$, where W = lb. solid per cu. ft. of pulp, S = sp. gr. of solid, and C = parts water per part of solid in pulp by weight). The depth of pulp of 1.16 : 1 consistency will, therefore, be $96.6 \div 43.2 = 2.23$ ft. Similarly the following 5-hr. supply will have an average consistency of 1.275 : 1, will contain 37.6 lb. solid per cu. ft. and will require 2.57 ft. depth in the tank. Corresponding figures for the next 5-hr. supply are 1.47 : 1, 33.7 lb. and 2.87 ft.; and for the last 4 hr., 1.7 : 1, 30 lb. and 2.58 ft. Add to these figures 1 to 2 ft. of clear solution for a margin of operating safety, and in a Dorr thickener, an additional allowance for the pitch of the rakes. The total is the depth required with no allowance for storage, or variation in tonnage, character of ore or solution, temperature, etc. If the tank thus calculated is too deep, the necessary volume may be obtained by increasing diameter. Coe and Clevenger recommend a minimum area of 6 sq. ft. per ton per 24 hr. for pulps composed of fine granular material with a considerable proportion of colloidal material which may vary in character.

Table 21 compares capacities computed by the tests outlined with actual capacities at a number of plants. The great discrepancies at PORTLAND and PRESIDIO correspond to underloaded tanks, as shown by the excessive depth of clear solution. The NIPISSING excess of actual over calculated capacity appears to correspond to overloading. All of the pulps in Table 21 are cyanide pulps containing lime, which is an aid to settlement.

Table 21. Comparison of computed and actual capacities of Dorr thickeners. (*After Coe and Clevenger*)

a Roasted ore.

SECTION 17

FILTRATION

Filtration is employed in milling to separate liquid from solid more completely than is possible by settling alone. The principal applications are in thickening flotation concentrate and, in the cyanide process, in separating pregnant solution from leached solid and in collecting precipitate. (See Sec. 15.) A FILTER is a permeable septum so mounted that the material to be filtered can be brought to one side at a pressure higher than exists on the other side. Under such circumstances, if the pores in the filtering medium are of suitable size, the solid particles are held back while liquid passes through. After the first short period of filtering the effective medium is the layer of solid deposited on the original septum.

1. Principles of filtration

Sperry (*15 CME 198, 17 CME 161*) has determined experimentally that the velocity of flow of liquid through a filtering medium varies directly with the pressure and inversely with the thickness of the cake and that the character of the flow is, therefore, the same as that in capillary tubes under low pressure, which is expressed in the equation $v = \pi p r^4/8l\mu$, where p = difference in pressures at ends of tube, r = internal radius and l = length of opening, and μ = viscosity of liquid. The terms l and r in this equation cannot be determined for any practical filtering problem, but Sperry has expressed them in terms of a unit of resistance R, defined as the resistance of a filtering medium of such permeability that 1 sq. ft. 1 in. thick will pass 1 gal. of water per hour at 68° F. under a pressure difference on the two sides of 1 lb. per sq. in.; and a unit of deposition or cake-forming ability K, possessed by the solid being filtered, which he defines by saying that a substance has a unit rate of deposition when, under standard temperature conditions a 1-per cent. mixture of the substance with water produces a flow of 1 gal. per hr. over an area of 1 sq. ft. with a pressure difference of 1 lb. per sq. in. With these terms he has developed from the preceding equation the relation

$$Q = \left[\sqrt{\frac{2PKT}{RS} + \left(\frac{KR_m}{RS}\right)^2} - \frac{KR_m}{RS}\right]\frac{N_S(1 + at_1 + bt_1^2)}{N_0},$$

where Q = quantity of liquid passing the filter, P = difference in pressure on two sides of septum, R = resistance of filter cake to passage of liquid, R_m = resistance of septum, K = rate of deposition of cake, T = time, S = percentage of solids in feed pulp, N_S = coefficient of viscosity of liquid at standard

conditions and $\frac{N_0}{1 + at_1 + bt_1^2}$ is Poiseuille's statement for viscosity at temperature t_1 compared with the viscosity at t_0, a and b being constants dependent upon the liquid. Sperry has verified this relation experimentally. The equation is not practically useful for purposes of design of filters but it shows that filtering rate increases when pressure and temperature increase and decreases with resistance of the filter and increase in thickness of the cake. Hatschek (*27 SCI 538*) has shown experimentally that resistance to filtration increases rapidly with decrease in size of particle forming the cake. Hence the equation of capillary flow can be taken as indicative of the effect of variation in the several factors involved in filtration. Young (*42 A 752*), working with vacuum filters and ore slimes confirms these conclusions. Fig. 1, *A* shows the effect

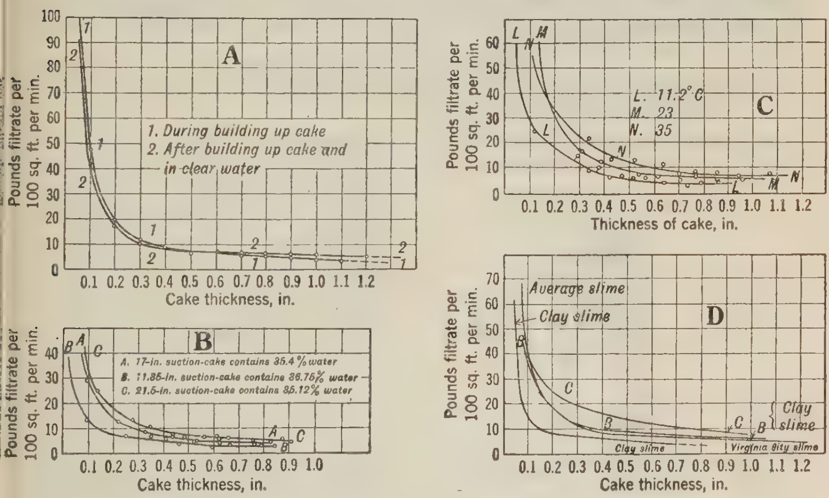

FIG. 1.

of cake thickness on filtering rate; Fig. 1, *B*, the effect of variation in vacuum; Fig. 1, *C*, of pulp temperature; and Fig. 1, *D*, of the character of the pulp, all taken from Young's results. He concludes from other work that small changes in the amount of clay in a pulp or in a cake have more effect on the filtering rate than much larger changes in the amount of sand.

2. Filter medium

The filtering medium is composed of the porous septum itself plus the cake of filtered material held thereon. The septum may be a bed of solid grains merely piled together and, therefore, incapable of use in any position other than horizontal; it may be a porous slab, such as the naturally-occurring tripoli or an artificial material like Filtros; most frequently cotton cloth is used, rarely a woolen, mineral-fiber or metallic cloth. In milling work a COTTON FABRIC is almost invariably employed. It has the ADVANTAGES of great tensile strength, flexibility, durability, small weight, ease of handling and cleaning, and, compared to porous slabs, low first cost.

The size and spacing of the pores in the filter septum have great effect on filtering rate, not so much on account of the resistance to passage of liquid as in their determining effect on the porosity of the first layers of cake deposited. The first layer of particles will tend to deposit over the mouths of the pores in the septum. If these are so spaced that the deposited particles are out of contact or are just in contact on all sides with adjacent particles, there will be maximum reduction of pore area. If the mean diameter of the particles is greater than the mean pore spacing, crowding will prevent all holes in the septum from being covered and increased porosity of the septum will result. On the other hand, the reduction in size of pores that accompanies decreased spacing may increase resistance of the septum itself, but this is rarely as important a factor as that of spacing. CHOICE OF A CLOTH is usually a balance between the desiderata of large pores and close spacing, which make for quick filtration but low durability, and the higher durability of heavier and less porous cloths.

Hixson, Work and Odell (*73 A 225*) have found that distinct bridges are formed over the filter pores by the solid particles, as shown in Fig. 2, that the relation between maximum particle size and maximum filter opening is as set forth in Fig. 3, that this relation holds for feed-pulp densities of 20 to 60 per cent. solids, but that for more dilute pulps smaller ratios must be used, and that the thicker the feed pulp the more porous the cake formed.

FIG. 2.—Bridging of solids over a filter pore.

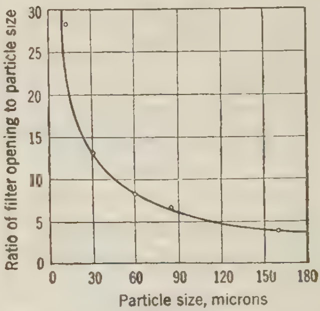

FIG. 3.—Relation between filter opening and size of largest particle in pulp to be filtered (*after Hixson et al.*).

TYPES OF FILTERS

The cyanide process produced a large number of different kinds of filters that may be classified fundamentally as (1) vacuum and (2) pressure, depending upon the means employed for effecting the required pressure difference on the two sides of the porous septum. Vacuum filters may be further classified as (*a*) continuous and (*b*) intermittent. Pressure filters are invariably intermittent.

3. Continuous vacuum filters

These filters are of the drum type, including the Oliver and Portland; the disk type, such as the American and Robacher; the horizontal revolving-leaf type, of which the Ridgway is best known; and the table type, such as the Caldecott.

Oliver filter (Fig. 4) is typical of the drum machines.

Drum (*a*), mounted on horizontal trunnions, is faced with selected wooden staves (*b*) forming a tight shell. At suitable intervals longitudinal wooden partitions strips (*c*) are

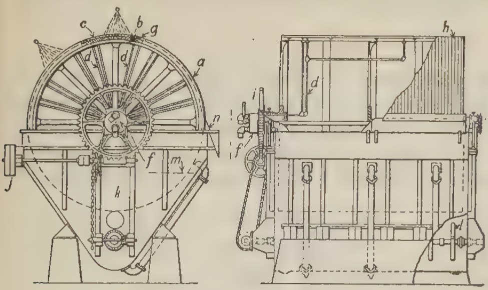

FIG. 4.—Oliver continuous filter.

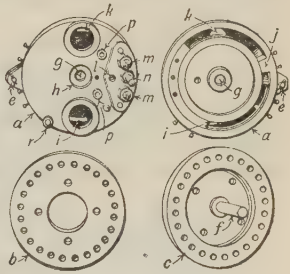

FIG. 5.—Valve for Oliver continuous filter.

fastened to the face of the shell, dividing it into a number of shallow troughs which connect by pipes (*d*) with valve (*f*) and thence with vacuum pump and compressor. The troughs on the face of the drum are filled with suitable backing to support the filter cloth (*g*), which covers the entire drum. Wire (*h*) is wound on the outside of the canvas to keep it tightly in place and protect it. The drum is driven by a worm gear (*i*) from pulley (*j*) and revolves in a clockwise direction with the lower segment immersed in pulp in tank (*k*). Feed pulp is kept in suspension by a paddle agitator (*l*) or by some other form of mechanical or air agitation. VALVE MECHANISM is illustrated in Fig. 5. It consists of a port plate (*a*), valve seat (*b*), and wear plate (*c*). The port plate is held stationary by adjusting-rod pin (*e*) and a rod therefrom attached to the frame of the filter. Pipes from the filtering compartments on the drum face are tapped into the valve seat and the wear plate (*c*) is bolted through the valve seat to the drum frame in such a way that the peripheral holes in the two plates register. The valve stem (*f*) passes through hole (*g*) in port plate (*a*) and the latter is held tightly against (*c*) by means of a coiled spring on the stem, which bears between a nut on the end of the valve stem and the ground surface (*h*) on the port plate. In simple filtering, a pipe from port (*i*) runs to the vacuum pump, bridge (*j*) is removed and port (*k*) is plugged. Under such circumstances that part of the drum surface extending from just below the pulp level on the down-coming side, at about point (*m*) (Fig. 4), to a point to the right of the top of the drum, is in suction all the time. The three small ports in plate (*a*) (Fig. 5), provide for blowing the cake prior to its removal by scraper (*n*) (Fig. 4). Air connection is made at (*l*) (Fig. 5) and the number of compartments under pressure is regulated by stops (*m*) and (*n*). Stop (*n*) is hollow, thus providing for a steam connection, if desired, and its position may be changed so as to give first a steam blow followed by one

or two air blows, or a steam blow between two air blows as shown in the figure, or a steam blow following two air blows. Holes (p) are for gage connections. When WASHING is to be done, or if two different vacuum pressures are desired, bridge (j) is inserted and port (k) is connected to a second vacuum pump. Wash solution is then withdrawn through the latter port. A grease cup at (r) supplies grease to the adjacent ground faces of plates (a) and (c).

Sizes of Oliver filters are given in Table 1.

Vacuum production in flotation work is usually DRY, *i.e.*, a vacuum receiver is connected between the filter and the vacuum pump, liquid separates from air in the receiver and therefore does not pass through the pump. Liquid is removed from the receiver by means of a centrifugal pump or through a stand pipe terminating in a sump at a distance below the receiver correspond-

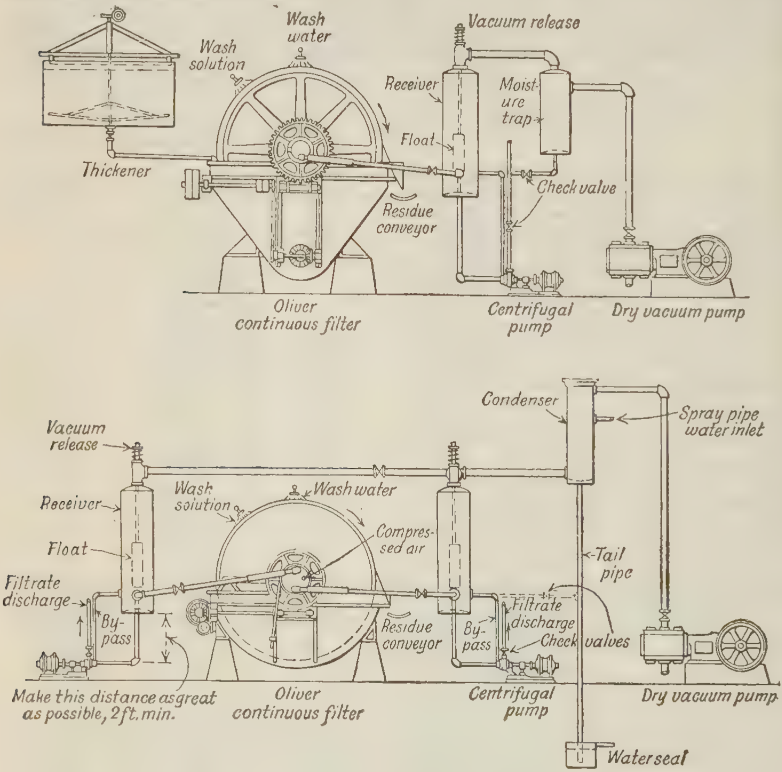

FIG. 6.—Layout for Oliver filter.

ing to barometric pressure. The CENTRIFUGAL EXHAUSTING PUMP should be set below the bottom of the vacuum tank so that liquid flows freely into the pump inlet. The pump should be self-priming or a check valve be placed at the high point on the discharge line and an equalizing pipe should be run back to the receiver from the suction line. BAROMETRIC LEGS should be sealed by extending into a sump, the capacity of which is greater than the volume of the drain pipe. The VACUUM TANK should be provided with a safety seal at the

outlet to the dry-vacuum pump to prevent liquid passing over into this pump, which is designed with small clearance and would be injured by liquid. For handling hot solutions a condenser tank should be inserted between the receiver and the vacuum pump. Lay-out as recommended by Oliver Filter Co. is shown in Fig. 6.

A reciprocating air compressor with the inlet port connected with the vacuum tank is commonly used to produce vacuum. The compressor provided should ordinarily have free-air capacity ranging from 0.5 to 1.5 cu. ft. per min. per sq. ft. of filter surface. For very porous cakes as high as 5 cu. ft. per sq. ft. per min. may be necessary. The vacuum-pump displacement necessary per sq. ft. of filter surface may be obtained from equation $V_2 = P_1V_1/P_2$, where P_1 and P_2 are barometric pressure and barometric minus vacuum-gage pressures respectively and V_1 is displacement volume per square foot per minute desired.

Rotary blowers, with suction end attached to vacuum tank are sometimes used in place of a reciprocating compressor for dry-vacuum production.

Wet-vacuum production, in which the filtrate passes through the pump, is often used in cyanide work where the volume of filtrate is relatively larger than in concentrate dewatering and filtrate must be transported for further treatment, so that the same pump can serve both ends. Reciprocating or centrifugal pumps and rotary exhausters are commonly used in this service. Grit that passes the filter causes considerable wear with corresponding decrease in efficiency.

Power requirement for dry-vacuum pumps is computed from the same equation as that for air compression, with appropriate change of symbols. For a pump working adiabatically,

$$Hp. = \frac{144}{33{,}000} \cdot \frac{n}{n-1} \cdot P_2V_2\left[\left(\frac{P_1}{P_2}\right)^{\frac{n-1}{n}} - 1\right],$$

in which P_2 = absolute pressure in vacuum produced in lb. per sq. in., V_2 = gas volume corresponding to P_2 in cu. ft. per min., P_1 = atmospheric pressure, and n is a constant ranging from a theoretical value of 1.406, down, probably, to 1.15 or 1.2 for ordinary vacuum-pump practice. Table 2 shows the estimates by Ingersoll Rand of the power required for their Type ER–1 dry-vacuum pump, which is frequently used. By investigation of the power equation throughout the range of the theoretically possible vacuum production for any given conditions, it is found that the power requirement per cubic foot of gas exhausted from a given vacuum passes through a maximum, as shown in Fig. 7.

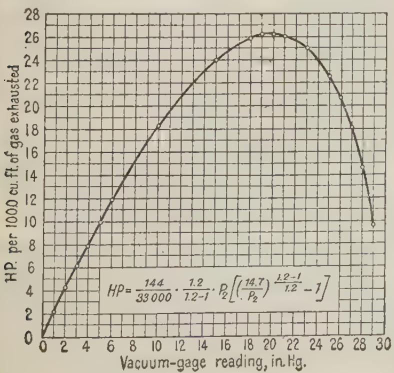

Fig. 7.

For blowing, compressed air is furnished at 10 to 15 lb. pressure; the usual provision is for 0.15 to 0.25 cu. ft. of free air per minute per square foot of filter area.

Operation. The factors that influence results are diameter of drum, speed, submergence, size of feed particles, percentage of solids in feed, reagents present, kind and condition of filter cloth, temperature of pulp, homogeneity of pulp in tank, vacuum, blowing, and uniformity of conditions.

Drum diameter, speed and submergence are dependent in that they determine the time during which cake is formed. Four minutes is about the maximum time that can be economically permitted for cake formation; the usual time is about 3 min. In general, low pulp level gives thin, dry cake and low capacity, high pulp level *vice versa*. The more granular material in the feed the more porous the cake and consequently the greater the capacity. Addition of fine granular gravity concentrate to flotation concentrate may, by increasing porosity of the cake, lower the moisture content and also prevent cracking, but it makes it more difficult to maintain the pulp in suspension in the tank.

Feed pulp should be as thick as possible, if high capacity and dry cake are desired.

Trauerman (*104 J 87*) reports a test on an 11.5 × 16-ft. machine on which 35 dry tons of cake containing 20 per cent. water were made in 8 hr. from a feed pulp containing 35 per cent. solids and 51 tons containing 12 per cent. moisture were made in the same time from a pulp containing 55 per cent. solids. At Sunnyside, with feed containing 30 to 35 per cent. water, cake was 1¼ in. thick and contained 8 per cent. water, while with feed containing 40 to 45 per cent. moisture, cake was ½ in. or less thick and contained 10 per cent. moisture.

Thickening in Dorr tanks costs less than 5¢ per ton of solids and filtration above 25¢, hence the more preliminary thickening, the cheaper the whole operation. The filter tank may be shallower with thick feed than with thin, which gives more time for drying cake.

Lime added to filter feed increases filtering rate, decreases moisture in the cake and, in case of acid pulps, increases life of cloth and solution passages. On the other hand, it increases clogging.

At Miami it prevented water from settling out in cars on the way to the smelter (*115 P 573*).

Young (*loc. cit.*) calls attention to the fact that thick cakes made from a given slime pulp contain more water than thin and that the increase in moisture content of the cake with increasing distances from the filter cloth is greater the greater the slime content of the feed pulp.

Filter cloth must be sufficiently "dense," *i.e.*, close-woven, to hold back the bulk of solid material and thus form, from the retained material, the filter wall proper, and it must be sufficiently heavy and strong not to break or deform materially under the pressures applied. It is desirable that all of the material retained be held at the surface of the cloth, since material that penetrates is not removed with the cake nor by scrubbing and therefore permanently decreases porosity. Cloth with considerable nap is harder to discharge than smooth, hard cloth on account of the binding effect of nap threads. Cotton cloth is almost invariably used in milling practice. The strongest is the close-woven canvas duck;. soft twilled canvas is more porous but less durable.

Woolley (*104 J 875*) recommends twill for fine concentrate that makes compact cake, and duck for more granular product for which the cloth itself must do much of the filtering.

The fiber of cotton cloths swells materially when the cloth is wet and fabrics that appear too porous when new may give entirely satisfactory service. Eight- to 10-oz. duck and 12- to 16-oz. twilled canvas are the commonest coverings in milling work. The best covering can be determined only by experiment.

Life of the above coverings on drum filters in flotation service is two to six months with the average between three and four months. Lighter weaves backed by coarse heavy material are sometimes used. Cloths should be scrubbed whenever the filtering rate falls off due to clogging of the filter medium. Scrubbing should be done with a brush stiff enough to work into the fabric sufficiently to loosen particles held therein. Weak hydrochloric acid solution (0.25 to 1.0 per cent. strength) should be used when carbonate precipitates. At some plants the filter is scrubbed every day, in most the period between scrubbings is less than a week.

Re-covering, including removal of old canvas and re-winding wire requires 16 to 36 hr. with a crew of 3 or 4 men.

Heating lowers the viscosity of the liquid and also tends to cause flocculation of fine solids. On both scores it increases filtering rate and it may also decrease the moisture in the cake. Heating to 100 to 120° F. is a common procedure in treating flotation concentrate but heating of cyanide pumps is not usual.

At Afterthought, heating pulp increased tonnage 17 per cent. to 750 lb. per sq. ft. per 24 hr. in a cake containing 15 per cent. water. Watt (*57 A 379*) stated that in treating lead concentrate in south-east Missouri, heating to 120° F. increased capacity 20 per cent. and decreased moisture in cake 2 per cent. (to 15 per cent. final). At Utah Copper Co. pulp is both heated and agitated by live steam injected into the filter tank. Experience shows that the hotter the pulp the dryer the cake (*117 P 752*).

The amount of vacuum to be carried depends on the porosity of the bed and the capacity required. With readily filterable pulp or low duty, the vacuum may be as low as 15 in.; the usual range is 20 to 25 in. High vacuum will frequently cause the cake to crack and will also clog cloths. Different pressures may be maintained on the submerged and unsubmerged parts of the drum by independent vacuum connections provided in the valve. Cracking may be lessened by speeding up the drum and making a thinner cake.

A mechanical method for preventing cake cracking is the application of a canvas belt and rollers; the belt is applied on the upcoming side just before cracking starts and removed before the vacuum is released. With cracking eliminated, a dryer cake can be made and less vacuum-pump capacity need be provided.

Blow-off pressure should be kept as low as possible; the usual pressures are from 7 to 15 lb. per sq. in. The higher pressures keep the filter cloth cleaner but excessive pressure is likely to cause the canvas to split under the wires, especially when acid cleaning is used and the acid is not completely neutralized before operation starts again.

Agitation. Mechanical agitation is generally superior to air agitation. The latter tends to make thin spots in the cake and also, under favorable conditions, to produce heavy carbonate deposits. Furthermore, if heavy granular sulphide is present, air is insufficient to keep it in suspension; the power consumed in air agitation is greater than in mechanical and much of it is wasted on account of excessive air consumption.

Bradley (*106 J 207*) reports the use of discarded rubber pump diaphragms for packing in the stuffing boxes of the rotating agitator shown in Fig. 4. Leakage here is not uncommon, it is mussy in any case and expensive in cyaniding. Rice (*106 J 899*) recommends driving the agitator from an independent shaft so that it can be kept running, if necessary, when the filter is stopped.

When the material to be filtered is difficult to keep in suspension, the difficulty may be lessened or overcome by feeding the pulp by gravity from a surge tank through a manifold in the bottom of the tank at a sufficient rate to maintain suspension and pumping the overflow back to the surge tank. The surge tank should have about twice the capacity of the filter tanks.

When a plant makes both table and flotation concentrate, a good scheme for dewatering is to send the table concentrate to a mechanical classifier, join the overflow with the flotation concentrate and thicken and join the granular discharge from the classifier with the spigot product from the classifier in a surge tank feeding the filters. The thickened slime concentrate keeps the granular material in suspension readily. The granular table concentrate will probably increase the capacity of the filter on the slimy flotation concentrate.

Scraper blade should be kept smooth on the upper edge by filing or grinding as necessary; otherwise removal of cake is not thorough and the filter cloth is likely to be torn. Adams (*105 J 724*) recommends the use of hard 15- or 16-gage wire instead of the usual 10- or 12-gage for winding since this allows the scraper to come closer to the cloth.

Shimmin filter is of the rotating-drum type but has the filter medium on the inside of a drum which is supported at one end by a trunnion bearing and at the other end by rollers. The roller end is open for feeding, removal of cake, and inspection. The drum itself acts as the pulp container. The size segregation in the pulp in the drum assists filtration because the coarser particles settle onto the filter cloth and form a relatively porous filter bed. The cake is carried up to a point at or beyond the top of the circular path. Here the filter cloth is caused to expand and contract suddenly by alternate subjection to pressure and vacuum. The valve is of the usual revolving-filter type. Cake drops into a hopper from which it is removed by belt or screw conveyor.

The machine can be used on coarser material than usual because the natural settlement of the solids brings them to the filtering surface.

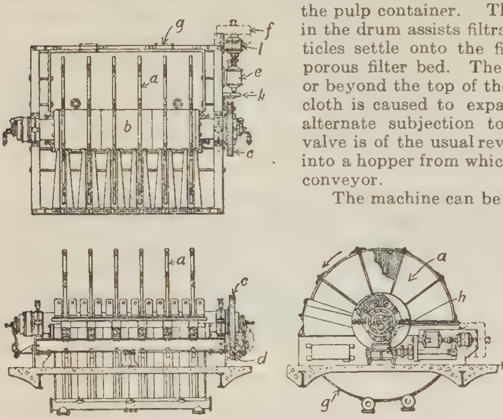

Fig. 8.—American filter.

American Filter (Fig. 8) consists of a plurality of disk-shaped filter leaves (*a*) mounted on a heavy hollow shaft (*b*), caused to rotate by means of the worm gear (*c*) and worm driven through gear (*k*) either by a motor-driven gear speed-reducer (*e*) and motor (*l*) or by pulley (*f*).

The lower parts of the revolving disks dip into a tank (*g*) which is partitioned on the front side of the central shaft in order to allow for discharge of cake. Each filter disk consists of several sector-shaped units which connect by means of conduits in shaft (*b*) with a special rotary plug valve (Fig. 9). This valve ordinarily has three outlet ports. During the time that any given sector is submerged and for a time after its emergence it is connected through a conduit in the shaft and a corresponding channel in the journal with the filtrate outlet port. On further emergence it connects with the wash-water outlet port, and finally, just before it reaches the scraper it connects with the compressed air port and the cake is loosened.

The standard disk diameters are 4 ft., 6 ft. and 8 ft. 6 in. The 4-ft. size is made with one to four disks, as desired; the 6-ft. and 8-ft. 6-in. with two to six disks.

Robacher filter is a continuous disk filter employing Filtros, a porous silica slab, as a filtering medium. It has not been used in metallurgical work.

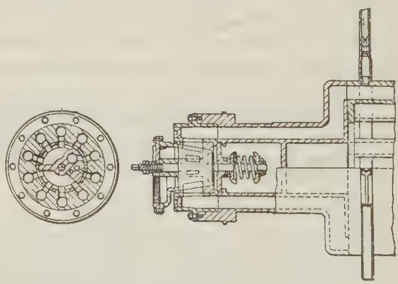

Fig. 9.—American filter valve.

Ridgway filter consists of a number of horizontal filter trays carried on the ends of radial arms extending from a central revolving spindle. The trays travel over a series of annular tanks, a mechanism being provided to lift each tray over the partitions between the tanks. In cyanide work the first tank contains leached slime; the second, weak solution; a third, wash water; and the remaining 15 to 20° of arc constitute the discharge hopper. The valve is similar in principle to the drum valve. The use of filter has been principally restricted to So. African and Australian cyanide mills.

Portland filter is similar to the Oliver.

Performance of Oliver and Portland filters treating flotation concentrates is given in Table 3.

Flotation concentrate. On zinc concentrate an Oliver machine at Butte and Superior Min. Co. handled 890 lb. per sq. ft. per 24 hr. from 55 per cent. water in feed to 10 per cent. in cake, and at Timber Butte corresponding figures were 1300 lb., 50 per cent. and 10 per cent. Round-table concentrate was thickened from 50 per cent. to 15 per cent. moisture at Anaconda at the rate of 850 lb. per sq. ft. per 24 hr. At Inspiration (*115 P 680*) six 12 × 12-ft. drum filters handled 700 tons flotation concentrate per 24 hr. from 40 per cent. moisture to 17 per cent. moisture (moisture content of cake varied with percentage of insoluble). This is 540 lb. solid per sq. ft. per 24 hr.

At the Arthur plant of Utah Copper Co., the filter installation for 1000 to 1200 tons per 24 hr. of mixed table and flotation concentrate, consisted of twelve 14 × 14-ft. Oliver filters and two 4-leaf 14-ft. 6-in. American filters. The table concentrate was all −10-mesh and constituted 20 to 40 per cent. of the total. The flotation concentrate was 90 per cent. −200-mesh and upwards of 10 lb. of oil per ton was used in flotation. The pulp was heated to 160 to 180° F. Filters were run at 3 to 4 rev. per hr. The cover on the Oliver drums was 4-mesh screen, one thickness of burlap and one of palma twill. Drums were wound with No. 6 galvanized-iron wire, coils spaced 2 in. American leaves were covered with two layers of palma twill. Vacuum displacement for the whole plant (13,354 sq. ft. of filtering surface) was 1.394 cu. ft. per min. per sq. ft. Dry-vacuum installation was one 36 × 20-in. duplex Imperial Type *XB* pump at 150-r.p.m. (7058 cu. ft. displacement) and two 27 × 14-in. Imperial *XB* at 170 r.p.m. (displacement 3143 cu. ft. per min. each). Vacuum produced was 21.5 in. Two 5 × 8-ft. receivers served the whole plant. Compressed air was received from the central plant and used at ½ to ¾ lb. per sq. in. Unit capacity of the entire plant was 230 to 280 lb. per sq. ft per 24 hr. from 50 per cent. to 15 or 20 per cent. water. Cake was about ¼ in. thick. Operating force consisted of one foreman, one operator and three repair men, total $66.75 per 24 hr. (1921). Life of cloth was 80 to 120 days. Live steam at 15 to 20 lb. pressure was used for heating and agitation in the filter tanks.

At Afterthought the installation for filtering 40 tons per day each of roasted zinc and copper flotation concentrate from the Horwood process was two 4-ft. 6-leaf American machines, one 14 × 8-in. Doak dry-vacuum pump at 250 r.p.m. producing an average vacuum of 14 to 16 in., one 7½ × 4-in. compressor at 400 r.p.m. furnishing air at 12 lb. pressure, and a barometric leg on the receiver. The filters were run at one revolution in 5 min. 10 sec. The zinc concentrate was all −40-mesh and 60 per cent. −200-mesh, the copper all −40-mesh and 50 per cent. −200-mesh. The feeds varied in moisture content from 45 per cent. to 85 per cent., on account of insufficient thickener capacity. Zinc cake averaged 11 to 12 per cent. moisture, copper 13 to 14 per cent. Average capacity was 600 lb. solids per square foot per 24 hr. Life of bags in the zinc filter was only six days and in the copper filter three days on account of the high sulphate content. The thickness of the cake on new bags on the copper filter was 1⅛ in. but by the third day had decreased to ¼ in. At Ducktown Copper and Iron Co. an American filter handled 500 lb. of copper concentrate per square foot per 24 hr.

At Doe Run Lead Co. one 11½ × 12-ft. Oliver filtered 65 to 70 tons of −100-mesh (70 per cent. −200-mesh) lead concentrate per 12 hr. making ⅜-in. cake containing 13 per cent. moisture. Temperature, 100 to 120° F.; 740 lb. per sq. ft. per 24 hr. At St. Louis S. and R. Co. one 12 × 12-ft. machine handled 30 dry tons per day (140 lb. per sq. ft. per 24 hr.) making a ⅜-in. cake containing 18 per cent. moisture. Feed contained 55 to 60 per cent. solids. Speed, 1 rev. in 10 min. Doak 14 × 8-in. dry-vacuum pump, 800 cu. ft. per min. displacement at 300 r.p.m. Receiver 30 in. × 5 ft.; trap, 12 in. × 2 ft. Centrifugal pump, 1½ in. Life of palma-twill covering, 3 months.

In handling flotation concentrate the duty per square foot of filtering surface is so greatly dependent upon the character of the ore and kind of frothing agent used that capacity ranges between wide limits. At Chino Copper Co. (1918), treating high-oil flotation concentrate, four 14 × 14-ft. Oliver filters averaged 100 lb. per sq. ft. per 24 hr. to 27 per cent. of water. At one copper company change from an oil mixture of coal tar, coal-tar creosote and wood creosote to xanthate and pine oil increased filter capacity fivefold.

Coal. Capacity on coal-flotation concentrate is 26 to 28 tons per hour on an 8 × 8-ft. drum when taking a feed containing 50 per cent. moisture and making a product containing 18 per cent. moisture (*67 IME 513*). This is at the rate of 6500 lb. per sq. ft. per 24 hr.

Iron.—At Mesabi Iron Co. a 5½ × 10-ft. Oliver filter making 1 rev. in 40 sec. was fed with 300 to 325 long tons per 24 hr. of a mixture of 94 per cent. of −100-mesh magnetite concentrate (78 per cent. −325-mesh) and 6 per cent. −14-mesh anthracite in a pulp containing 75 per cent. solids. Cake was ⅜ in. thick, and contained 10.5 per cent. water. Submergence was 3 to 6 in. Vacuum of 2 to 3 in. was used to pick up cake and 18 in. to dry. Life of 12-oz. duck was 60 days. Dry vacuum capacity was 1655 cu. ft. displacement for two filters; this was sufficient with old cloth but insufficient with new.

Roasted zinc concentrate. In filtering solutions in the electrolytic zinc plant at Anaconda the capacity of a 12 × 12 drum-type filter was 300 lb. dry residue and 0.063 ton of solution per sq. ft. per 24 hr. and the cake contained 30 per cent. moisture. At the Consol.

a 17-oz. canvas twill. *b* Normal. *c* All −65-mesh. *d* Normal heat increased capacity but did not reduce moisture in cake. *e* 10 lb. unslaked lime per ton of solid added at elevator ahead of filter. *f* Filter Fabrics Co., No. 31. *g* In good condition only 30 da. A hard iron scale forms on both surfaces of cloth. *h* All −100-mesh. *i* Less than 24 hr. *j* For filter only. *k* 6-oz. single twill. *l* Estimated. 150 tons to this and a 14 × 14-ft. *m* Low duty accredited to low percentage of solids in feed. Cannot be improved, even with intermittent settling using lime, caustic soda or soda ash. Cold weather affects adversely. *n* Oliver filter cloth. *o* No. 12 M. S. cloth. *p* Installed. *q* Heavy cheese-

MIN. AND SM. Co., Trail, B. C. a disk-type filter handled 600 lb. dry solid and 0.097 ton solution per sq. ft. per 24 hr. with 25 per cent. moisture in the final cake.

Cyanide. There is great difference in behavior of cyanide pulps. At ARGONAUT mine, Dane, Ontario, two 6-ft. 4-disk machines filtered and washed cyanide pulp at the rate of 200 lb. dry solid per sq. ft. per 24 hr. Feed pulp contained 48 per cent. moisture and cake 20 per cent. moisture. Speed, 4 min. 45 sec. per rev. At HOLLINGER seven 14 × 16-ft. drum-type machines filter and wash 550 tons dry solid (7 per cent. + 150-mesh, 70 per cent. −300-mesh) per 24 hr. or 225 lb. per sq. ft. Feed varies from 1.0 to 0.65 ton solution per ton of solid; cake contains 21 per cent. moisture. COST of plant complete, including building, was $152,500, of which $95,000 was for the filters, vacuum and other pumps, tanks, receivers, etc. Total cost of filtering (1923) was $0.045 per ton, about half of which was labor.

cloth and twill. *r* Light canvas. *s* This filter is much underloaded. Another performance shows 2700 lb. per square foot per 24 hr. dried from 50 per cent. moisture in feed to 10.8 per cent. in cake. *t* Have run up to 70 tons per 24 hr. and dried to 17 per cent. water. *u 112 J 217.* Submergence varies. The greater the submergence (up to 3 ft. 6 in.) the greater the capacity but the wetter the cake. *v* Canvas over hessian. Wound with No. 14 copper-covered steel wire at 5/8-in. centers. 16 hr. to re-canvas and re-wire. *w* No. 3 Oakdale.

Capacity of continuous-vacuum filters varies greatly as may be seen from the foregoing figures. For normal lead and copper flotation concentrate made with 1 to 2 lb. of oil, 400 to 600 lb. dry solid per sq. ft. of filter surface per 24 hr. is a fair figure for estimate. If for any reason, as *e.g.*, the use of more oil or a de-flocculating agent, the concentrate is slow-settling so that the feed to the filter is unduly dilute, the filter duty may run down to 100 lb. or less per sq. ft. while admixture of granular table concentrate may increase duty to 700 or 800 lb. Duty on zinc-flotation concentrate with low oil goes as high as 1300 lb. at Timber Butte. Granular products filter very rapidly, *e.g.*, coal-flotation concentrate, 6500 lb. per sq. ft. per 24 hr. and the mixture of coal and

magnetite at MESABI (3600 lb.). Cyanide pulps, which require washing in addition to filtration average from 200 to 400 lb. per sq. ft. per 24 hr., the lower figure being the safer for estimate.

Cost of continuous-filter installation. Table 4 gives an estimate for an American filter installation as of 1924.

Table 4. Estimated cost of an American-filter installation

1 @ 6-ft. 3-disk machine	$2600
Extra for agitating device	60
Extra for variable-speed motor drive	375
1 @ 12 × 8-in. Ingersoll-Rand dry-vacuum pump, Type ER-1, 311 cu. ft. per minute displacement at 300 r.p.m. 10 hp	776
Extra for short-belt drive	104
1 @ 10-hp., 3-phase, 60-cycle, 2200-volt, 1900-r.p.m. motor	195
2 @ 18 × 60-in. vacuum tanks	96
2 @ 1½-in. centrifugal pumps	295
2 @ 3-hp. motors, 1900 r.p.m.	240
1 No. 3 roots positive blower, 850 r.p.m.	84
1 @ 1-hp. motor	79
1 @ 12 × 30-in. moisture trap	40
1 @ 12 × 36-in. air receiver	22
	$4966

Cost of continuous filtration (1922) ranges from 25 to 45¢ per ton of concentrate, of which labor is 35 to 50 per cent., supplies 30 to 35 per cent., and power 20 to 30 per cent. At one plant using 65 hp., 6 per cent. was for driving drum, 19 per cent. for air-lifts for keeping pulp suspended in the filter tank, 12 per cent. for compressed air for blowing, 40 per cent. for dry vacuum pump, 7 per cent. for pump exhausting filtrate from receiver, and 16 per cent. for agitation of pulp in the feed tank.

Cost of re-covering a 13 × 37½-ft. drum filter in the electrolytic zinc plant at ANACONDA was as shown in Table 5. Eight blankets handled 40,000 tons of solid at a cost of $0.0325 per ton for blankets.

Table 5. Cost of re-covering a 13 × 37½-ft. drum filter at Anaconda

Blanket (wool), 57 sq. yd.		$48.35
Burlap, 57 sq. yd.		15 40
Copper wire, 242 lb.	$31.80	
Less salvage, old wire	5.50	
		26.25
Labor		18.00
		$108.00

4. Sand filters

Caldecott sand table is a revolving annulus about 25 ft. outside diameter by 3 ft. wide with horizontal porous top over suitable vacuum compartments. It is run at about 20 ft. per min. peripheral speed with a vacuum of 5 to 10 in. Thickened sand pulp from diaphragm cones or mechanical classifiers is fed at any given point in the revolution and removed, after filtration, by a diagonal plow just ahead of the feed point. About 0.5 cu. ft. per min. vacuum-pump displacement is required per square foot of filter area.

At SIMMER AND JACK PROPRIETARY MINES, LTD. one such table handled 500 tons quartz sand per 24 hr. and reduced moisture from 30 per cent. to 15 per cent. (*RMP*). At NEW JERSEY ZINC Co. 6-ft. tables with 21 sq. ft. of filtering area (made by Oliver Filter Co.) treat 7, 2 and 6 tons per hr. respectively of shaking-table concentrate, middling and tailing, all of which passes 8-mesh screen and contains about 4 per cent. −200-mesh. Feed contains 30 per cent. water and product about 8 per cent. The layer of solid on the filter is about

4 in. thick. Speed is 1 rev. in 3 min.; vacuum, 6 in. Hg. The canvas used for filtering medium lasts 30 days.

Rotary hopper dewaterer is essentially a drum-vacuum filter with the sides of the filtering compartments extended beyond the filtering surface to form V-shaped hoppers with radial sides in which granular materials can be piled and retained on the drum. The hoppers are fed by overhead chutes at a point slightly ahead of the zenith and discharge by gravity, aided by compressed air, if necessary. Rock sands will discharge with 10 to 15 per cent. water, if feed contains not more than 30 to 40 per cent. and if substantially free from slimes. Capacities are not well enough established to be accepted without experiment, but in filtering granular slate ranging from about 0.3 mm. to 1.5 mm. and substantially slime-free, 2 tons per sq. ft. per 24 hr. has been handled.

Filter tanks are rectangular or cylindrical in shape, fitted with porous false bottoms, through which liquid passes by gravity, aided by vacuum toward the end of the draining period, if desired. They are frequently used for dewatering granular concentrate. The filter bottom must be supported on a grid-like frame sufficiently close-spaced to prevent harmful deformation of the filtering medium, which usually consists of a filter cloth laid over cocoa-matting or the like. A second grid is usually placed above the filter cloth to protect it when the filtered charge is shoveled out. Shoveling may be manual or a mechanical shovel of the orange-peel or clam-shell type may be used.

At SHATTUCK ARIZONA (*110 J 761*) gravity concentrate containing 21 per cent. water is drained in concrete tanks with sand-filter bottom to a product containing 10 per cent. water.

In the BLAISDELL SYSTEM the tank is circular with a central bottom-discharge opening about 12 in. diameter under which a belt conveyer runs. The discharge hole is closed during filling by a downward-tapering hollow steel-plate plug extending to the top of the tank. When this is removed it leaves a steeply-conical hole through the charge to which the filtered material is scraped by a revolving plow arm carrying a plurality of disk plows. A series of tanks is served by one plow mechanism.

5. Pressure filters

These are of two general types: (*a*) plate and frame presses, and (*b*) pressure tanks. The first are widely used in the chemical industry, but have had only a restricted use in milling; the second have been used to a considerable extent in cyanide work and slightly in filtering flotation concentrate.

Plate-and-frame filter. A typical form is shown in Fig. 10. The essential parts are a framework consisting of two uprights (*a*) and two parallel tie-rods (*b*), a fixed head (*c*), a movable head (*d*), and a plurality of plates (*e*) alternating with frames (*f*). Plates are of cast iron, suitably perforated with ports (*g*) and slightly recessed at the center as shown. The recessed portions are grooved to allow passages for solution behind the filter cloth. Frames are similar to plates with the recessed portion removed. Both are practically square in the section at right angles to the plane of the drawing. Plates and frames have outside lugs which rest loosely on rods (*b*) when the press is open and they may be lifted out separately. When assembling the press for operation, filter

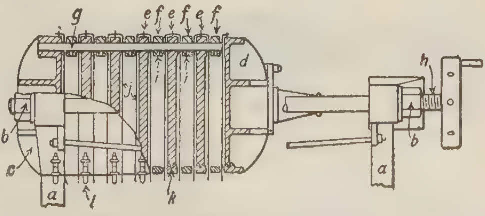

FIG. 10.—Plate-and-frame filter.

cloths are draped over the plates, perforated to correspond with the opening (g), are set on rods (b) alternating with the frames, and, when the desired number are in place the movable head is pushed forward by power screw (h) until all joints are made tight by reason of the canvas packing between the machined faces of plates and frames. Holes (g) in plates and frames, now registering, form a passage for feed pulp which is pumped in under pressure and passes through openings (i) into the space between the plates. Liquid passes through the cloth and along the faces of the plates to passages (k) which discharge through cocks (l). When the chambers are filled or nearly filled with cake, wash water may be sent through the press to wash the cakes. finally compressed air or steam to dry them, after which the movable head is run back and cake is dropped out of the chambers one at a time. The MERRILL PRESS, which is the only one that has had any considerable use for pulp treatment in cyanide work has an interior passage along the bottom for discharge of cake and a high-pressure water pipe with jets into the individual compartments for washing spent cake into the discharge passage. Hence it may be discharged without opening.

Plate-and-frame presses are rated by the size and number of plates. The usual sizes are 18 × 18-in., 24 × 24-in., 30 × 30-in., and 36 × 36-in. with from 25 to 50 plates per press. Pressures depend on the filtering character of the material. They usually start at a low figure, say 5 to 10 lb. per sq. in. and finish at 50 to 60 lb. High initial pressure clogs the cloths and makes the initial layer of solid too compact; high final pressures are necessary to force liquid through the thick cakes.

Design of plates and frames is highly various. Complexity and number of ports depends on the number and kind of washes, whether blowing is to be practiced, and whether both air and steam are to be used. For considerable further detail as to construction and operation of presses see D. R. Sperry, vols. 18 and 19, *CME*.

Centrifugal pumps are the best type for forcing feed pulp into plate-and-frame presses, because pressure is low at the beginning and gradually increases as resistance builds up, and also there is no pulsation to compact cake as by tamping, which effect is distinctly noticeable with reciprocating pumps.

Pressure-tank filters are of several varieties of which the Kelly and Burt are best known in milling work. The former has had considerable use in cyanide work and some in concentrate filtration, the latter in cyanide work alone.

Kelly pressure filter (Fig. 11) consists of a basket (a) of filter leaves, carried on a frame (b) that can be slid in or out of a pressure tank (c). The tank is inclined so that gravity aids egress of the loaded basket. One end of the movable frame forms the closing head (d) for the pressure tank. Each filter leaf consists of a bag or slip carried on a rectangular pipe frame. Collapse of the covers under pressure is prevented by spacers of wood, wire cloth or coarse fiber held between the walls. The lower pipes of the frame are perforated within the slips and are extended outside the slip covers through the movable head and terminate in cocks (e). When the tank is closed, pulp is introduced under pressure, filtrate passes through the canvas and out through cocks (e) while a cake of retained solid builds up on the leaves. When sufficient cake has built up, judged by the pressure on the gage and the rate of flow of filtrate, air is introduced to displace the remaining pulp through drain pipe (g) and to maintain pressure within the tank and hold the cakes in place, then water or

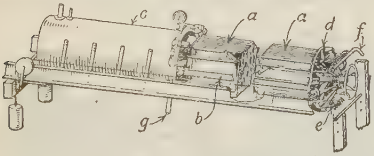

FIG. 11.—Kelly filter.

dilute solution may be pumped through for washing or air or steam for drying. Finally the leaves are run out and cake forced off by steam or compressed air introduced within the covers through pipes connecting with header (*f*). Gravity pressure may be used instead of pumps, if sufficient head is available.

Performance on flotation concentrate:

At TIMBER BUTTE a 5 × 14-ft. tank with 850 sq. ft. of filtering surface treated 200 tons (max.) per day of zinc concentrate (470 lb. per sq. ft. per 24 hr.), 15 per cent. + 200-mesh, reducing moisture content from 45 per cent. to 10 per cent. Cake was 1.5 to 2.5 in. thick. Cycle was 10 min. for charging, 10 for filtering and 20 for discharging. Pulp was unheated. At FEDERAL MINING AND SMELTING Co., Morning mill, a Kelly press with 240 sq. ft. of filter surface treated 18 tons per 24 hr. (150 lb. per sq. ft. per 24 hr.) of lead concentrate, 99 per cent. −200-mesh, and reduced the moisture content from 50 per cent. to 8 per cent. Pulp temperature was normal. The cycle was 5 min. charging, 30 min. filtering, and 7 min. discharging. Oliver filters treating the same material made a cake containing 6 to 6.5 per cent. water at the rate of 280 lb. of solid per sq. ft. per 24 hr. At BRADEN, Kelly filters made a cake containing 18 per cent. water as against 23 per cent. in Oliver filter cake, the feed to both machines containing 35 per cent. water.

Sweetland filter is similar to the Kelly except that the leaves are transverse and stationary, the tank is jointed along a cylindrical element, and the bottom swung open for discharging cake.

Burt leaf filter is similar to the Kelly. Leaves are transverse to the axis of the cylinder and hang vertically with the cylinder set at 45°. The leaves are fixed. Cake is blown off the leaves by compressed air or steam and flushed out of the tank with enough water to cause solid to flow on the steep angle.

Burt revolving filter (Fig. 12) consists of a steel-plate cylinder (*a*) similar to a tube mill or rotary kiln, one end supported by a hollow trunnion (*b*), the other on a tire and rollers (*c*). The cylinder is closed by hydraulically operated toggles (*d*). The interior of the shell is lined with filter mats bolted on. The whole is revolved about 15 r.p.m. by means of gear (*e*). Feed is introduced through feed valve (*f*) until a proper charge has entered, when the air pressure is turned on. Filtrate is forced through filter mats and out through holes in the shell. Wash liquid is then introduced, as desired. Finally the closing head is withdrawn and the charge is tumbled out, sluicing water being used, if necessary.

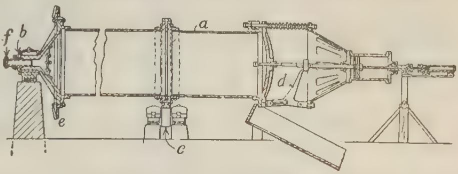

FIG. 12.—Burt revolving filter.

Ordinary PRESSURES are from 25 to 45 lb. The usual SIZES are 36 to 48 in. diameter and 20, 40 or 60 ft. long. CAPACITY of 700 to 800 lb. solid per sq. ft. per 24 hr. on quartzitic slimes are claimed with cake thickness of 4 to 4½ in. Average cycle at EL ORO MIN. & RY. Co. (*Chalmers & Williams catalog*) was: charging pulp, 3.8 min.; forming cake, 25.5 min.; adding wash water, 7.4 min.; washing 41.7 min.; discharging, 2.9 min. Average POWER consumption for running a 42-in. by 40-ft. filter was 4 hp, with a peak of 20 hp. at the time of discharging. (For detailed operations, see Rhodes and Myers, *97 J 1185*.)

6. Vacuum-leaf filters

Moore filter (Fig. 13) consists of a basket (*a*) formed by a plurality of individual filter leaves (*b*) (shown in detail in Fig. 14) all suspended from a traveling crane over a compartmented tank (*c*). LEAF (Fig. 14) consists of a canvas bag (*a*) slipped over a rectangular pipe frame (*b*) and stitched between wooden separating strips (*c*). The bottom pipe of the frame is perforated and is connected to header (*d*) and thence to a vacuum pump. In operation one of the tank compartments is filled with pulp and the filter basket is lowered

therein and allowed to stay, with vacuum on, until a cake of the desired thickness, usually 1 to 2 in., has built up. The basket is then lifted to an adjoining compartment and immersed in wash liquid and finally, after washing in one or

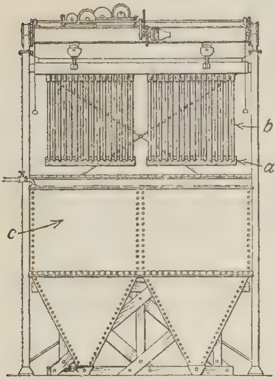

FIG. 13.—Moore filter.

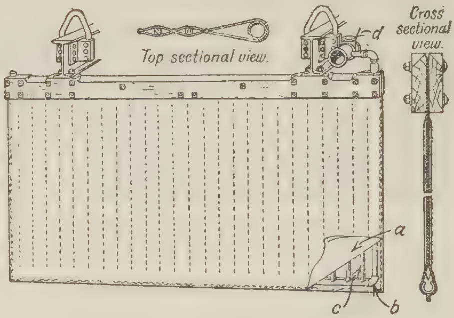

FIG. 14.—Detail of Moore filter leaf.

more compartments, as desired, is transferred over a discharging hopper where the cake is blown off by compressed air.

Butter's filter is similar except that the filter basket is stationary in one tank, into which are pumped in succession feed pulp and wash liquids. Finally the cake is blown off into the same tank and flushed away. Cake in this type of filter must be at least 0.5 in. thick to insure clean discharge.

Performance of Butters and Moore filters on cyanide pulps is given in Table 6. This type of filter is not used in filtering flotation concentrate.

Table 6. Performance of Butters and Moore filters handling cyanide pulps

Filter	Butters	Butters	Moore
Plant	Cobalt Reduction	Nipissing	Hollinger
Size, mesh	All −200, 97%–200	All −100, 80%–200	All −100, 96.5%–200

Discharge	45	45	30–40
Total	255	215–230	110–120

7. Centrifugal filters

Centrifugal filters are essentially the familiar basket centrifuge of the chemical laboratory adapted to large-scale continuous operation. They are used to dewater granular materials only, *e.g.*, to dry fine granular bituminous coal as an alternative to gravity draining.

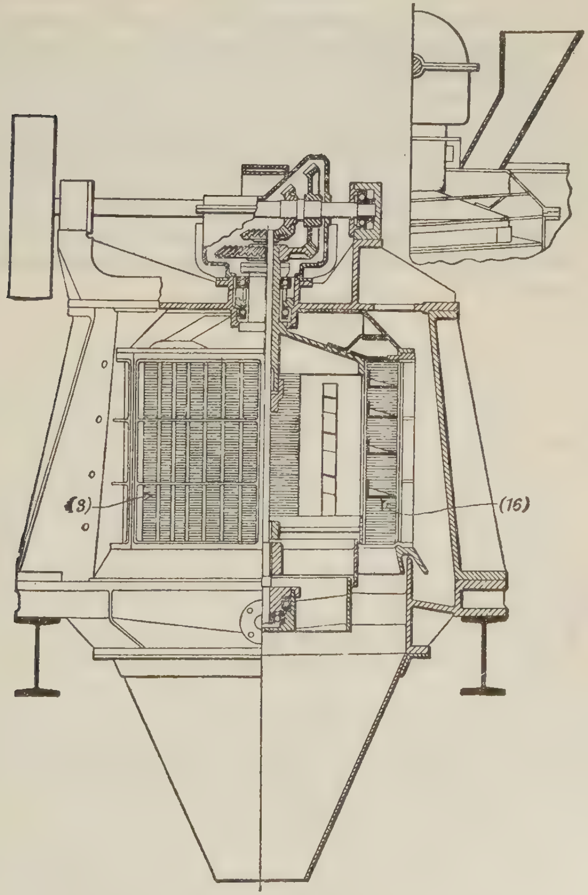

FIG. 15.—Hoyle centrifugal coal dryer.

Hoyle dryer (Fig. 15) is typical of a continuous machine. The essential parts are the screen basket (*3*) revolving at 600 r.p.m., and the spiral scraper (*16*), revolving slightly slower, which scrapes the deposit downward. Air is forced upward inside the basket by means of a fan to aid in drying.

Cost of centrifugal coal drying is said to be less than $0.02 per ton (*23 CA 784*).

8. Comparison of filters

Continuous filters have the surpassing advantage of continuous operation with consequent low attendance charge and non-necessity for provision for storage of thickened feed pulp or alternative intermittent operation of thickeners. They are and should be used whenever a cake of ¼ in. upward in thickness can be built in 3 to 4 min. under the vacuum available (this time being the economic maximum time allowable) and when sufficient washing can be effected. Intermittent filters of both vacuum and pressure types have the advantage of complete control of cake-making and washing periods, they wash more thoroughly and with less water than the continuous machines, and have greater filtering area per unit of floor space. Disadvantages are the intermittent operation. Pressure filters are better than vacuum when the cake has low porosity, but in them porosity of cake is less, cake is less uniform and consequently not so uniformly washed, wear on filter cloth is greater than in vacuum filters, and in those pressure filters in which pulp is forced in by pump the high wear on the pump is a charge against filtration. Porous-bottom tanks, filter tables and rotary dewaterers can be used only on highly permeable granular pulps. Centrifugal filters are used only in drying granular materials, notably bituminous coal.

SECTION 18

DRYING

Drying, in milling, is the process of evaporating, from ores and mill products, moisture that cannot be removed by mechanical means such as draining, decantation and the like. The process enters into mill operations at two places, *viz.:* (*a*) when wet ore or an intermediate wet-mill product is to be treated by a dry process, *e.g.*, dry screening, magnetic or electrostatic concentration or pneumatic separation; (*b*) when a mill product, *e.g.*, concentrate, is to be shipped a considerable distance and freight on water is more costly than its removal.

1. Principles

The fundamental principle in all drying operations is to maintain the partial pressure of the water vapor in contact with the liquid water below the vapor pressure of the liquid water.

If a liquid (*e.g.*, water) is introduced into a vacuum, it evaporates quickly and, if the amount introduced is sufficient so that not all will evaporate a condition of equilibrium is soon reached at which vapor exerts a steady pressure on the walls of the container. This pressure is independent of the volume of the container but varies with the temperature. It is called the VAPOR PRESSURE. When it has reached a constant value the space is said to be SATURATED with vapor and the numerical value of the pressure is the same as the VAPOR PRESSURE (OR VAPOR TENSION) OF THE LIQUID. At this point any further evaporation of liquid is accompanied by condensation of an equal weight of vapor. Numerical values of the vapor pressure of water at different temperatures are given in Sec. 25, Table 11, Col. 2.

If the liquid, instead of being introduced into a vacuum, is introduced into a space containing air or another gas not the vapor of the liquid, evaporation takes place, although more slowly than in the preceding case, until a constant state obtains, when the amount of vapor in a given space will be practically the same as though no other gas were present, and the partial pressure due to the vapor will be the same as the total pressure before and numerically equal to the vapor pressure of the liquid. Now the air or gas is said to be saturated with the vapor of the liquid. Since the amount of vapor in the gas-and-vapor-filled space is greater the higher the temperature, it follows that the amount of vapor in saturated air likewise increases with increase in temperature. The relation is given in Table 11, Sec. 25.

If, instead of being placed in a container, the liquid is open to the atmosphere, evaporation similarly takes place and continues until the adjacent atmosphere is saturated, *i.e.*, until the partial pressure of the water vapor in

contact with the liquid water is equal to the vapor pressure of the liquid water. The rate of evaporation increases with increase in the difference between the vapor pressure of the liquid and that of the adjacent vapor, hence it increases with increase in temperature of the liquid and with the vapor-absorbing capacity of the surroundings. Since evaporation into a vacuum is more rapid than into a gas-filled space, the vacuum gives maximum vapor-absorbing capacity. Since heated air can carry more vapor than cold air, it accelerates evaporation, and since the partial pressure of dry air is less than that of moist air, continuous replacement of the gas in contact with the liquid will likewise accelerate evaporation.

Heat required. It is fundamental, of course, to the discussion, that heat is the cause of evaporation. The molecular explanation is that heating increases the velocity of the liquid molecules sufficiently so that some of these that leave the liquid surface travel far enough not to return, and, in the presence of the elevated temperature, have sufficient molecular velocity to maintain the gaseous spacing.

The heat necessary to cause evaporation may be transmitted directly to the liquid through the walls of the container or may be carried by the air or other gas that is brought into contact with the liquid surface. Both methods of heating are employed in the dryers used in milling practice. In both cases heat must also be supplied to raise the temperature of the apparatus to the working temperature and to maintain it there in the face of heat loss by radiation and conduction, to raise the temperature of the solid from the inlet to the discharge value, to similarly raise the temperature of all of the entering water, to evaporate the water, and to insure that the discharged gases are above the temperature at which condensation of water vapor will take place in the exit flues.

Rate of evaporation of water from a mixture with discrete solid particles depends, during the first part of the drying operation, principally upon the difference maintained between the vapor pressures of the liquid and adjacent gaseous medium, but after the moisture has been lowered to the point that the material can be caked by pressure, the rate of diffusion of liquid to the surface of the cakes controls. At this time the evaporation rate can be greatly increased by agitation that will break up lumps and shorten the distance through which liquid must diffuse. The drying rate from the point where liquid is visible to a moisture content below the caking point varies with the character and size of the solid particles. Porous and finely-divided materials reach the caking point more quickly than dense and coarse materials, hence their average drying rate over the above range is slower. Unsized material dries more slowly than sized. There is no method of theoretical analysis of the problem of rate, but Atwater and Borkland (*29 CME 226*) report tests on several typical substances using an indirect-heat steam dryer. Their results are summarized in the curves in Fig. 1.

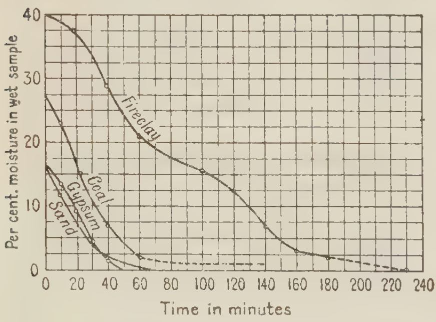

FIG. 1.—Rate of drying various materials.

The low drying rate at the beginning of the operation on coal, gypsum and fire-clay represents time during which the material and apparatus were being brought up to efficient evaporating temperature. The flattening at the lower end of all the curves begins at the point where caking becomes important. The average drying rates for lump gypsum and for quartz sand were substantially the same throughout the drying range and remarkably alike above the caking point. The rate for slack bituminous coal was less, due to its greater porosity and mixed sizes while that for fire-clay was minimum, due to the fineness of grain and high caking point (18 per cent. water). Apart from these facts the noteworthy feature in all of the curves is the disproportionate time required to drive off the last of the moisture. Thus bituminous coal dried from 27 to 2.5 per cent. moisture in, roughly, 55 min. or 0.45 per cent. reduction in moisture per minute, while to dry from 2.5 per cent. to 1 per cent. required 80 min. or 0.014 per cent. per min., roughly one-thirtieth as fast. Gypsum dried from 17 to 2.5 per cent. moisture in 36 min., 0.4 per cent. per min.; and from 2.5 per cent. to substantial bone-dryness in 26 min. or 0.1 per cent. per min., say one-quarter as fast. Sand behaved substantially the same as gypsum. Fire-clay required 150 min. to dry from 40 to 2.5 per cent. or 0.25 per cent. per min., and 80 min. more to reach substantial dryness, equivalent to 0.031 per cent. per min., say one-eighth as fast. While these curves cannot be read directly to give drying time for similar materials in other types of dryers, the relative times required to dry down to and below 2.5 per cent. moisture with similar materials may be used in lieu of more direct experimental information in any given case.

TYPES OF DRYERS

2. Drying floor

The simplest drying operation consists in spreading material on floors, protected from the elements but open to free circulation of air. Under these circumstances drying takes place even with freezing temperature, although very slowly. The rate is increased by turning material over from time to time. This type of dryer is used in certain small and crude non-metallic milling plants, *e.g.*, tripoli, bauxite, etc. It is applicable only where labor is the cheapest commodity entering into the treatment process, tonnage is small, and time is not an important element.

Heated floor is used at Tul Mi Chung mill (*119 P 814*) for drying flotation concentrate. The floor is of concrete (1 of cement, 2 of washed sand, 4 of ¾-in. gravel), 2½ in. thick, reinforced with barbed wire laid in 3-in. squares at ¾-in. from the bottom of the slabs. Checker-work flues underlie the floor. The slope toward the stack end, which is also the loading end, is 1 in. per foot for the last 3 ft. and ¼ in. per ft. for the rest of the length. Concentrate is brought in cars from the thickeners, dumped at the stack end and allowed to drain. Material is then raked by hand toward the fire end, where it arrives dry. Six floors, each 15 × 40 ft. are needed for 30 to 35 tons per day of concentrate screening 97 per cent. −200-mesh. Fuel consumption ranges from 0.1 to 0.2 cord of wood per ton dried, summer and winter respectively, and averages about 0.14 cord. Cost of drying, sampling, sacking, and weighing is $0.90 per ton with wood at $3.60 per cord and labor at $0.25 per day of 10 hr. At Tonopah Mining Co. (*91 J 1214*) fine gravity concentrate was drained in an 8-in. layer on sloping (⅜-in. per ft.) plank floors to 15 per cent. moisture in 20 hr., then dried to 3.4 per cent. on a steel-plate floor. With coal at $13.50 per ton and wood at $9.50 per cord the total cost of drying 4 tons per day was $0.84 per ton.

3. Tower dryer

Tower dryer consists essentially of a furnace with high vertical brick stack down which the material to be dried falls. Fall is impeded by grids or baffles set at right angles across the stack or by a series of shelves projecting from the walls.

Fig. 2 shows two different forms in use at the Franklin mill of New Jersey Zinc Co. The stack is usually laid up of three or four courses of common red brick, bound both ways at about 3-ft. intervals with tie-rods laid in the brick work. or with buck-stays and tie rods. The sides and arch of the fire-box and the first few feet of the stack are lined with one course of fire brick. Racks for T-bar grids are carried on the inner walls or, as at the Empire Iron and Steel Co. mill (*99 J 560*), carried on independent hollow sectional cast-iron columns, built up like tile pipe, set in the corners of the stack. If shelf baffles are used, they are

usually carried on the stack walls and may be made of adjustable slope. At Empire Iron & Steel Co.. the stack is 5 ft. square and 45 ft. 4 in. high and is set on a concrete block 10 × 10 × 10 ft. The baffle bars are arranged in ten sections or groups. The lowest seven sections consist of five tiers of five bars each, the bars in alternate tiers at right angles. The upper surface of the bars (the cross-bar of the T) is 6 in. wide and ¾ in. thick. The bars are set to give 6 in. clear horizontally and 8 in. vertically. In section No. 8 there are 4 tiers of 4 bars per tier, each bar 9 in. wide and 1 in. thick. This leaves 7 in. clear between bars horizontally and 10 in. vertically. In section 9 there are three tiers of 3 and 4 @ 9-in. bars per tier, leaving 10- and 10½-in. spaces horizontally and 12 in. vertically. In the top or No. 10 section there are two tiers with 3 and 4 @ 9-in. bars per tier, leaving the same hori-

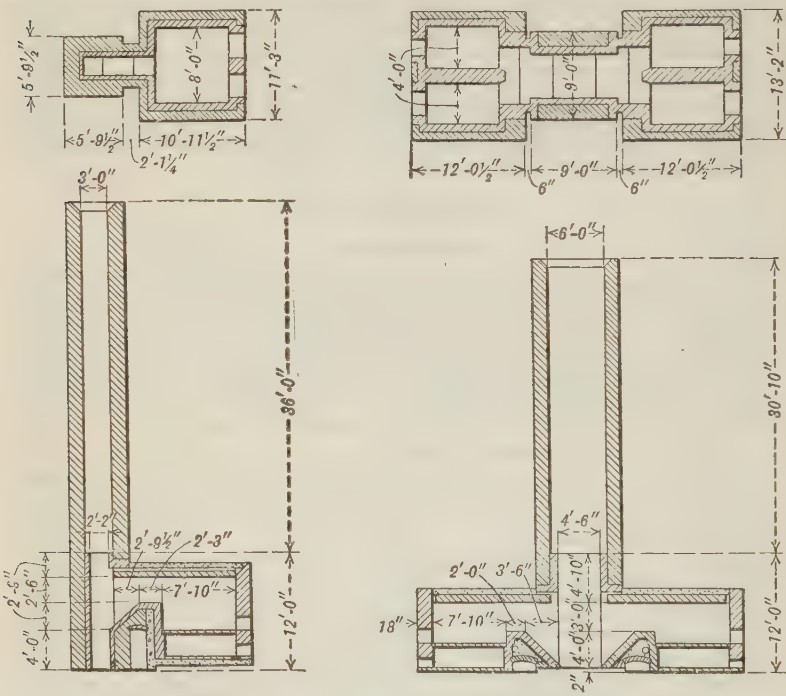

Fig. 2.—Tower driers at New Jersey Zinc Co.

zontal spacing as in No. 9 but 15-in. vertical spacing. The web of the bars fits loosely into the supporting racks and doors are provided at each section for ease in changing. The firebox is 6 ft. 9 in. × 7 ft. 6 in. with grate for burning No. 2 buckwheat coal under forced draft. Additional air is furnished by a No. 80 American Blower Co.'s steel-plate exhaust fan. This air is pre-heated by drawing it over the arch of the furnace; it then passes under the arch, where it joins the gases of combustion in passing up the stack. A 30-in. (diam.) by 20-ft. stack is provided and a damper arrangement to cut in the blower or the stack for draft, as necessary. Feed is through a 1⅛ × 2½-in. slot and carries an average of 14 per cent. moisture. Average feed rate is 25 tons per hr., maximum 35 tons. Product is substantially dry. At New Jersey Zinc Co., Franklin mill, the double-furnace dryer shown in Fig. 2 dries 100 tons of −1-in. feed per hour from 3 per cent. moisture to apparent dryness. Fuel consumption is 700 lb. anthracite buckwheat per hour. The air used amounts to 20,000 cu. ft. per min. and the blower draws 30 hp. The single-furnace dryer is fed 6 tons per hr. of −10-mesh material containing 8 per cent. moisture; discharge is substantially dry. Coal consumption is 250 lb. per hr. (anthracite). The blower supplies 5500 cu. ft. of free air per min. with a consumption of 10 hp. A similar dryer at the same plant with a stack 3 ft. 6 in. square and

32 ft. high handles 11 tons per hr. of −6 + 35-mesh feed carrying 10 per cent. water and brings it to substantial dryness with a coal consumption of 170 lb. per hr., air consumption of 3200 cu. ft. per min. and power draft of 15 hp. At the OGDENSBURG mill of the same company 20 tons of −1-in. ore per hr. is dried in a stack 3 ft. 6 in. square and 40 ft. high from 10 per cent. water to apparent dryness. Fuel consumption (anthracite) is 450 lb. per hr., air consumption 10,000 cu. ft. per min., requiring 10 hp. at the blower motor. In the same mill a double-stack dryer, each stack 3 ft. square and 38 ft. high dries 3 tons per hr. of −8 + 35-mesh feed from 15 per cent. moisture to apparent dryness. Fuel consumption is 200 lb. per hr. of powdered bituminous coal, air consumption is 8000 cu. ft. per min. and power consumption about 10 hp. In all of these NEW JERSEY ZINC CO. dryers the attempt is to keep the exit gases down to 200° F. At WITHERBEE-SHERMAN MILL No. 3, −¾-in. roll product (magnetite gneiss) is dried from 3 per cent. to 0.2 per cent. moisture at the rate of 50 tons per hr. in a stack 4 ft. 9 in. square × 50 ft. high. Coal consumption is given as 1 ton of anthracite (birdseye) per 24 hr., but this is undoubtedly below the actual consumption for the reduction in moisture stated. Average evaporation in tower dryers is between 4 and 6 lb. of water per pound of 13,000-B.t.u. coal.

The DISADVANTAGE of the tower dryer is the difficulty of regulating the rate of fall and, consequently, the amount of drying. In dryers with adjustable-shelf baffles this may be done by changing the inclination of the shelves, but not much is to be gained here because, if the shelves are made flat enough to materially retard flow, the wet material sticks and piles up and substantially all drying effect of the shelf surface is lost. Another disadvantage is the large loss in head room. The ADVANTAGES are simplicity of design and operation.

4. Rotary dryers

The rotary dryer is the commonest form of mechanical dryer. It consists essentially of a long cylinder mounted on a slight incline (acute cones and horizontal cylinders with internal spirals are also used), revolved slowly while the material to be dried and the heated gases pass therethrough. Lifting angles on the interior of the shell lift the drying material and drop it through the current of gas, thereby both spreading the material out in a manner favorable to evaporation of the contained moisture and aiding its progress through the shell. Several types are manufactured.

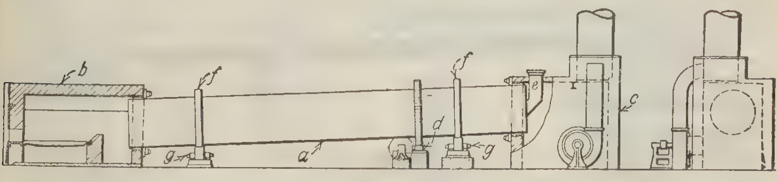

FIG. 3.—Direct-heat cylindrical drier.

Direct-heat cylindrical dryer (Fig. 3) is the simplest form. The essential parts are the drying cylinder (*a*), furnace (*b*), exhaust chamber (*c*) and driving mechanism (*d*). Feed enters through spout (*e*) and is discharged into a suitable receptacle or conveying mechanism at the other end of the shell. The shell is made of heavy steel plate with riveted joints. Longitudinal lifting angles are riveted to the inner surface. Heavy steel tires (*f*) bolted to the shell, ride on hardened-steel rollers (*g*).

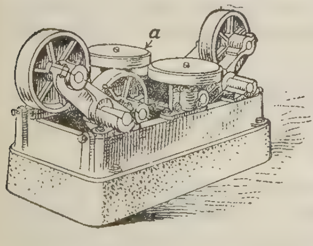

FIG. 4.—Roller bearing for rotary dryer.

Various methods are employed to resist end thrust. Fig. 3 shows flanged rollers used at the head end. Fig. 4 shows a more efficient, although more expensive form with horizontal rollers (*a*) that bear against the sides of the tire.

A gear drive is usual although chain-and-sprocket drive is used on some small, light machines. Coal is the usual fuel, but any fuel may be used. The use of a blower in addition to a stack is wise, since it gives positive control of draft and increases thermal efficiency.

It is, of course, possible to place the furnace at either end of the shell, as desired. The arrangement shown in Fig. 3 is the usual one, as combustion is not checked by contact of the gases with cold wet material and dust losses are less because the sheet of wet solid at the feed end serves as a sort of filter for the dust-laden gases.

Usual cylinder sizes are 4-, 5-, and 6-ft. diameter with lengths ranging from 25 to 35 ft. for the 4-ft. shell and 35 to 60 ft. for the 6-ft. shell. Usual SPEEDS are 3 to 6 r.p.m. POWER required for dryer cylinder and fan averages about 10 hp. for a 3 × 25-ft. machine; 15 hp. for a 4 × 30-ft., 25 hp. for a 5 × 35-ft., 25 hp. for 6 × 40-ft., 50 hp. for 7 × 50-ft., and 70 hp. for 8 × 60-ft. (*C. O. Bartlett and Snow.*) FUEL consumption averages about 1 lb. of 13,000-B.t.u. coal per 5 lb. of moisture evaporated.

Direct-indirect-heat cylindrical dryer is shown in Fig. 5. The elements of the shell are the same as those in the dryer just described but the circulation of hot gases is first around the outside of the shell, then through the shell.

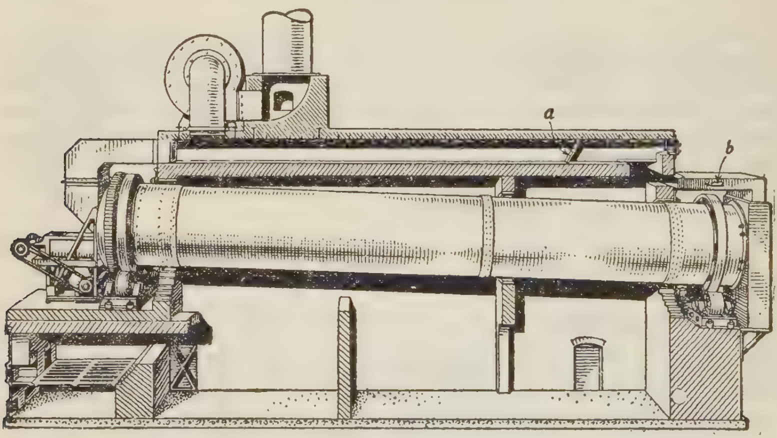

FIG. 5.—Direct-indirect-heat cylindrical dryer.

Dampers (*a*) and (*b*) determine the proportion of gas passing through the shell interior. By closing (*b*) and opening (*a*) the machine becomes an indirect-heat dryer. The usual cylinder sizes are the same as those of the preceding machine.

This machine utilizes heat more completely and efficiently than the direct-heat machine, both on account of the enclosure of the shell, which decreases radiation losses, and the longer time that the gases are in contact with surfaces to be heated. FUEL consumption is about 1 lb. of 13,000-B.t.u. coal to 6 or 6½ lb. of water evaporated.

Another form of direct-indirect-heat cylindrical dryer is shown in Fig. 6. Hot gas directly from the furnace passes through the inner shell and returns between the two shells, as indicated by the arrows. Feed enters at the furnace end of the outer shell, is lifted by the ribs of the outer shell, showered through the stream of hot gas onto the ribbed outer surface of the inner shell,

held for a while in contact with this hot surface, and then showered again through the gas stream onto the outer shell. This cycle is repeated many times in the passage to the discharge-end head where the material is finally picked up by buckets on the inner surface of the outer shell, dropped onto the fluted discharge cone (*a*), and carried out through the discharge trunnion.

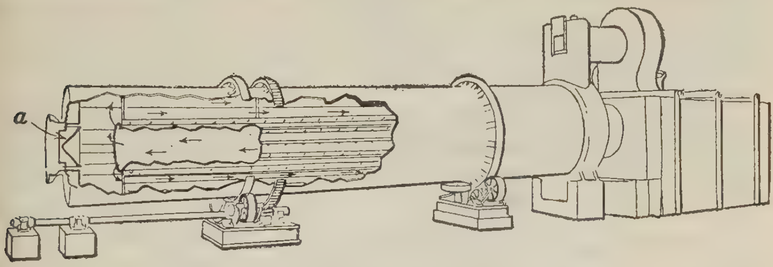

FIG. 6.—Ruggles-Coles double-shell dryer.

Cylindrical dryers in concentrating mills are usually of the direct or direct-indirect type, since discoloration and overheating are of no importance. Their use is ordinarily limited to granular materials, however, on account of the high dust losses with finer feeds.

Performance of double-shell dryers on different classes of material are indicated by Table 1.

Table 1. Tests on Ruggles-Coles dryers. (*Ruggles-Coles Eng. Co.*)

* Estimated. *a* Completely indirect.

In PHOSPHATE WASHING (*50 A 929*) a 5 × 40-ft. machine dries 135 to 165 tons of − ¼-in. slime-free gravel per 24 hr. from 20 per cent. to 2 or 3 per cent. moisture with a consumption of 75 lb. bituminous coal per dry ton and 15 to 20 hp. for driving the shell and fan. At the U. S. SMELTING, REFINING AND MINING CO., Midvale plant, a 5 × 30-ft. Ruggles-Coles (double-shell) machine dried 90 tons of −16-mesh table middling per 24 hr. from 14.5 per cent. moisture to bone-dryness with a consumption of 3 tons of bituminous coal per 24 hr. Temperature of exit gases was 350° F. Speed, 5 r.p.m. Power consumption, driving shell, 6 hp.; fan, 4 hp. About 5.5 per cent. possible running time was lost due to shell repairs. At AFTERTHOUGHT COPPER CO. (*119 P 154*) a 5 × 30-ft. oil-fired machine was used to dry about 150 tons flotation concentrate per 24 hr. from 15 per cent. to 5 per cent. moisture. About 10 tons of flue dust was collected monthly. Some caking occurred near the feed end when concentrate was sticky.

Multiple-tube dryer is a form of cylindrical dryer with the shell replaced by a number (usually 3 to 5) of parallel tubes aggregating in outside diameter the usual 3 to 8 ft. of the single-shell machines. Various arrangements are shown diagrammatically in Fig. 7. Sufficient space is maintained between the tubes to allow free circulation of hot gases. The machines may be run either indirect-heat or direct-indirect.

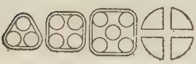

FIG. 7.—Arrangements of tubes in multi-tube revolving dryers.

ADVANTAGES are greater heating surface for indirect heating and reduction in power consumption due to distribution of the ore stream around the axis of revolution. POWER CONSUMPTION is from 70 to 80 per cent. of that required for a single-tube dryer. C. O. Bartlett & Snow claim an average of 8 lb. of water evaporated per pound of 13,000-B.t.u.-coal in their multi-tube dryer operated with both direct and indirect heat.

Dust losses may be an important factor in drying in rotary and tower dryers. Dietz and Keedy (*43 A 342*) give the data shown in Table 2 for operation of a 4½ × 24-ft. rotary

Table 2. Dust loss in a rotary dryer. (*After Dietz and Keedy*)

Products	Weight, per cent.	Assay		Percentage of total	
		Pb, per cent.	Ag, ounces	Pb	Ag
Total feed	100	10.35	9.68	100	100
Dry discharge	96.2	9.77	9.34	90.7	95.40
Settled in chamber	1.77	35.30	10.30	6.04	1.94
Settled in smoke-stack	0.76	18.50	8.60	1.36	0.69
Lost in gases	1.27	14.30	15.20	1.75	2.04

dryer running at 8 r.p.m. with light draft, the feed carrying 5 to 8 per cent. moisture. At a dry-crushing cyanide plant, drying −2-in. material in rotary dryers that needed strong draft, from 5 to 6 per cent. of the feed, which assayed 0.31 oz. Au and 0.15 oz. Ag, was lost as −150-mesh dust that assayed 0.48 oz. Au and 3.48 oz. Ag. In an elaborate test with a 4 × 30-ft. rotary dryer, sloped ¼ in. per ft., they found that in drying −2-in. zinc ore, about 12 per cent. of the feed was reduced from +16-mesh to −16-mesh by the tumbling action in the dryer, and that this 12 per cent. of the feed carried 19 per cent. of the zinc. In a dust-collecting system in the same plant substantially 16 per cent. of normal dryer feed was collected carrying 19 per cent of the total zinc and the more-gritty part of the collected product had the higher assay.

5. Rabbled-hearth dryer

Rabbled-hearth dryer is of the indirect-heat type. It consists essentially of a long bottom-heated trough through which the material to be dried is slowly moved and at the same time turned over by suitable rabble arms attached to a reciprocating or chain-drag mechanism. Inclination of the rabble blades is made adjustable to permit variation in the speed of travel of material. In the reciprocating machines, length of stroke and height of

lift are also adjustable. The firing box is usually placed at the feed end and the hot gases pass through a checker-work under the cast-iron plate bottom. Common sizes are 3 × 30-ft., 3 × 40-ft., 4 × 40, 4 × 50, 5 × 50 and 5 × 60-ft. The Lowden dryer (Fig. 8) is the best-known of the hearth machines.

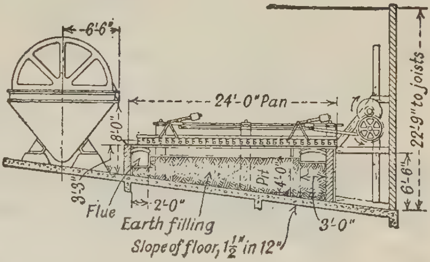

FIG. 8.—Lowden dryer and Oliver filter.

Performance of rabble driers. According to Watt (*57 A 385*), Lowden dryers require 70 to 120 lb. of coal per ton of lead-flotation concentrate to dry from about 14 per cent. to about 6 per cent. moisture and the usual size allowance is 10 sq. ft. of hearth area per ton of concentrate to be dried per 24 hr. At FEDERAL LEAD CO. MILL No. 4 one 12 × 24-ft. machine dried 50 tons per 24 hr. of −80-mesh flotation-lead concentrate from 15 or 16 per cent. moisture to 4 to 6 per cent. with a consumption of two tons of soft coal. The machine was run at 2½ strokes per min. and consumed about 6 hp. Lost time for tightening rakes, replacing crank pins and repairing furnace hearth and arch amounted to about 2 per cent. A common set-up, with gravity feed from filter and gravity discharge to a car-loading hopper is shown in Fig. 8. At HAYES MILLING CO. (*111 J 909*) a 5 × 17-ft. Lowden dryer, oil-heated, dried 175 tons per month from 35 to 15 per cent. water at a cost for fuel of $6.90 per ton of water evaporated. Results of efficiency tests on two Lowden driers are given in Table 3. Reynolds (*116 P 745*) gives data on FUEL CONSUMPTION in drying flotation con-

Table 3. Efficiency tests on Lowden dryer. (*Colorado Iron Works Co.*)

Efficiency	55.6	55.5

a 10,285 (weight of dry solids, lb.) × 160 (temperature rise) × 0.25 (specific heat of solid, B.t.u.) = 411,400. *b* 1674 (weight of water, lb.) × 160 (temperature rise) × specific heat of water, (B.t.u.) = 267,840. *c* 959 (weight of water evaporated) × 966 (latent heat of evaporation) = 926,394.

centrate at three different plants as follows: (1) 56 tons (dry weight) per 24 hr. from 15 or 16 per cent. to 4 per cent. moisture with 3½ tons of coal; (2) 30 tons (dry weight) per 24 hr. from 15 to 16 per cent. to 5 per cent. moisture with 1¾ tons of coal; (3) 31 tons (dry weight) per 24 hr. from 29 per cent. to 13 per cent. moisture with 2 tons of coal. At LIBERTY BELL two steam-heated rabble-type hearth dryers with 4 × 10-ft. drying surface, in series, are used to dry 12 tons of 300-mesh flotation concentrate per 24 hr. from 20 per cent. to 10 per

cent. moisture. The company estimates a fuel consumption of 0.5 ton of coal per 24 hr. for the two dryers.

A hearth dryer with chain-drawn rabbles is shown in Fig. 9. This form is likely to give trouble by dragging sticky concentrate in a thick sheet along the hearth, resulting in high-power draft and wet discharge. C. O. Bartlett & Snow estimate the CAPACITY at between 2 and 3 lb. of moisture per square foot of heating surface per hour with a feed containing 25 per cent. moisture, and a FUEL CONSUMPTION on the same material of 1 pound of 13,000-B.t.u. coal per 3 lb. of moisture evaporated.

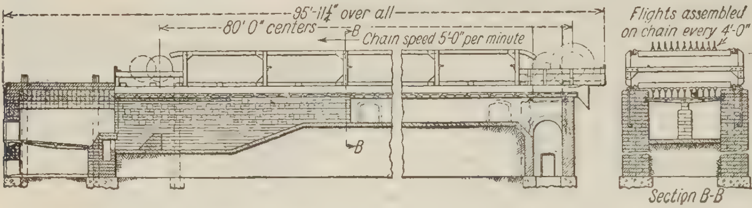

FIG. 9.—Chain-drawn rabbled-hearth dryer.

Applicability. The rabble dryer is particularly useful for drying sticky material that would ball up in a revolving dryer and for fine material such as flotation concentrate that shows excessive dust loss in such a machine.

6. Design of cylindrical dryers

Cylindrical dryers are designed by a method of cut-and-try, using in part accurate thermodynamic data and in part empirical data, finally checking the result, if possible, against actual performance under similar conditions. The items to be determined are, (*a*) the dimensions (volume or area) of the drying zone, (*b*) the amount of gas that must be handled, (*c*) the amount of heat that must be furnished, (*d*) the amount of power that will be consumed. The data required are, (1) the amount of solid to be handled per unit of time, (2) the inlet moisture content, (3) the exit moisture content, (4) the character of the material, its size, specific gravity, and whether it will suffer from overheating or discoloration, (5) the type of fuel.

Type of dryer. If material is not sticky and breakage and dust loss are not serious items, a tower dryer or a rotary dryer may be employed, preferably the latter. This is the case with most mill products other than fine concentrate; with such material a dryer of the rabbled-hearth type should be used.

Size of dryer depends upon the amount of drying that is to be done, the type of dryer and the character of the material. These factors combine to give the DRYING TIME, which, if determinate, forms the basis of the calculation. Published data on drying time are very scanty (see Art. 1). An approximation may be made by laboratory experiment that reproduces the method of drying as closely as possible. Thus heating in a thin-bottomed metal pan over a naked flame, with intermittent stirring and a gentle draft blowing over the surface of the material will give drying time for a layer of material of given depth. Similar heating of a thin bed with constant stirring and a current of hot air passing across the surface of the material will give a maximum figure for drying time in a tower or rotary-shell dryer. Unless the necessary reduction in moisture is very small and the final moisture content required is upwards of 3 or 4 per cent. a tower dryer should not be considered, and if considered, can probably be most safely designed by following the particulars of such a device successfully working under similar conditions as to size and kind of solid, and initial and final moisture content.

If a reliable figure for drying time can be obtained, the proper size of cylinder for a rotary dryer can be determined as follows: If the drying time is between 20 and 30 min., it is usual to make the volume of the shell (V) five times the volume of material in it at any one time, or

$$V = 5tTc/24, \qquad (1)$$

in which t = drying time in hours, T = tons feed per 24 hr. and c = cu. ft. of feed per ton. The diameter (d) and length (l) of the shell may be found from V through the relation, ordinarily prevailing, that $l = 7.5d$, from which

$$V = 6d^3 \text{ (approx.)}. \qquad (2)$$

Usual commercial cylinder diameters are 3, 4, 5, 6, 7 and 8 ft. and the usual corresponding lengths are the nearest 5-ft. to 7.5-times the diameter.

Slope and speed (r.p.m.) may next be settled from the relation

$$l = tnsd[d/2 + \sin(\alpha - 90)], \qquad (3)$$

where l, t and d have the significance already assigned, n = r.p.m., s = slope in ft. per ft., and α = the average angle, reckoned in the direction of revolution, from the bottom of the shell to the point where the lifters discharge. With radial lifters, α may be taken as 112°, with U-shaped lifters at 135°. The USUAL SPEEDS range from 3 or 4 r.p.m. for 8-ft. diameter to 5 to 8 r.p.m. for 3-ft. diameter. The usual slope is 1 : 24. With α fixed, setting either n or s obviously sets the other.

Temperature. When no limits are set by the requirements of the material itself, the attempt should be to make the temperature drop of the gases in passing through the drying zone as great as possible. The temperature limit is then imposed by the amount of heat that the dryer shell itself can stand. The strength of steel plate reaches a maximum at about 600° F. and falls very rapidly at higher temperatures until at about 660° it is the same as at ordinary temperatures. At 1000° the strength is only 40 per cent. of maximum, at about 1200° F. the plate becomes dull red and hereabout the susceptibility to corrosion increases greatly. Hence the temperature of the incoming gas should never be as high as this unless the gas-inlet end of the shell is protected by very moist, cold ore, and even with this protection the shell should not be called upon to support any great load at the heated portion.

High inlet temperatures with direct-heat dryers almost invariably result in high exit temperatures, hence if large temperature drop is to be attempted the dryer should be of the indirect-direct type with the hot gas entering under the feed-inlet end, passing around the shell to the discharge end and passing through the shell counter to the flow of ore.

The lower temperature limit may be anything desired, except that it must be borne in mind that the volume of gas necessary to carry the heat to effect evaporation will be very great when the inlet temperature is low, that as a result the heat loss in the outlet gases may be greater than when a smaller volume of gas at higher temperature is used, that the power required to move the larger volume of gas will be greater and that dust loss will be increased. On the contrary, radiation loss will be less and the life of the dryer shell will be longer with low inlet temperature.

Best exit temperature is stated by different writers at between 120 and 170° F. With lower temperatures there is danger that the gas will become supersaturated and deposit moisture while with higher temperatures heat loss is unnecessarily high.

Heat required is that needed (1) to raise the solid from inlet to outlet temperature, (2) to raise all of the water in the feed through the same temperature

range, (3) to evaporate the water, (4) to supply radiation loss and (5) to supply the loss through gas leaks.

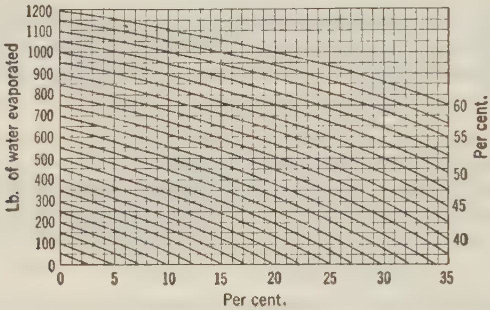
Heat required to raise the temperature of the solid is given by the equation

$$H_S = W_S h_S (t_e - t_i), \qquad (4)$$

where H_S is the required number of B.t.u., W_S is the weight of solid heated, in pounds; h_S is the specific heat of the solid in B.t.u. per lb. per deg. F.; t_e is the exit and t_i the inlet temperature in deg. F. The specific heats of common materials are given in Sec. 25, Table 7.

Heat required to raise the temperature of the water is obtained by the equation

$$H_W = W_W (t_e - t), \qquad (5)$$



Enter chart on diagonal representing percentage of moisture in feed, follow diagonal to intersection with ordinate representing moisture in product and read on left-hand scale pounds of water to be evaporated per ton of wet feed.

FIG. 10.—Weight of water evaporated per ton of wet feed from a given inlet to a given outlet moisture percentage (*after Ruggles-Coles Eng. Co.*).

where H_W is the required quantity of heat in B.t.u., and W_W = total weight of water entering. The specific heat of water is practically 1.0, so does not need to appear in the equation.

Heat required for evaporation (H_e) is the product of the weight of water evaporated (W_e) and the latent heat of evaporation of water at the outlet temperature (h_l). See Sec. 25, Table 11.

$$H_e = W_e h_l. \qquad (6)$$

Fig. 10 gives a graphical solution of the amount of water to be evaporated in terms of moist weight of feed and feed and discharge moisture percentages.

Heat lost by radiation depends upon the construction of the dryer and upon the inside temperature. Heat loss in terms of B.t.u. per sq. ft. per hr. per degree F. difference in temperature inside and outside the dryer walls is given in Table 4 for various kinds of dryer enclosures.

Heat lost by leakage of gas forms a considerable part of the total heat supplied. An allowance of 10 to 20 per cent. of the sum of the above four items should be made to cover.

All heat to perform the above computed heating duty must be supplied by gas passing around and through the heating zone. The heat balance is shown in the equation

$$W_G h_g (t_I - t_E) = H_s + H_w + H_e + H_{\text{radiated}} + H_{\text{lost}}, \qquad (7)$$

in which W_G = total weight of gas required in lb., h_g = specific heat of the gas (0.23, for air, is sufficiently accurate, since air predominates), and t_I and t_E are inlet and exit temperatures of the gases respectively. With this air there will pass through the exit passages of the dryer the vapor of the evaporated water. The DEGREE OF SATURATION may be determined by adding to the evap-

orated water the water entering with the inlet air. Compare the ratio of total pounds of water in exit gas to total pounds of dry air therein with the column headed "Ratio, vapor/air" in Sec. 25, Table 11. If the corresponding temperature in the table is well below the exit temperature no precipitation need be feared.

Table 4. Heat loss by radiation from dryer walls. (*After Buck, 29 CME 626*)

Material	Heat loss, B.t.u. per square foot per hour per degree F. temperature difference
Asbestos, Johns-Manville special, Type A, built-up	0.13
Asbestos, Johns-Manville special, Type B, built-up	0.20

Wood, ⅞-in. T. and G. sheathing, and sheet steel	0.72
Wood, ⅞-in. T. and G. sheathing, building paper, 4-in. air space, building paper, ¼-in. Transite, built up on 2 × 4-in. studs	0.41

Volume of gas. To determine the volume of gas to be handled by the blower, take the reciprocal of the corresponding value in the column headed "Weight in lb. per cu. ft. of saturated mixture" and multiply by the ratio $(t_E + 491)/(t_t + 491)$ where t_t is the tabular temperature corresponding to saturation, as above.

Velocity of air leaving the dryer shell should not exceed 300 to 400 ft. per min., if dust loss is an important consideration. If a dryer, calculated as above, shows greater velocity than this, and dust loss must be prevented, higher initial and lower final temperatures should be investigated. If such change in conditions does not reduce velocity sufficiently, a dust collector is probably the cheapest method of overcoming the difficulty.

Amount of fuel required is determined by dividing the total heat requirement $(H_s + H_w + H_e + \ . \ . \ .)$ by the heating value per pound of the fuel that is to be used. See Table 5.

Table 5. Approximate heating value of various fuels

Fuel	B.t.u. per pound
Anthracite	12,000 to 14,000
Bituminous	10,000 to 15,000
Lignite	6,000 to 12,000
Air-dried peat	5,000 to 9,000
Dry wood	8,000 to 9,000
Fuel oil	18,000 to 19,000

C. O. Bartlett & Snow estimate the consumption of 13,000-B.t.u. coal as 1 lb. per 5 lb. of moisture evaporated in an exposed-shell direct-heat revolving dryer, 1 lb. per 6.5 lb. of moisture in an enclosed-shell indirect-direct heat machine and 1 lb. per 8 lb. of moisture in the enclosed-shell, indirect-direct heat, multi-compartment machine, when the final moisture content required is not below 3 or 4 per cent.

Size of grate necessary for coal-burning dryers may be determined by reference to Fig. 11.

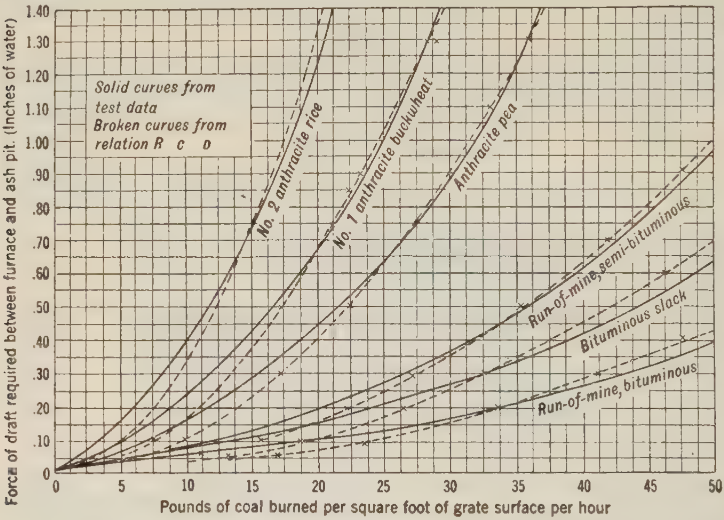

Fig. 11.—Size of grate required for different kinds of fuels (*after Lucke, Engineering thermodynamics*).

Centrifugal dryers. See centrifugal filters, Sec. 17, Art. 7.

Electrical dryers.—At Gold Hunter (*111 J 909*) eight coils of high-resistance wire wound on 1-in. iron-pipe supports were spaced at 1-ft. intervals across and near the face of an Oliver filter. Each unit consumed 3.95 kw. The filter handled 30 tons mixed table and flotation concentrate per 24 hr. The cake without the dryer averaged 11 per cent. water; with the dryer, 8.7 per cent. The cost per ton of water evaporated was $6.86. At Bunker Hill and Sullivan (*ibid.*) a rotary dryer consisting of a piece of 12-in. iron pipe 10 ft. long, covered with ⅜-in. asbestos was wound with 205 turns of bare No. 4 hard-drawn copper wire (90 lb.) terminating on collector rings. A current of 82 amp. at 282 volts was supplied and heat generated by hysteresis and eddy-current losses in the pipe walls. The pipe rotated 7 r.p.m. spiral rabbles inside, turning 1.4 r.p.m., moved the ore through. Pre-heated air was forced through counter-current. The capacity was 17 tons of flotation concentrate per 24 hr. from 11.4 to 6 per cent. moisture; cost of power, $5.66 per ton of water evaporated.

SECTION 19

STORAGE

1. Introduction

Necessity for storage arises from the fact that different parts of the operation of mining and milling ores are performed at different rates, some are intermittent and others continuous, some are subject to frequent interruption for repairs and others are essentially batch operations, so that unless reservoirs for material are provided between the succeeding different steps the whole operation is rendered spasmodic and, consequently, uneconomical. Storage bins are the best means of distributing the product of a crusher of high capacity to several crushers of low capacity, as for instance, jaw-crusher product to stamps. Large bins are desirable because they allow mill feed to be well mixed and tend toward uniformity. When a bin is fed with undersize from run-of-mine ore and crushed oversize, these products should be delivered at the same point in the bin or segregation of sizes, and probably, of values, will be unavoidable in drawing.

Amount of storage necessary is ordinarily considered and expressed in terms of the daily tonnage capacity of the plant. It depends on the equipment of the plant as a whole, its method of operation, and the frequency and duration of regular and unexpected shut-downs of individual units. At many mines ore can be taken out during a part of each day only on account of the necessity for getting supplies into the mine through the same opening; on the other hand concentrating mills are most efficient when continuously operated, due to unavoidable tailing losses in shutting down and starting up the machinery. Mine operations are more subject to unexpected interruption than mill operations and coarse-crushing machines are more subject to clogging and breakage than fine crushers and concentrating machinery. Consequently both the mine and the coarse-crushing plant should have greater hourly capacity than the fine-crushing, and concentrating units and storage reservoirs should be provided between them and the mill proper. Ordinary mine shut-downs, expected or unexpected, will not generally exceed 24 hours duration and ordinary coarse-crushing plant repairs can be made within an equal period, if a good supply of repair parts is kept on hand. Therefore, if a 24-hour supply of ore that has passed the coarse-crushing plant is kept in reserve ahead of the mill proper, the mill can be kept running independently of shut-downs of less than 24 hours' duration in mine and coarse-crushing plant. It is wise to provide for a similar shut-down of the mill. In order to do this the reservoir between coarse-crushing plant and mill must contain at all times unfilled space capable of holding a day's tonnage from the mine. Ore-storage reservoirs ordinarily are not of such shape that they can be filled or emptied completely without shoveling and, since to incur the expense of shoveling would to a large

extent defeat the purpose of storage, additional storage room must be provided so that a day's tonnage may be *drawn* into the mill proper, in case the ore supply stops for a day, and the same tonnage may be discharged into the partly-filled bin in the usual way, in case the mill ceases to draw. The amount of space that must be provided for un-drawable material and the additional amount that cannot be loaded without shoveling depend upon the shape of the bin, the method of drawing, and the method of loading. In ordinary rectangular bins it will amount to something more than that necessary to hold a day's supply of ore. Hence a bin to fulfill the conditions set down must have a volume equivalent to something more than three days ore supply and should be run about half full to provide against unexpected shut-downs at either end of the plant. Similar methods of analysis are applicable at other points in the path of the ore. The average of present-day practice, derived from data from 23 mills chosen at random is three-days' storage capacity; individual figures range from 0.9 to 10 days. These figures in many cases comprise both coarse- and fine-ore storage, *i.e.*, between mine and coarse-crushing plant and between coarse-crushing plant and mill. Peculiar conditions, such as long and uncertain haul from mine to mill, great variety in character of ores treated in a given mill, and the like, give rise to special storage problems, resulting in the provision of storage in excess of the average.

Methods of storage. Considerable storage is usually provided in the mine itself, in stopes and skip pockets, thus allowing actual breakage of ground and some underground haulage to proceed even after available surface storage space has been exhausted. When for any reason an extended mill shut-down is incurred and it is particularly desirable that underground breaking be carried forward in excess of the underground storage capacity, stockpiles may be built on the surface in a location convenient both for building and subsequent excavation. This may be the solution when extensive exploration work is carried forward during the building of a mill. STOCKPILING is resorted to when winter conditions are such as to prohibit excavation in open-cut mines and the year's mill supply must be taken out in the open months; or when transportation is stopped during the winter, though mining can be carried forward, as is the case in the Lake Superior iron ranges; or when the product of a milling operation is bulky, as in the case of coal or crushed stone and the demand is seasonal and in excess of mine or mill capacity. RAILROAD CARS may form a considerable part of the storage system; particularly when the haul from mine to mill is long. BINS are the commonest type of ore-storage reservoir. They are built in several different shapes, of masonry, concrete, steel and wood. Shape is determined primarily by the service the bin is to render, secondarily by the materials of construction. Wooden bins are ordinarily cheapest in first cost and easiest to construct. Masonry and concrete bins have the longest life. Steel bins are lightest and occupy the least space for a given capacity. They can be built in shapes that better withstand the pressure of the filling material and they maintain their original rigidity much better than wooden bins. Fire hazard is great in wooden bins, and, if the ore is wet, the bottom rots rapidly unless well ventilated. If bins are loaded by trains they are subjected to much vibration and heavy racking strains. Under these conditions the tension rods in wooden bins must be continually watched and tightened and the bins will, in time, become so rickety as to be dangerous. The large sticks of timber needed in high and wide wooden bins are becoming so scarce and expensive that the cost of such bins approaches more and more closely that of the other types.

2. Shape of bin

Common shapes are shown in Fig. 1.

Flat-bottom bin (*a*) is suited to timber, steel or concrete construction. It is the cheapest type of all to build and in it the ore forms its own bottom so that there is no wear on the bottom of the bin itself in drawing.

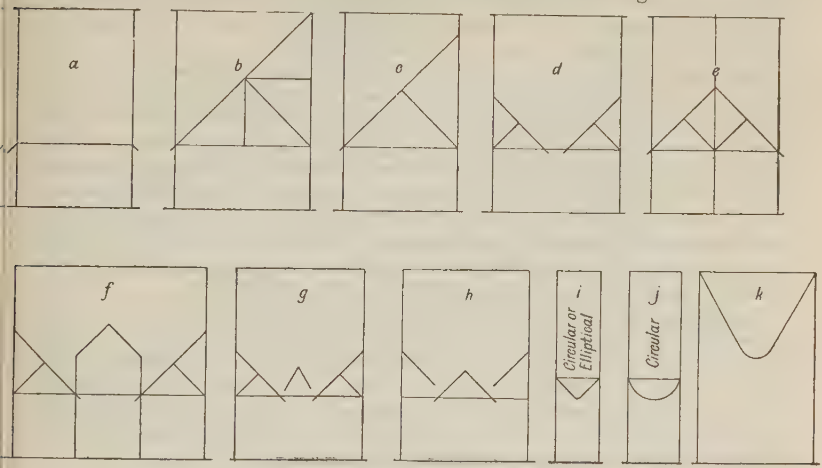

FIG. 1.—Typical bin shapes.

DISADVANTAGES are (1) that the bin cannot be emptied without shoveling, and (2) that the angle of repose material in the dead part of the bin may be as great as 60° when the ore contains a large amount of fines and an appreciable percentage of moisture, so that the free-running bin capacity is much less than in a sloping-bottom bin of the same horizontal cross-section. A flat-bottom bin is not suitable for service where material must be treated in lots, as in custom plants. Flat bottoms are frequently filled with waste, particularly if the ore is high-grade, so that interest will not be lost on high-grade ore locked up in bottom filling. But if the mill is working to capacity in any case, treatment of material that would otherwise form bin filling leaves a corresponding amount "locked-up" in the mine. The loss with high-grade ore by passage of fine material down into the waste filling may well exceed an actual interest loss. If the dead space in a flat bin is filled with ore, this ore forms a reserve if the emergency justifies shoveling, but after the bin has been thus emptied no ore can be drawn therefrom until an amount substantially equal to that shoveled out has been replaced. Anthracite coal should not be handled through flat-bottom bins because of breakage of coal in the dead space by pressure of the coal above.

Slanting-bottom bins. Type (*b*) is typical of small bins that it is desired to empty frequently, such, for instance as shipping bins and concentrate bins. Type (*c*) is perhaps the commonest around milling plants. It is suitable for distributing to and feeding gravity stamps, rolls, ball mills, or other multiple units. Completeness of discharge depends upon the spacing of gates lengthwise of the bin and the bottom slope. The minimum slope upon which material will slide depends upon the kind of material, size of pieces, percentage of fines, percentage of moisture and surface of bin bottom. Minimum sliding angles for dry materials containing only a small percentage of fines, on steel-lined bottom, are given in Table 3. The slope of the bin bottom should be at least 2°, better 5° greater than these figures. Type (*e*) is a modification of (*c*) rarely used on coarse feeds, but sometimes used for fine-ore bins and shipping bins. It saves timber for a given capacity, and is useful when delivery on two sides can be utilized.

Hopper-bottom bin (*d*) gives the highest percentage of gravity delivery of any of the first five types. Discharge must ordinarily be collected and transported to the following machines by a conveyor or cars. This type is particularly suitable for long bins of large capacity. Types (*f*), (*g*) and (*h*) are typical coal bins. They give a relatively high percentage of discharge by gravity; are shallow and do not cause the coal to crush, yet are of good capacity per foot of length. All of these types, while best adapted to timber construction, may be built of steel or reinforced concrete.

Steel bins. Forms (*i*), (*j*) and (*k*) are particularly adapted to steel construction, although both (*i*) and (*j*) have been built with reinforced concrete. Wood-stave circular tanks with flat bottoms have been used for both coarse-ore and concentrate-storage bins, but the gravity discharge percentage is low. Circular and elliptical shapes are particularly suitable for deep-bins, since the metal of the walls is under tensile rather than bending stresses and the pressure on the bottom is relatively small. Such bins with conical bottoms will draw practically clean, if the ore is not too moist. Stress in the hemispherical bottom (*j*) is less for a given loading than in a conical-bottom, hence lighter material can be used, but the gravity draw-off is not so complete.

Suspension bunker (*k*) puts all of the wall in tension and can be extended indefinitely at right angles to the section shown without any increase in weight of section, and without the loss in storage capacity that is attendant upon placing circular or elliptical bins side by side. It has been used extensively in fuel storage and handling plants, but not much in milling work. Its merits warrant investigation, however, when the amount of storage needed per foot of length of mill bin is within the limits of its capacity.

3. Design of bins

This problem involves the usual elements of determination of loads and design of members to bear them. Wear due to passage of material through the bin must be anticipated and structural members guarded against blows and abrasion that would weaken them. Determination of loads is by the same methods that are employed in the design of retaining walls (see Sec. 27, Art. 14). Many formulas and graphical methods have been proposed. Those by Rankine, Coulomb and Cain, summarized by Ketchum (*Design of walls, bins and grain elevators*), are best known and should be investigated in the case of large and elaborate structures. The graphical method given below, based on Coulomb's theory of "maximum wedge thrust" is satisfactory for most cases.

Preliminary considerations are: (*a*) required capacity in tons; (*b*) corresponding cubical content based on weight of filling (Table 1), space that cannot be loaded and space that cannot be emptied without shoveling; (*c*) location of bin and effect of topography on shape; (*d*) purpose of bin and effect of delivery requirements on shape, *e.g.*, the length of a bin to feed a battery of secondary crushers is determined to a considerable extent by the overall length of the battery; (*e*) material of bin, *e.g.*, height and breadth of a timber bin are limited to a great extent by maximum sizes of stock timber, deep steel bins are more economically loaded and drawn than shallow ones, etc.; (*f*) angle of repose of material to be stored (Table 2); (*g*) angle of friction of material on bin walls (Table 3).

Graphical method of determining pressures on bin walls. If $ABCD$ (Fig. 2) represents a transverse section of a flat-bottomed bin, broken rock, when poured therein, along the center line, will come to rest with inclined surfaces BE and EC. Angle EBC is known as the ANGLE OF REPOSE (ϕ). Its magnitude depends on the friction between the particles of

Table 1. Weights of bin-filling materials

Material	State	Weight per cubic foot, pounds
Ashes, coal	Dry, packed	40–45
Barite	Broken, loose	180
Cement	Clinker, broken	95
Cement	Ground, loose	50–56
Clay	Moist	120
Coal	Any size, broken, loose	45–60
Coke	Loose	23–32
Earth	Slightly moist	70–90
Earth	Soft, flowing mud	104-120
Gravel	Dry	120
Iron ore (hematite)	Loose	150
Lime, quick	Ground, shaken	64
Phosphate, rock	Ground, loose	75
Quartz	Pulverized, loose	90
Quartz	Pulverized, well shaken	105
Sand	Dry, loose, even sizes	90–106
Sand	Dry, loose, uneven-sized grains	117
Sand	Even sizes, voids full of water	118-120
Slag	Granulated	53-60
Slag	Bank, crushed	80
Stone, average	Crushed	95–100
Stone, heavy (trap, greenstone)	Crushed, loose	107

Note.—Volume of broken rock in dumps and bins is from 1.6 to 1.9 times volume in place.

Table 2. Angle of repose of bin fillings = ϕ

Material	State	Angle ϕ, degrees
Anthracite	Broken, loose	27

a With grain. *b* Angles will be increased by presence of large amount of fine, damp material. Range of figures, where given, represents limits of authorities.

material and is different with different substances, sizes, mixtures of sizes, and moisture content. (See Table 2, compiled from various sources.) A heap of ore with cross-section *BEC* will exert no pressure on walls *AB* and *DC*. Side pressures are all taken up within the pile of material itself. Herein lies one of the differences between such materials, known as SEMI-FLUIDS, and true fluids. If bin *ABCD* is charged level full, the mass of material will tend to rupture by sliding of the upper part over the lower along some plane such as *BF*, lying between *AB* and *BE*. The thrust of wedge *AFB* against wall *AB* is the pressure against the bin front, according to Coulomb's theory. This thrust is a maximum when *BF* bisects angle *ABE*. If wall *AB* is considered displaced a small distance to the left, wedge *ABF* will slide a small amount along *BF* and in coming to rest will exert a force *P* on *AB* that is the resultant of a force *N*, normal to the wall and another *F*, acting vertically downward in the plane of the wall. This latter force is due to friction between the material and the wall. The ratio F_1/N_1 is equal to the coefficient of friction of the filling on the bin wall. (See Table 3.) To determine *P*, consider a wedge of material having the section *AFB* and 1 ft. in thickness along the length of the bin, in equilibrium under the action of forces exerted by the wall *AB* and the material lying to the right of *BF*. Lay off *AN* proportional to the weight of block *AFB*. The resultant of the reaction of the material to the right of *BF* on *ABF* acts in a

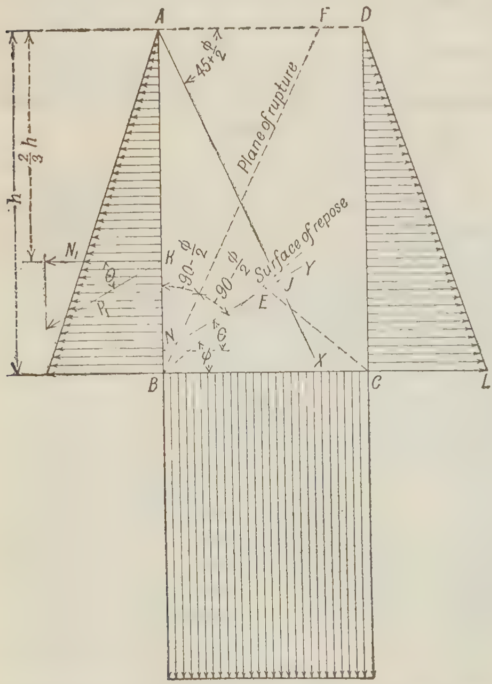

FIG. 2.—Solution of stresses in flat-bottom bin, based on Coulomb's theory.

direction inclined ϕ below the normal to BF. This will be $\left(45 + \frac{\phi}{2}\right)$ deg. below AF. Draw AX making angle FAX equal $\left(45 + \frac{\phi}{2}\right)$ deg. Through N draw NY so that angle θ is equal to the angle of friction ($\tan\theta = \mu$ = coefficient of friction) between the material and the bin wall. (See Table 3.) NJ is the total pressure in 1 ft. length of wall AB, in magnitude and direction. The point of application is K located $2h/3$ downward from A. Normal pressure N_1 is the horizontal component of P_1 ($= NJ$). Pressures on CD are the same. Total pressure on BC is the weight of block $ABCD$ and is uniformly distributed along BC. The distribution of pressure along wall $DC(= AB)$ is determined by placing $N_1 = \frac{1}{2}\overline{CL} \times h$, solving for CL and completing the triangle as shown. Unit pressure at any point along DC can then be read off directly.

In a slanting-bottom bin (Fig. 3) take $\phi = 40°$, $h' = 8$ ft., breadth of bin = 12 ft , weight of bin filling = 100 lb. per cu. ft., and $\theta = 30°$. Solve for P_1 as described in the preceding paragraph. To determine P_2, draw $CN = RQ$, determine area DCN and lay off N_2 through the point of application, $2h'/3$ down from D. Through this point draw the line of action of P_2 making an angle $\theta(=30°)$ with N_2, then complete the triangle of forces. Consider block $ABCD$, weighing W, in equilibrium under the action of the forces P_1, P_2, W and P_3, P_3 being the total reaction of the bottom to the load, unknown in magnitude and direction. W acts through the center of gravity of $ABCD$, located at T. (See Sec. 26, Art. 13.) To solve for the magnitude and direction of P_3, lay off TS to scale, equal and parallel to W; SV equal and parallel to P_1, and VU equal and parallel to P_2; UT, closing the force polygon, determines P_3 in magnitude and direction. The line of action of P_3 is determined as follows: Choose any point O so that angles between lines OT, OS, OU and OV are as large as conveniently possible. Choose any point such as b on the line of action of P_1 and draw lines vo and so parallel to OV and OS, respectively. Produce so to intersect TS, produced if necessary. Through this intersection draw to parallel to OT. Produce vo to meet line of action of P_2. Through the intersection draw uo parallel to OU. Produce uo and to to intersection. Through this intersection draw ut parallel to UT; ut is the line of action of P_3. To determine N_3 = (normal component of P_3) lay off P_3 along line ut from the point where ut cuts the bin bottom. Project this length onto a normal to the bin bottom through the same point and scale off N_3. To find the distribution of N_3 along the bin bottom, lay off the pressure trapezoid $BCaZ$ so that the area = N_3. Now $\frac{1}{2}(BZ + Ca) \times BC = N_3$. **(1)** If BC and Za were produced they must meet at Y on AD produced, then $Ca/BZ = YC/YB$. **(2)** Scale YC and YB and solve for Ca in equation (2). Substitute in equation (1) and solve for BZ. Lay off $\overline{BZ}$ and ΔYBZ. Lay off Ca parallel to BZ and scale off or solve by the preceding equations.

Ketchum gives another method for this solution in which friction between the walls and material is disregarded. In bin $ABCD$ (Fig. 4) the total normal pressure on wall AB is $P_1 = \frac{1}{2}wh^2 \frac{1 - \sin\phi}{1 + \sin\phi}$, acting through a point $2h/3$ below A, where w = weight of material in lb. per cu. ft. Similarly $P_2 = \frac{1}{2}wh'^2 \frac{1 - \sin\phi}{1 + \sin\phi}$. To find total pressure on BC, produce BC and AD to intersect at J. Calculate weight of wedge $ABJ = \frac{1}{2}\,\overline{AB} \times \overline{AJ} \times w = W$. This acts vertically downward through the center of gravity of triangle ABJ. Produce the line of action P_1 to intersect the line of action of W at K. Lay off KL to scale equal to W. Lay off LM equal and parallel to P. $MK = P_3$. Construct the normal component of $P_3 = N_3$. Construct ΔJBO so that area = N_3. CQ = unit pressure at point C. Area $BCQO$ = total normal pressure on the bottom per foot of length of bin. Lay off $CH = FG$. Complete the pressure triangle DCH. Area DCH = total normal pressure on CD. Note that the assumption of smooth walls results in larger values for the pressures on walls and bottom than does the preceding solution.

Surcharged bin. Pressures on the walls of a surcharged bin are much greater than in one level full. Fig. 5 gives the pressure analysis for such a bin assumed surcharged at an angle equal to the angle of repose of the material ($= \phi$). Weight of filling = 100 lb. per cu. ft., dimensions are shown; $\phi = 40°$. The resultant pressure on the bin wall for this condition is a maximum and is inclined parallel to the surface of the ore.

To determine the pressure against AB: Lay off BX parallel to AM. Draw AE perpendicular to BX and lay off AF so that angle $EAF = \theta$ = angle of friction between wall and filling. From F as a center with radius FA strike arc AG and draw the straight line AG. $P_1 = \Delta AGF \times w$. The point of application is $2h/3$ down from A. Lay off P_1

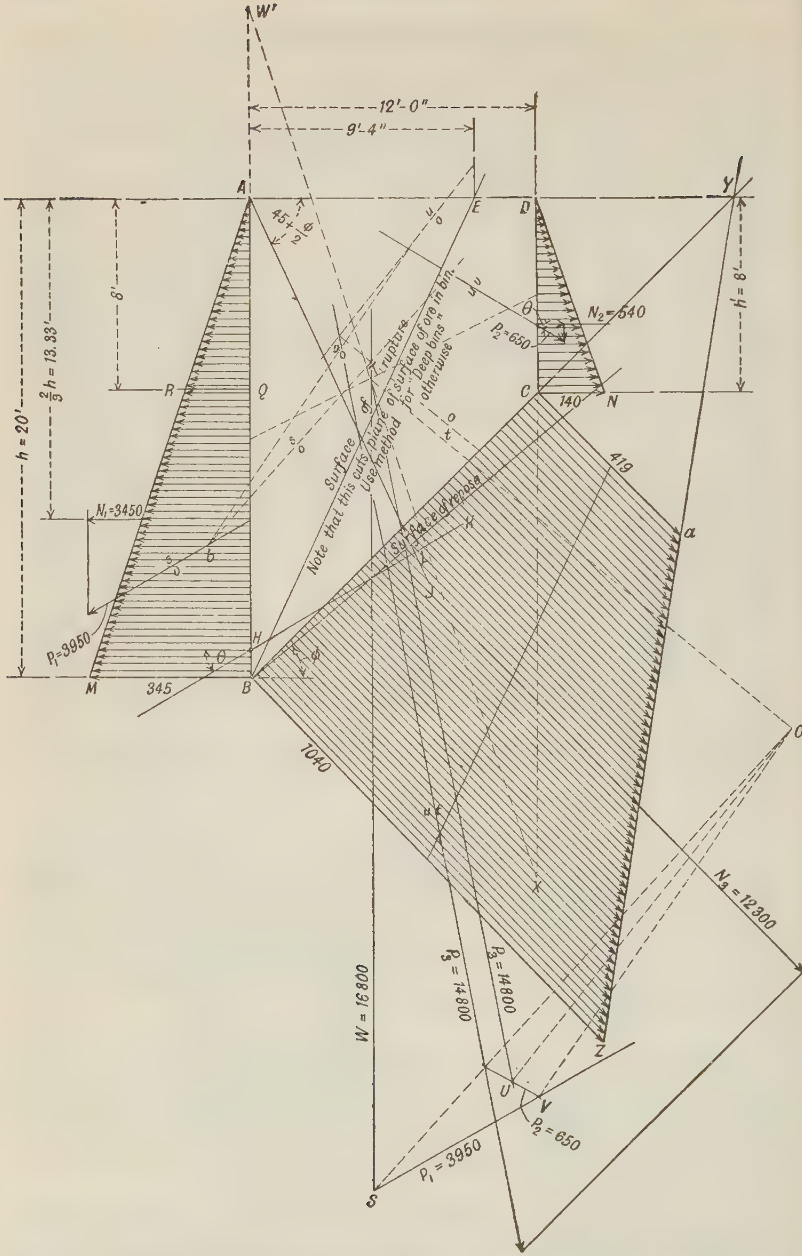

FIG. 3.—Solution of stresses in slanting-bottom bin, based on Coulomb's theory.

and the normal component N_1 in the usual fashion. Lay off the pressure triangle $ABH = N_1$. Lay off $CL = JK$ and complete the pressure diagram DCL. Area $\triangle DCL = N_2$. P_2 acts parallel to MD and is determined from N_2 as shown in Fig. 5. Total pressure on bottom

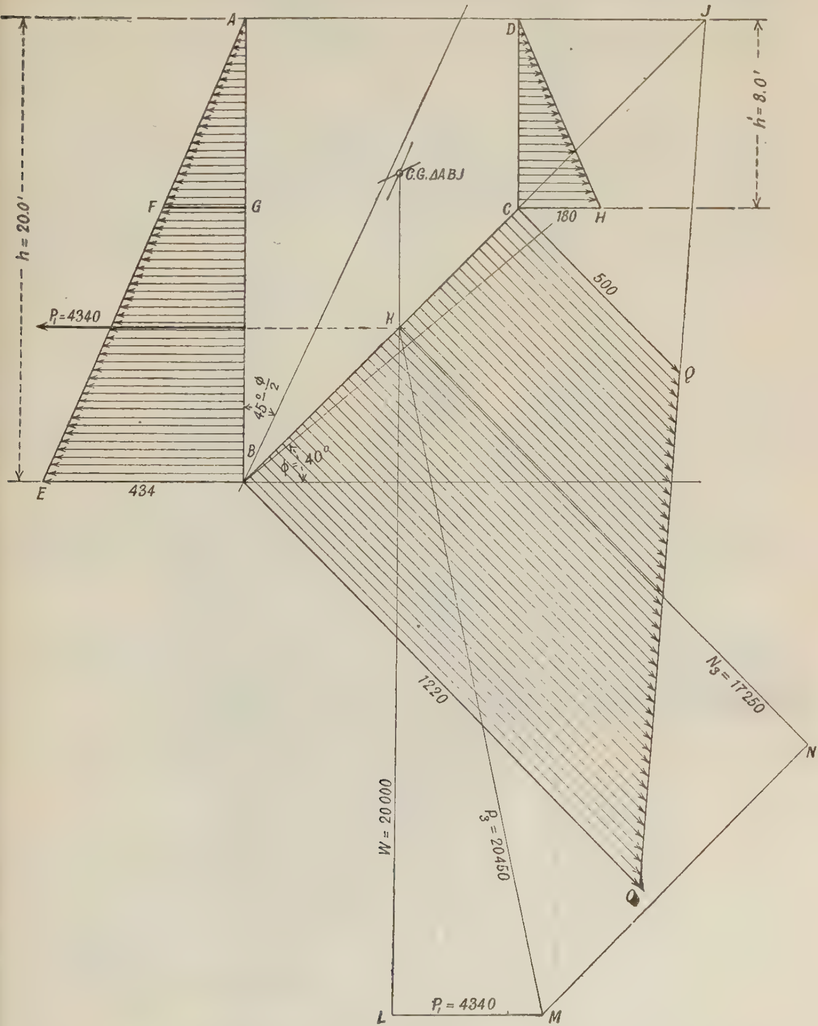

Fig. 4.—Graphical solution for slanting-bottom bin, neglecting friction against walls.

may be calculated by assuming block $ABCDM$ as a rigid body in equilibrium under the action of the non-concurrent forces $-P_1$, $-P_2$, $W (= \textit{area } ABCDM \times w)$ and P_3. The method of solution is as described for Fig. 3 and is shown in Fig. 5, taking the center of force polygon $SUQR$ at T. This assumption results in a value for P_3, in a bin of a given size, less than the value for P_3 in a bin level full, when calculated as in Fig. 4. For maximum pres-

SURES ON BOTTOM, assume block $ABCDM$ in equilibrium under the non-concurrent forces N_1, N_2, W and P_3 and solve for P'_3 and N'_3, as in Fig. 3. (To determine the center of

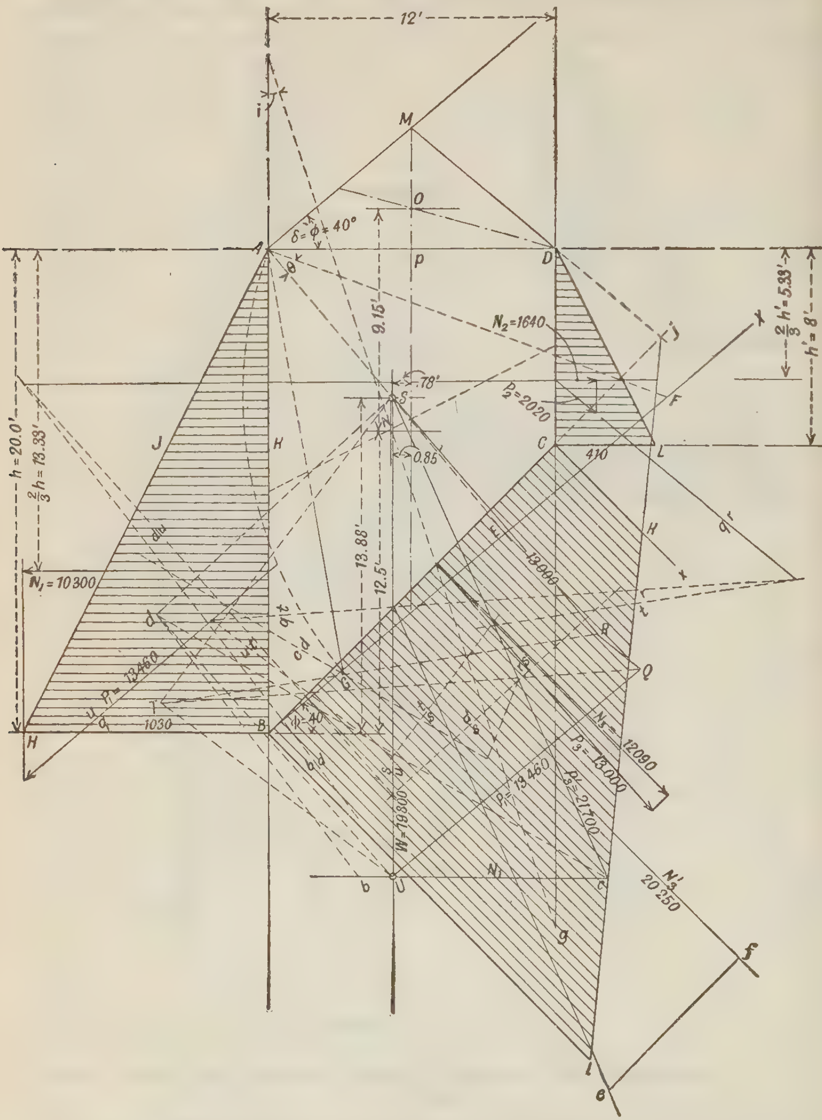

FIG. 5.—Graphical solution for surcharged bin.

gravity of block $ABCDM$, determine the centers of gravity of $ABCD$ (see Fig. 3) and ADM separately. Take moments around axes at right angles, for instance, lines HB and DC, and solve for the resultant moment arms.) TO DETERMINE DISTRIBUTION OF NORMAL PRES-

SURE ON BOTTOM, produce MD and BC to intersect at j. Lay off the trapezoid $BCkl$ to equal N'_3 as follows: $Bl = \dfrac{2N'_3}{BC\left(\dfrac{jC}{jB}+1\right)}$. Lay off Bl to scale, draw lj. Point k is determined by the intersection of Cx (parallel to Bl) with lj. The bottom pressure may also be determined by assuming a block $ABjM$ in equilibrium under action of forces W'' (= weight of this block) N_1 and P''_3, as in Fig. 4 and solving for P''_3, N''_3, and the pressure trapezoid as in that figure.

Deep bins. The preceding methods apply only to shallow bins, *i.e.*, those in which the plane of rupture cuts the surface of the filling material. In deep bins a large part of the vertical pressure is taken by the walls of the bin, which must, therefore, be designed to withstand the resulting compression. Either of two methods of solution is commonly used; both accord well with experimental results.

Janssen's method arrives at the equations:

$$V = \frac{wR}{k\mu'}\left(1 - e^{\frac{-k\mu' h}{R}}\right),$$

$$L = \frac{wR}{\mu'}\left(1 - e^{\frac{-k\mu' h}{R}}\right),$$

where V = vertical pressure in lb. per sq. ft., and L = lateral pressure in lb. per sq. ft. at any point on the bin walls; w = weight of filling material in lb. per cu. ft.; R = hydraulic radius of bin = area in sq. ft. ÷ perimeter in ft.; k = an experimental constant that can be approximated by the formula $k = \dfrac{1 - \sin\phi'}{1 + \sin\phi'}$ where ϕ = the angle of repose of the bin filling; $\mu' = \tan\theta$ = coefficient of friction of filling against bin wall (Table 3); h = depth in feet of the point investigated below the surface of the filling; e is the Napierian base (Sec. 24, Art. 14).

Airy's method (*Pro. Inst. Civ. Engrs., vol.* 131 [1897]) gives

$$P = \frac{wd(2h - d\tan x)(\tan x - \mu)}{2(1 - \mu\mu' + (\mu + \mu')\tan x)},$$

where P = total pressure on bin wall, d = breadth of bin, $\mu = \tan\phi$ = coefficient of internal friction of filling material, μ = coeficient of friction of filling material on the bin wall, and x = angle that plane of rupture makes with horizontal $= 45 - \dfrac{\phi}{2}$. P is a maximum when $\tan x = \sqrt{\left(\dfrac{2h}{d} + \dfrac{1-\mu\mu'}{\mu+\mu'}\right)\left(\dfrac{1+\mu^2}{\mu+\mu'}\right)} - \dfrac{1-\mu\mu'}{\mu+\mu'}$, hence the equation for $P_{max.}$ is

$$P_{max.} = \frac{wd^2}{2}\left[\frac{\sqrt{\dfrac{2h}{d}(\mu+\mu') + 1 - \mu\mu'} - \sqrt{1+\mu^2}}{\mu+\mu'}\right]^2$$

and

$$L \text{ at any depth} = \frac{wd}{\mu+\mu'}\left[1 - \frac{\sqrt{1+\mu^2}}{\sqrt{\dfrac{2h}{d}(\mu+\mu') + 1 - \mu\mu'}}\right]$$

V at any point $= L/k$.

Compression in bin walls at any depth y is given by *Ketchum* as

$$F = wR\left[y - \frac{R}{k\mu'}\left(1 - e^{\frac{-ku'y}{R}}\right)\right],$$

where F is the total compressive load in the plane of the wall per foot of length of bin. When the height of the bin is more than twice the diameter (or breadth), this equation may be written without serious error,

$$F = wR\left(y - \frac{R}{ku'}\right).$$

Bins with conical bottom. In Fig. 6 to determine unit stresses T parallel to an element of the conical bottom across any section such as $x - x$, determine first the total vertical load W' acting at this section. In a shallow bin W' = entire weight of right cylinder of material whose base is the section $x - x$, plus the weight of the part of the bin below $x - x$ and the contained material. In a deep bin $W' = \pi r^2 V$ plus the weight of bin and material below $x - x$. In either case $T = W' \csc s/2\pi r'$. In the deep bin the weight of bin material and filling below $x - x$ may be so small in relation to the total pressure that $T = Vr' \csc s/2$ is a satisfactory approximation. Unit stress T' in the ring $x - x$ in a shallow bin is $T' = r'V \left\{ \dfrac{\sin^2 (s/\phi)}{\sin^4 s \left(1 + \dfrac{\sin \phi}{\sin s}\right)^2} \right\}$; in a deep bin $T' = Lr'$. (*Ketchum.*)

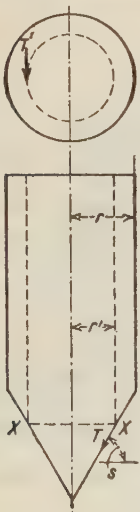

Fig. 6.—Conical-botton bin.

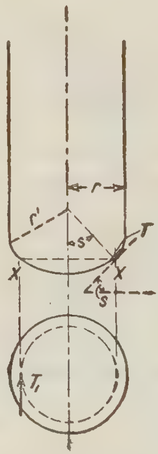

Fig. 7.—Spherical-bottom bin.

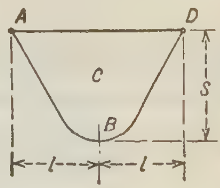

Fig. 8.—Suspension bunker.

Bins with spherical bottom. Stresses in the bottom are calculated as in conical-bottom bins. Referring to bin in Fig. 7, unit stress T tangent to the bin bottom at x and in a plane through the bin axis is $T = W'/2\pi r' \sin^2 s$ and for a deep bin this may be approximated as $T = \frac{1}{2}Vr'$. Tension in the ring cut by section $x - x$ is $T' = \frac{1}{2}Vr'$. (*Ketchum.*)

Suspension bunkers. In Fig. 8 let S = sag in feet, l = ½ of span in feet, C = capacity in cu. ft. per ft. of length, P = maximum pressure, located at B, w = weight of filling in lb. per cu. ft., V = vertical component of force exerted by the bunker on supports at A and D, H = horizontal component of the same force, T = lb. maximum tension in plate per ft. of length of bin, L = length of curve AB. When the bin is level full, $P = 1.25Sw$; $H = Cwl/3S$; $V = 5Slw/8$; $T = Cw\sqrt{\frac{1}{4} + l^2/9S^2}$;

$$L = \frac{1}{60l^2}\left[y_0 + y_{10} + 4(y_1 + y_3 + y_5 + y_7 + y_9) + 2(y_2 + y_4 + y_6 + y_8)\right],$$

where $y = 4l^6 + 9S^2(2xl - x^2)^2$. Substitute for x values 0, $l/10$, $2l/10$, $3l/10$, etc., to obtain values for y_0, y_1, y_2, y_3, etc., respectively. Table 4 gives values of L for values of the ratio s/l ranging from ⅓ to ³⁄₂.

Table 4. Length of one-half curve of suspension bunkers = L. (*From Ketchum, "Walls, bins and grain elevators"*)

$\frac{S}{l}$	L
⅓	1.06378l
½	1.13686l
⅔	1.22992l
¾	1.28307l
⅞	1.36651l
1	1.45722l
⁶⁄₅	1.61131l
⁴⁄₃	1.71906l
³⁄₂	1.85815l

Notes on design. With loads known, the design and spacing of members to carry them is done by the usual methods. LINING must be provided wherever moving ore comes in contact with the bin structure. Walls and slanting bottoms are lined with hard pine or hardwood planking set usually with the length parallel to the run of the ore, or with steel plate or old rails. Hardest wear comes just around the gates and special, easily removable wearing surfaces should be provided at these points. Rails and old crusher-jaw plates are commonly used. TENSION RODS running through timber bins should be placed just above or just below a timber. Timbers directly under loading points may be protected by iron straps bent over the top and spiked on with a space of 1 to 2 in. between straps. Steel members may be protected by riveting to their upper surfaces steel plates 1 to 3 ft. wide on which ore will collect and form a cushion. When ore is allowed to form the bottom in flat-bottom bins, the discharge-chute liner plate should be projected 2 to 3 ft. into the bin to make discharge easier. It is well to make the dimensions of a bin such that stock lengths of planking will not have to be cut on the ground. A change of a few inches one way or another in dimensions will ordinarily accomplish this. Where possible lay end and partition PLANKING so that it forms a tie between front and rear posts of bent, in order to gain added stiffness.

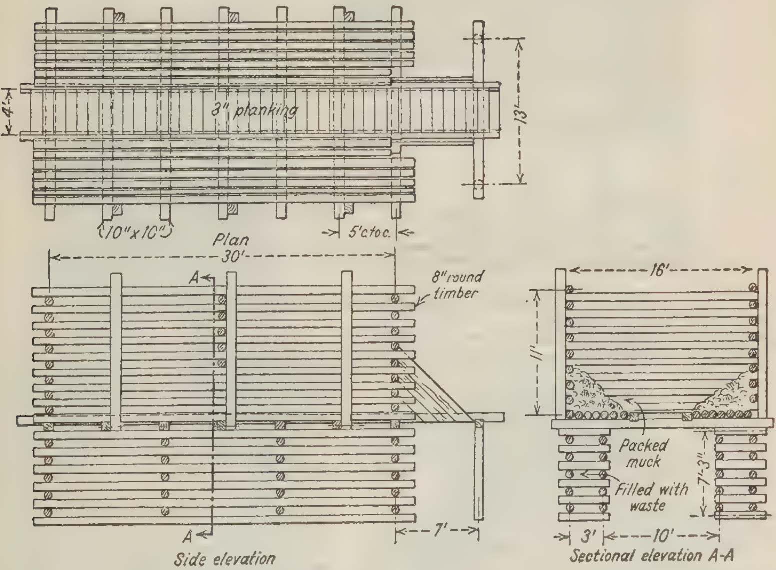

FIG. 9.—Cribbed bin made of round poles (*98 J 739*).

Examples of timber bins. In flat-bottom timber bins the bents are spaced 3-ft. to 6-ft. centers, depending upon the height of the bin and weight of filling; 2-in. and 3-in. plank are usual for front and back; 6-in. plank or 2 × 6 laid on edge are usual on the bottom. The flat-bottom bin lends itself to CRIBBED CONSTRUCTION, similar to that shown in Sec. 9,

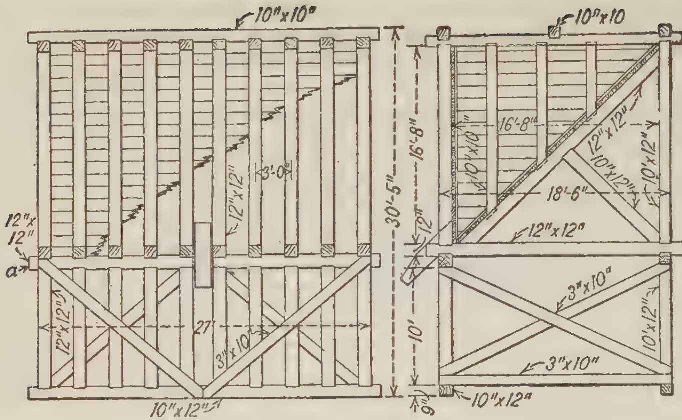

FIG. 10.—150-ton slanting-bottom timber bin (*99 J 195*).

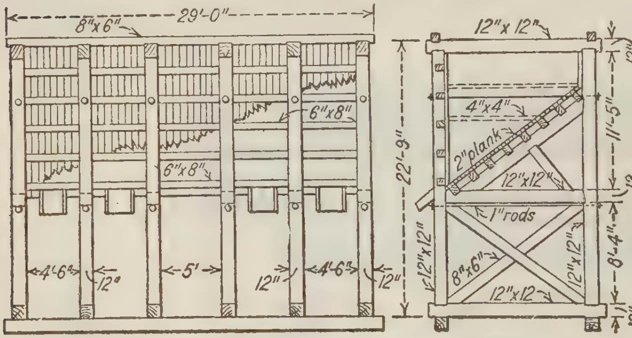

FIG. 11.—100-ton slanting-bottom timber bin (*99 J 195*).

Fig. 6, which is much cheaper than the framed type on account of the fact that framing and expensive carpenter labor are eliminated, and that the smaller sizes of lumber are cheaper per MBM than big sticks. Fig. 9 represents a 220-ton bin built of 8-in. round timbers notched at the corners, with the crevices chinked with 3-in. and 4-in. round poles. This particular bin had no gates but was unloaded by moving the 3-in. bottom planks along with a pick. With a full bin ore piles up in the chute; a car is run under the platform at this point and planks are moved along toward the end of the platform until the edge of the pile is reached when, upon moving the next plank ore will fall into the car. With the bin only part full, a man enters the bin through the chute and proceeds as before, first removing the plank nearest the pile of ore. Figs. 10 and 11 are typical slanting-bottom timber bins. The wide spacing of bents in Fig. 11 is made possible by the small height of the bin; vertical

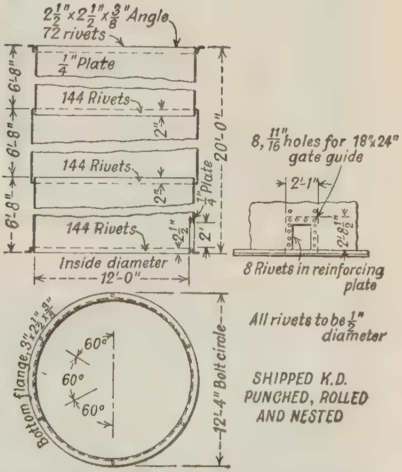

FIG. 16.—100-ton flat-bottom cylindrical steel bin (*99 J 195*).

timbers are carried through to the sills. In Fig. 10 the greater depth requires closer spacing of bents and the greater over-all height requires the use of the intermediate sill (*a*), if special sticks of timber are to be avoided. Fig. 12 shows the double-hopper type of slanting-bottom bin with variation in size for heavy ore and light coke. The batter of the walls is to give stability when the empty bin acts as a trestle. Bin walls are 20 ft. high above the foundations; the width of the bins is 30 ft. at the bottom; ore bins are 26 ft. and coke bins 44 ft. wide at the top. Fig. 13 is the cross-section of a bin at TENNESSEE COPPER Co. This bin is 168 ft. long with bents spaced 6-ft. centers. Figs. 14 and 15 show two types of coal bins.

Examples of steel bins. Fig. 16 shows a small circular steel bin with flat bottom and side discharge. Central bottom discharge is more usual. Flat-bottom circular steel bins in the Lake Superior copper-mine rock houses are 40 ft. diameter by 45 to 50 ft. high, built of 5/16- and 3/8-in. plates. Fig. 17 is a small rectangular bin with flat bottom. At TIMBER BUTTE (*116 J 549*) steel bins 25 ft. diameter and 32 ft. high are set on a V-shaped concrete bottom of two slabs sloping 40°.

Examples of concrete bins. Fig. 18 shows a circular reinforced-concrete bin built by WITHERBEE, SHERMAN AND Co. at Mineville, N. Y. for crude-ore storage. The free-running capacity is about 1000

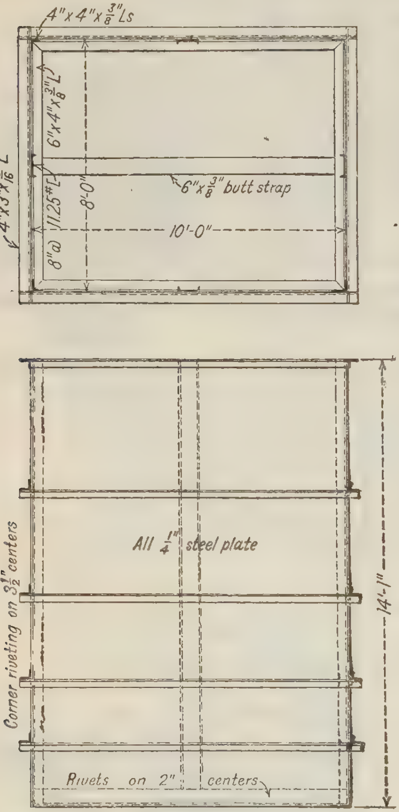

FIG. 17.—50-ton flat-bottom rectangular steel bin.

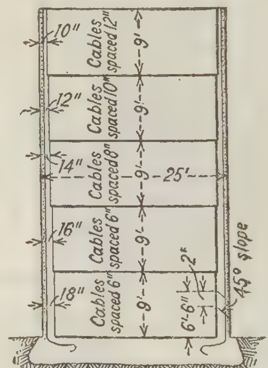

FIG. 18.—Circular reinforced-concrete bin, Witherbee, Sherman Co. (*91 J 704*).

tons. The foundation block is of coarse stone bonded with a 1 : 10 mixture of cement and fine tailing; the wall mixture is 1 : 4 cement and fine tailing. Reinforcement, placed 4 in. from the outside of the walls, consists of horizontal hoops of worn 1 1/8-in. hoisting cable, spaced as shown, with vertical cables at 4-ft. centers wired to the hoops. The bin was filled to the discharge point with barren rock before ore was run in. Fig. 19 (*71 EN 1234*) shows another bin of the same type but with central bottom discharge. Vertical reinforcement consisted of ½-in. round rods spaced 18 in.; horizontal, of worn ¾-in. cable spaced 4¼-in. for the bottom 5 ft., 6 in. for the next 10 ft. and 9 in. to the top. Cables were lapped 3 ft. at the joints, raveled and clipped; vertical rods were lapped 2 ft. at the joints. The concrete mixture was 1 : 3 : 6 for foundation and 1 : 2 : 4 for walls; the maximum size of stone used was 2½ in. Fig. 20 (*96 J 305*) shows a rectangular hopper-bottom bin reinforced with "corrugated bar" and complicated interlocking hooks. The mixture was 1 cement, 2 sand and 4 mill tailing about ⅓-in. size. Shallow cylindrical bins

for fine materials may be cheaply made by setting up a frame of expanded metal lath, properly reinforced, and plastering inside and out with sand-cement plaster. Such bins cannot, however, be made to bear any heavy superstructure.

Examples of suspension bunkers. Fig. 21 (*118 J 566*) shows two recent typical steel suspension bunkers for ore. The Inspiration bin is 330 ft. long with a nominal capacityof 40 tons per running foot. Columns are spaced 16 ft. 8 in. longitudinally and draw gates are spaced at the halfway points between columns. The New Cornelia bin is 330 ft. long; nominal capacity is 33 tons per running foot, columns are spaced 20 ft. longitudinally and gates on 10-ft. centers. The dotted lines in the drawings show the positions assumed by the loaded bins. At New Cornelia the distortion strained the hopper fastenings badly. Fig. 22

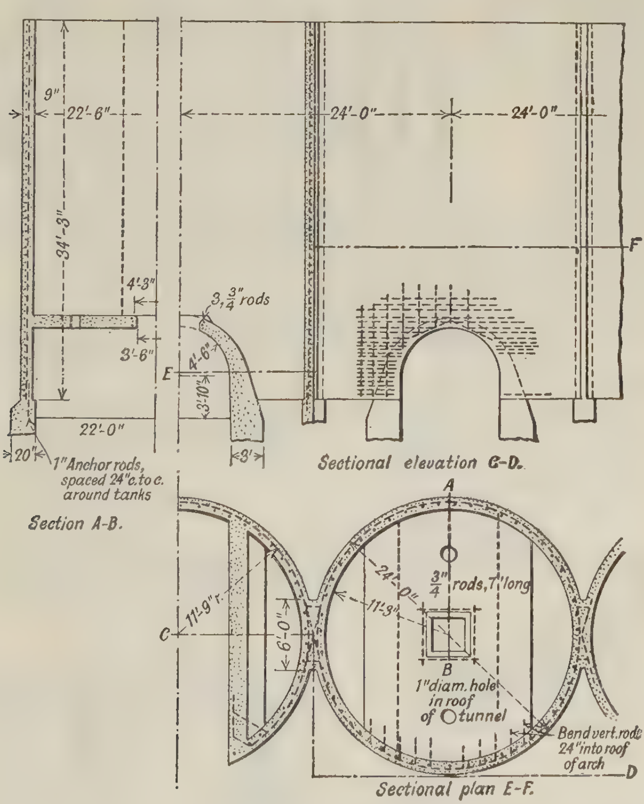

Fig. 19.—Concrete bins at Croton Iron mine.

(*97 J 908*) is a modification of the ordinary suspension bunker, in which a rigid bottom is carried on a series of transverse triangular frames hung by suspension rods from the main supports; the walls are supported against these rods. The cut shows wood, reinforced-concrete and steel sides.

Steel *vs.* wooden bins. An instructive comparison of construction costs of small steel and wooden bins is given by Barbour (*99 J 195*). Bins are shown in Figs. 10, 11, 16 and 23. Comparative cost data are given in Table 5. Labor in timber framing and erecting was found to be equal to the cost of the timber itself ($30 per MBM) in other classes of work, and was thus estimated.

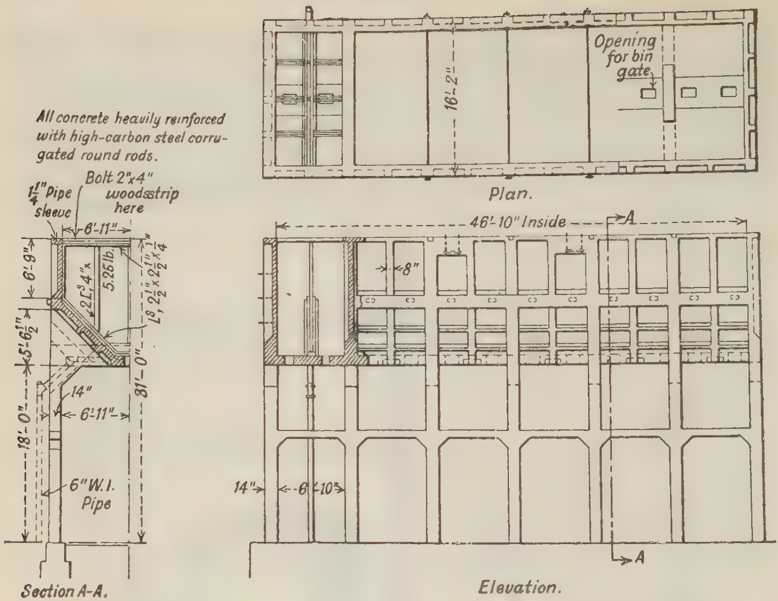

FIG. 20.—Reinforced-concrete tailing bin, St. Joseph Lead Co.

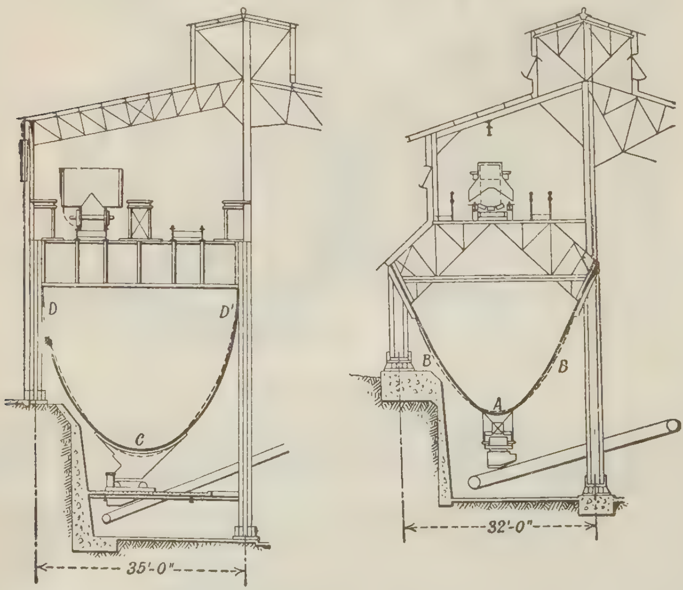

FIG. 21.—Steel suspension bunkers.

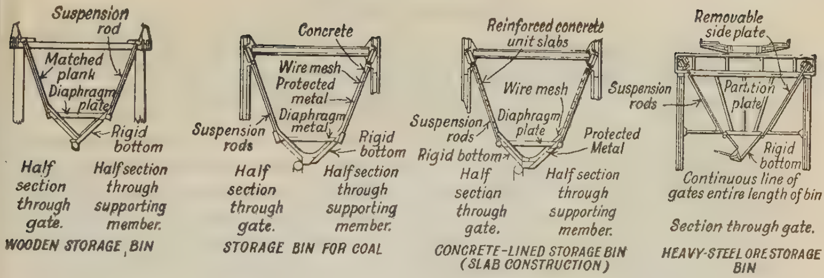

FIG. 22.—Baker types of suspended bins.

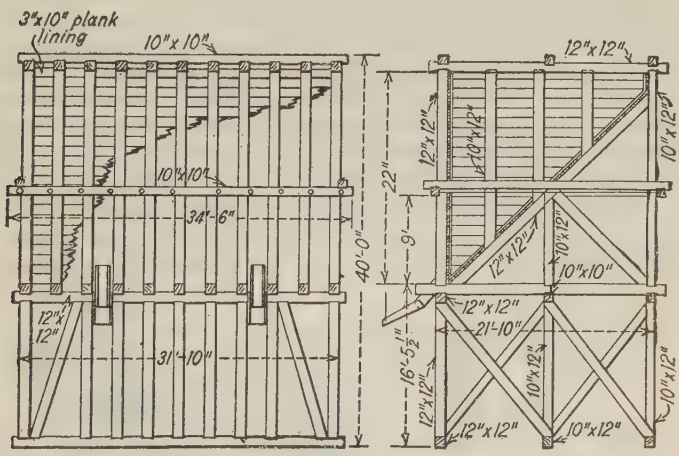

FIG. 23.—350-ton slanting bottom timber bin (*99 J 195*).

The bin shown in Fig. 11 is the cheapest form of wooden bin, due to the wide spacing of bents, but this method could not be applied to the larger bins without using excessively large and expensive posts.

Table 5. Comparative costs of small steel and timber bins

	Cylindrical steel bin	Slanting-bottom timber bins		
Figure number	16	11	10	23
Nominal capacity, tons	100	100	150	350

a Pounds of steel. *b* Actual. *c* Estimated.

4. Discharge from bins

Bins are discharged through openings placed in the bottom or the side walls. The size of opening is made adjustable by means of gates. Rate of discharge may be regulated by a feeder. The minimum size of discharge opening should be not less than three times the maximum dimension of particles passing through, if the material is sized; nor less than twice the maximum dimension when material is a mixture of coarse and fine. These minimum dimensions will usually be greatly exceeded in fine-ore bins, but with run-of-mine rock it is difficult to control the flow of material through such large openings and there is a tendency to cut down the dimensions, with resulting clogging and lost time.

Gates. The type used depends on the size of material, destination, and regularity of discharge. When material contains large lumps, a gate that readily cuts completely across the stream is wanted; if the destination of the discharged material is a car, a quick, wide-opening gate is desirable; if discharge is highly intermittent, a gate that opens and closes readily and quickly is necessary, while for regular discharge a slow-opening gate may be used and it is not so important that it be easily moved. Usual types are: (*a*) Sliding gates that move in grooves set into bin walls or bottom. These gates are hard to open when the pressure of the filling against them is great and under such conditions must be geared down so much that they are slow. (*b*) Cut-off gates, that present a portion of a cylindrical surface to the stream of ore, usually in a chute. Either the convex or the concave surface may be presented. (*c*) Finger gates, for coarse ores. (*d*) Lifting chute or apron gates.

Slide gates. The LEVER SLIDE GATE, Fig. 24, is the simplest of this type. Ordinary SIZES are 12 × 15 and 12 × 18 in. It is not suitable for heavy pres-

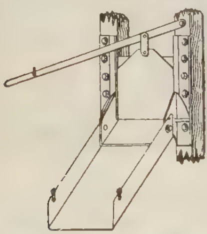

FIG. 24.—Lever slide gate.

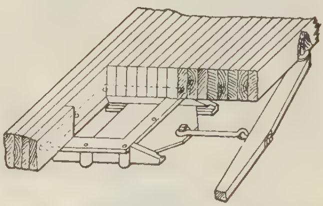

FIG. 25.—Standard bottom-draught bin gate.

sures and is difficult to close tightly when the ore contains both coarse lumps and fine material, as a lump caught under one side will stop the gate and hold it open, allowing fine material to run until larger pieces bridge the opening. For heavier service, up to 36 × 36-in. size, the slides are made with rollers against which the gate works. Fig. 25 shows a similar gate for bottom draught. Usual sizes are 12 × 12 and 12 × 18-in. A bottom-draw valve for fine concentrate may be made of ordinary 6-in. pipe and fittings and strap iron (*90 J 704*).) Fig. 26 shows two forms of upward-closing slide gates. These have the advantage over the downward-closing gate that they will not jam against lumps in closing. They have the disadvantage, however, that fine material causes wedging in the slot through which they work and that wear on this slot is excessive. RACK-AND-PINION GATE, Fig. 27, is perhaps the most widely used of all types. While slow and sometimes difficult to move, it is easy to regulate closely and a pawl on the pinion will hold it in any position desired. The

usual size range is 18 × 18 to 30 × 36 in.; corresponding weights are 250 to 450 lb. A double-rack is used for very heavy service; some have roller slides and chain-controlled hand wheel. Fig. 28 illustrates the use of air for operating sliding gates; these gates are quick-opening even under heavy pressures.

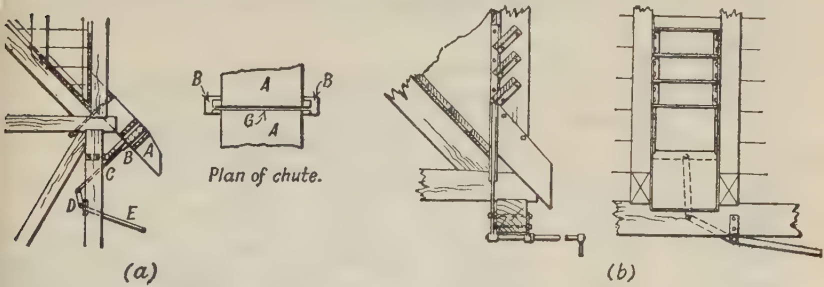

FIG. 26.—Upward-closing slide gates.

At WITHERBEE, SHERMAN AND CO. the gate for a lump-ore (6-in. to 2-ft.) bin was 4 ft. 8 in. square, made of 2-in. plank faced both sides with ½-in. plate, weighed 1300 lb., operated under 60-lb. pressure and was capable of crushing large lumps that wedged under it. It was run on rollers (*89 J 809*).

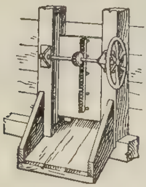

FIG. 27.—Rack-and-pinion gate.

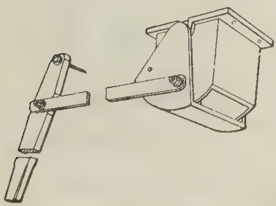

FIG. 29.—Standard bottom-draught arc cut-off gate.

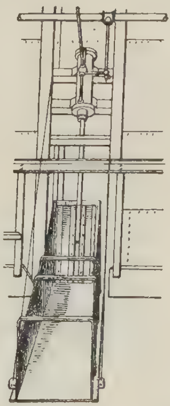

FIG. 28.—Air-operated slide gate.

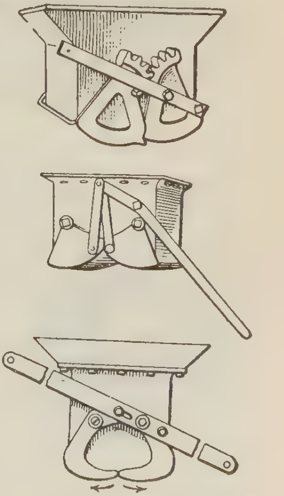

FIG. 30.—Duplex bottom-draught arc cut-off gates.

Arc cut-off gates are used both for bottom draught and side draught. Fig. 29 shows a standard bottom-draught type made in 10 × 10, 15 × 15 and 20 × 20-in. sizes. This gate is not hard to open, and is easy to close, but may catch against a large lump and therefore not cut off quickly. This same gate is made for side draught. Fig. 30 shows three types of duplex bottom-draught arc gates. These are made in sizes from 12 × 12 to 26 × 26 in.

The gear type is the least rugged of the three. Fig. 31 shows details of a particularly rugged type of arc gate for side draught, used at Cananea Cons. Copper Co. (*92 J 933*). These gates should be so set as not to back into the ore in opening yet to run with the stream to some extent in closing. With such an arrangement they are readily and quickly opened and closed and are

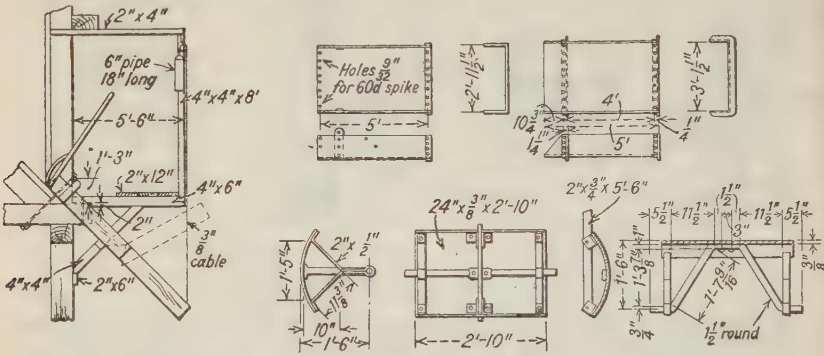

Fig. 31.—Side-draught arc gate, Cananea Cons. Copper Co.

the best kind for intermittent service such as loading cars from a bin front. Fig. 32 shows one of these gates arranged at the lower end of the bin chute, instead of at the bin wall. There is less pressure against the gate in this position, and hence it will be more readily opened. When open, one side of the sector forms part of the chute bottom. This type of gate cannot jam in closing,

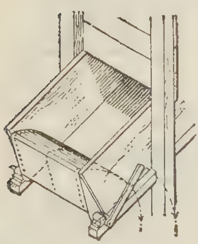

Fig. 32.—Convex arc gate in chute (*92 J 740*).

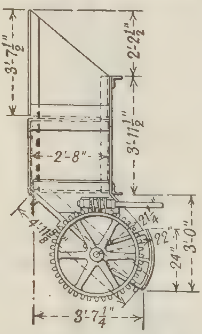

Fig. 33.—Geared undercut concave cut-off valve, side-draught type.

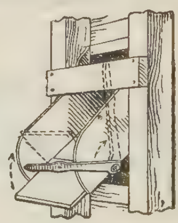

Fig. 34.—Flap-valve bin gate.

but is likely to cause material to jump out of the chute when it begins to close. The gate may be air-operated. Fig. 33 (*94 J 64*) is a geared concave form for coarse ore, designed to open downward. It does not jam in closing but will cause fast running lumps to jump as it begins to close. By failing to open full, a layer of ore is kept in the bottom of the chute, thus protecting it from wear.

Flap-valve gates. Fig. 34 shows the simplest form; it opens and closes readily and quickly, but is subject to wear by discharging material, particularly at the crack in the chute bottom. An air-operated form is used at Quincy Mining Co. (*98 J 827*).

Finger gates are particularly useful in discharging coarse ore. Fig. 35 (*97 J 856*) shows an air-operated form with all fingers operated together. Fingers are sometimes arranged for independent operation; this allows closer regulation of coarse material than is possible with any other type of gate.

Jamming at bin discharge occurs either by reason of bridging of large lumps or by compacting of moist material under the pressure of the overlying filling. The usual cures are barring through the open gate, sledging the outside face of the bin around the gate opening, and dynamite. Much trouble of this character can be saved by means of openings in the bin walls that give access to the material immediately around the gates. Fig. 36 (*122 P 593*) shows the method applied to a hopper bottom; it may be similarly applied to a vertical wall. In either case the angle θ should be less than the angle of repose of the filling. At some Lake Superior rock houses bins for coarse ore have two gates in the same chute, the lower one so placed that it will stop flow through the upper; this permits opening the other wide in case it clogs; the arrangement also allows stopping the stream for picking.

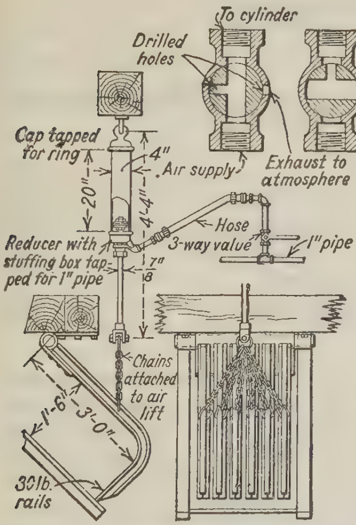

Fig. 35.—Air-operated finger gate.

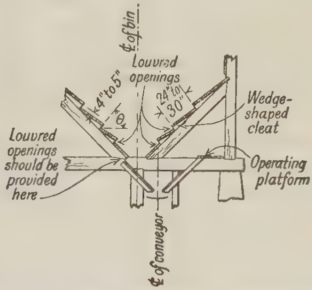

Fig. 36.—Louvres in hopper-bottom bin.

Moist material, especially when fine, may have an angle of repose of 90° or more and a sliding angle against wood or steel almost as great. The most difficulty is met in storage bins following intermediate crushing and those for mixed granular and flotation concentrate. Compressed air is most effective for starting such material. In bins a series of perforated compressed-air pipes set vertically and extending nearly to the bottom will, when blown, break up most hang-ups. Elsing (*89 J 203*) describes the use of a pointed 9-ft. length of 1¼-in. pipe supplied with air at 80 to 90 lb. per sq. in. pressure for unloading fine gravity concentrate from cars. Prior to its use it required 60 to 90 min. to bar material out of a 6-car train; with it, 15 to 20 min. was sufficient.

SECTION 20

TRANSPORT OF MATERIALS

BY

Henry A. Behre, Assistant Professor of Mining, Sheffield Scientific School, Yale University

Handling comprises transport over considerable distances, both vertical and horizontal; and movement through relatively short distances into and out of storage containers. The specific problems ordinarily encountered are: (*a*) handling run-of-mine ore from mine delivery point to the primary breaker; (*b*) handling coarsely-broken dry rock between primary and secondary crushers and into and away from the mill storage bins; (*c*) handling relatively coarse wet products, such as jig feed, jig products and the like in the mill; (*d*) handling wet sand and slime pulps; (*e*) handling the same material dry; (*f*) handling froth-flotation concentrates. The apparatus described in this section includes conveyors and elevators, chutes and launders, bins, tanks, feeders, pumps and air lifts. Transport by wagon, truck, railroad, rope haulage, etc., is treated of in Sec. 23.

Conveyors are used to transport material when the point of delivery is at the same level as or not too much above or below the point of departure (rarely, however, when the delivery point is below the starting point); and when the horizontal distance of transport is relatively short. There is no arbitrary limit of distance beyond which a conveyor system of transport cannot be used, but batch transport, as by railroad, is usually more economical when the distance exceeds a rather small number of hundred feet.

Types of conveyors. Belt conveyors are most commonly employed within the conveyor range. They consist of a continuous belt, fabricated of various materials, passing around head and tail pulleys, and supported at intervals along both upper and return runs by various kinds of idlers. Pan conveyors are similar to belt conveyors in method of drive and support, but differ in that the carrying surface consists of a series of articulated plates or shallow pans supported on rollers and tied together by pins. Bucket conveyors differ from pan conveyors in that buckets of rectangular horizontal cross-section are substituted for the shallow pans or plates of the latter. The buckets may be continuous, *i.e.*, overlapping, or spaced so that definite inter-

vals occur between successive buckets. FLIGHT CONVEYORS are essentially a trough through which a series of scrapers attached to a chain or rope is drawn. SCREW CONVEYORS push material along the bottom of a semi-cylindrical trough by means of a spiral screw revolving therein.

1. Belt conveyor

The carrying element is a continuous belt passing around a head pulley and a tail pulley, supported on its carrying run by troughing idlers (Fig. 1) properly spaced, and on the return run by return idlers (Fig. 1). The simple horizontal conveyor is loaded near the tail pulley through a chute and delivers over the head pulley. It is normally driven through the head pulley. This type of conveyor may be run on an incline up to somewhat more than 20° from the horizontal, the allowable slope depending upon the kind of material being transported, the speed of the belt and the character of the belt surface, but for ordinary service it is well to limit the inclination to 18°. Fig. 2 represents various types of belt-conveyor installations. In the fourth arrangement the radius of the curve should be at least 125 ft., if the belt is to remain on the troughing idlers when running empty. If this cannot be allowed, the third arrangement is frequently employed, but it is better to use two conveyors and do away with the necessity for running the belt around a snub pulley, as this grinds grit into the carrying face.

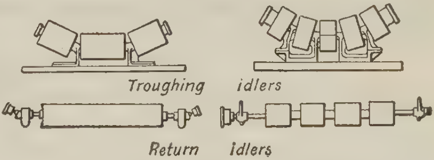

FIG. 1.—Belt-conveyor idlers.

Conveyor belting is usually so-called RUBBER BELT made of several layers or PLIES of heavy cotton duck bound together with rubber "friction" and covered completely with a layer of best-grade vulcanized rubber. The strength of the belt depends upon the weight and strength of the duck and the number of plies; also upon the way in which the joints in the plies are spaced. Belt duck is made with the lengthwise or WARP threads heavier, stronger and closer together than the transverse or FILLER threads. The strength of the duck depends upon the weight, which in turn depends on the number of yarns per thread and the degree of twist. Weights are stated as the number of ounces per piece 36-in. long in the direction of the warp threads and 42 in. wide. The ordinary weights are 28-oz. to 42-oz. The number of plies ranges from 3 for short, narrow belts to 9 or more for long, wide belts. The ultimate tensile strength of duck depends on the width of the test specimen, the method of holding in the test machine, the percentage of moisture and the rate of pulling. Under fair test conditions with not more than 6 per cent. moisture, the breaking strength of 28-oz. duck should be not less than 300 lb. per in. of width; of 30- or 32-oz., 325 lb.; 36-oz., 360 lb.

The life of belt under a given carrying service depends upon the character of the bond between plies, *i.e.*, "FRICTION," and the thickness and quality of the rubber cover. The friction should be of such strength that plies will not separate under the tension of the power pull or in passing around the pulleys. The ordinary specification, best directed toward ensuring this service, is to cut a 1-in. strip lengthwise of the belt, separate the plies at one end and suspend the strip by means of one of the outer plies, attaching to the lower end a 10-lb. weight to keep the strip vertical; then peel away the other plies, one at a time, by attaching thereto, by means of a coiled spring, a weight of from 13 to 18 lb. or more, specifying that the rate of separation of the plies shall not exceed 2 in. per min. The character of the rubber cover depends upon service demanded. The quality should be of best-grade pure vulcanized rubber in order to resist abrasion and keep out moisture. The minimum economical thickness is about 1/32 in., and this is too thin for any but the lightest service. On heavy service the pulley side of the belt has a cover 1/16 in. thick and the carrying side up to 1/4 in. The resistance of rubber covers to impact and abrasion depends on the tensile strength and stretching quality of the rubber compound. The ultimate tensile strengths as determined by the U. S. Bureau of Standards range from about 300 to upwards of 2500 lb. per sq. in. Results vary according to method of taking the test pieces and the manner of

testing, and hence should be definitely set forth in the specifications. The stretching quality should be such that, for instance, a piece 1 in. wide between marks 2 in. apart will stretch to, say, 6 or 12 in. before breaking and, if immediately released, will return so that after a few minutes' rest it will show not more than, say, 10 per cent. elongation between the marks. A so-called FLOATING PLY, or single layer of heavy duck, is sometimes imbedded in thick covers to prevent pieces of the cover from being gouged out. If belts in service wear out first in the middle of the carrying side, the cover may be stepped by rolling on an extra strip of cover rubber down the center, or the ordinary cover may be made thicker at the middle of the belt. The friction between cover and belt should be the same as between plies or greater. The edges of conveyor belts may be subjected to hard wear by rubbing against guide rollers,

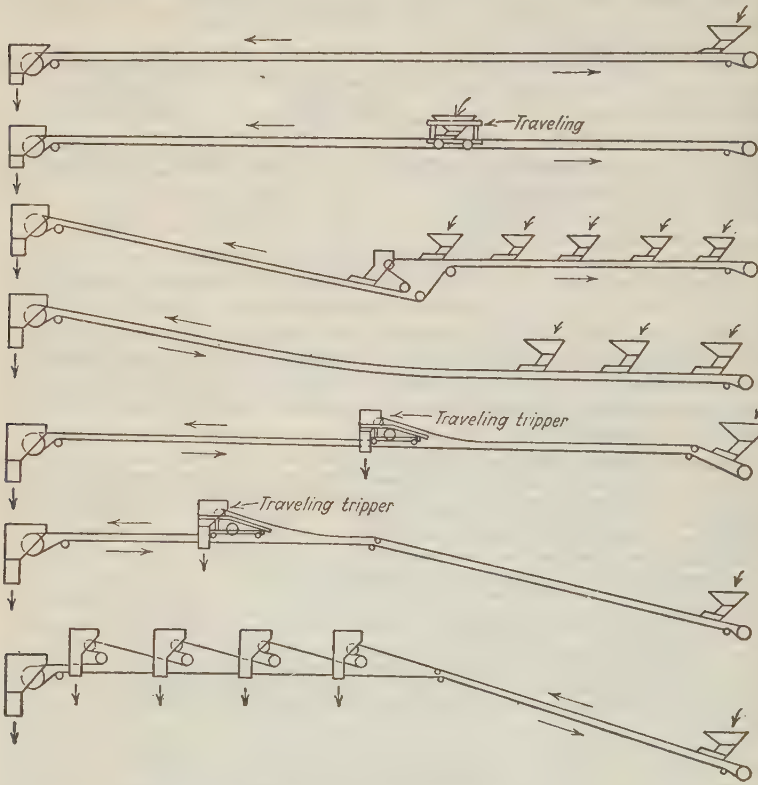

FIG. 2.—Arrangements of belt conveyors and trippers.

or the inside of discharge boxes, trippers and the like. They should, therefore, be protected with extra thicknesses of rubber, firmly bonded to the rest of the belt to prevent tearing away.

Age, light and heat are all destructive to rubber belts. Age causes hair-line cracking of the cover and this deterioration goes forward most rapidly in sunlight. Aging lessens both the tensile strength and stretch of rubber compounds, deterioration in both directions being most rapid in the first year and amounting to as much as 50 per cent. of the tensile strength and 63 per cent. of the stretch (ultimate elongation) in the case of samples tested by the U. S. Bureau of Standards. As a result of the consequent breakdown of the cover in service, dirt and moisture get into the belt fabric, the friction is destroyed, plies pull apart, and the belt is ruined. Heat causes deterioration of the rubber cover similar to that caused by age and also causes breakdown of the friction rubber with consequent loosening of plies and cover.

Special belts with under-vulcanized rubber for friction and cover are made for handling hot materials, but even such belts deteriorate rapidly.

Life of belt (*Q*) varied from 110 days for 20-in. belt at 190 ft. per min., carrying 25 tons per hr. to 6 yrs. for 24-in. belt at 380 ft. per min. carrying 200 tons per hr. A 20-in. 6-ply belt at 200 ft. per min, transporting material 4-in. max. size, carried 857,225 long tons of a magnetic iron ore at the WITHERBEE-SHERMAN Co. and a 20-in, 6-ply belt at 220 ft. per min, carried 764,224 long tons of – ¾-in. ore. At CHINO a 34-in. 6-ply stitched canvas belt at 325 ft. per min. lasted 550 days and carried 400 tons per hr. of – 9-in. material.

Balata belt is multiple-ply canvas belt without covering. The duck is impregnated with some waterproofing compound and balata gum is used for the friction material. This belt is said to be somewhat stronger than rubber belt for the same number of plies because the strength of the duck has not been impaired by the heat of vulcanizing. It cannot be used in hot locations because the gum softens at 120° F. It has been used extensively in South Africa but not much in the United States. Robertson and Johnston (*102 J 10*) report lives ranging in days from 414 to 672 and in tons handled from 400,000 to 800,000 for balata belts carrying crusher product (– 3 in.) in RAND gold mills, as compared with 345 to 1700 days and 200,000 to 850,000 tons for rubber belt in similar or harder service.

Idlers are used on both carrying and return runs. Carrying idlers are usually TROUGHED, *i.e.*, set so as to bend the belt up at the sides, and thus increase carrying capacity. Return idlers are invariably straight-faced. The carrying capacity of a belt loaded so that the upper surface of the load comes within a given distance of the edge increases with steepness of troughing up to 45°. The disturbance of the load in passing over the troughing idlers increases, likewise, with increase of side slope, and there is a corresponding increase in belt wear and power consumption. As a result, standard troughing rarely exceeds 30° maximum side slope. At this angle it is easier to keep the belt straight and there is less failure of belts by longitudinal cracking than is the case with steeper slopes.

Troughing idlers (Fig. 1) are commonly made with 3 or 5 rollers. In the 3-roll type, used with narrow belts, the usual slopes of the inclined rollers are 22½° and 30°; in the 5-roll type, commonly used for wide belts, the inner rollers are sloped 15° and the outer, 30°. The cheap grades of rollers are made of cast iron with babbitted hubs running on cast-iron shafts bored for grease-cup lubrication. Ball-bearing and roller-bearing idlers of pressed steel or cast iron show savings in power losses due to idler friction alone of as high as 60 per cent. The important economies effected in the use of such idlers lie, however, in the saving in labor for lubrication and in reduced wear on belts.

Troughing idlers are spaced according to width and stiffness of the belt and the load carried. With light loading and ordinary belt a spacing of 5 ft. is allowable but this should be the limit of spacing under any conditions; with heavy loading and wide belts, spacing should be reduced to 3 ft. or 3 ft. 6 in.

Return idlers are made of the same materials as troughing idlers, but ordinarily with one pulley only. They are 1 to 2 inches wider than the belt and are commonly spaced 10 ft. apart.

Side or guide idlers are set to bear at right angles to the edges of the belt at places where the latter tends to run off the troughing idlers. They are hard on the edges, both wearing the belt and tending to fold it back, causing a crack 1 or 2 in. in. They should not, therefore, be used, unless it is unavoidable. Belts can sometimes be straightened and side idlers avoided by canting troughing idlers slightly toward head pulley, thus giving the horizontal idler pulley more bearing and more effect on the belt, or they may be skewed. An automatic straightening idler (Fig. 3) has been successfully used at several of the large copper mills. It consists of an ordinary troughing idler (*a*) mounted on a pivoted plate (*b*) with guide idlers (*c*) carried on projecting arms. If the belt rides, *e.g.*, to the left, the troughing idler is swung forward on the right, which causes the belt to travel back toward that side.

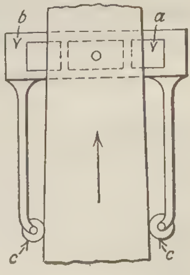

FIG. 3.—Automatic guide idler.

Pulleys should be crown-faced, one or two inches wider than the belt, mounted on sufficiently heavy shafts to insure against bending, and the driving pulley (usually the head pulley) should be securely keyed and clamped to the drive shaft. The diameter in inches should be at least five

times the number of plies and 8 to 10 times is better. Robertson and Johnston (*102 J 15*) tell of an 8-ply belt on a 20-in. pulley that separated along the plies in four months. The pulley at the other end of the conveyor from the driving pulley is fitted with a TAKE-UP MECHANISM (Fig. 4) to compensate for small changes in belt length and hold belt tension constant. The usual allowance is 12 to 18 in. for belts under 100-ft. centers; 18 to 24 in. from 100 to 200 ft. and 30 to 36 in. for longer belts.

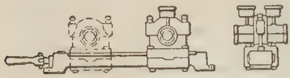

FIG. 4.—Take-up for conveyor tail pulley.

Capacity depends upon width of belt, degree of troughing, speed, slope, size and specific gravity of the material carried and its angle of repose.

Width of belt is determined primarily by the size of material to be carried, after that by the capacity desired. The minimum width is preferably fixed at 14 in. as a belt narrower than this will not conform to the troughing idlers when empty unless of very light-weight. The loading chute should not exceed two-thirds the projected width of the troughed belt, if material is to be prevented from falling off, and the chute should be more than three times the size of the particles, if they are of uniform size and more than twice as large as the largest where mixed sizes are handled. Troughing allows the load to be carried up nearer the edge of the belt than is safe on a flat belt.

Capacity formula. Manufacturers give formulas for capacity in terms of belt width in the form $V = KW^2$, in which V = cu. ft. per hr. at 100 ft. per min. belt speed, W = width of belt in in. and K is a constant ranging, according to the conservatism of the manufacturer from 2.8 (for narrow belts only) to 3.5. The smaller figure contemplates about 9 per cent. of the belt width unloaded at each edge; the larger, 4 per cent.

Speed depends upon the size of particles carried, character of material, width of belt and slope. The limiting speed in every case is that at which material is blown off the belt by air resistance. With small material that flows easily and steadily in a loading spout so that the belt is evenly loaded, belts may be run fast, but with coarse material the feed is necessarily irregular and bare spots will be left on a belt run too fast. With large lumps there is danger of throwing material off the belt in passing idlers when the belt is run too fast. If material is friable and breakage undesirable, as, for instance with coke and coal conveyors, belts must be run slowly if excessive breakage at the discharging end is to be avoided. Ordinary idlers are not carefully turned and balanced as is necessary for high speeds and will rattle and vibrate at speeds much over 400 ft. per min. This limitation does not apply with well-made ball- or roller-bearing idlers. Minimum speed is limited to the necessity for throwing material clear of the head pulley, if head room is an important consideration. The minimum speed to effect clean discharge is about 150 ft. per min. Lower speed is necessary on inclined runs than on horizontal due to the greater difficulty in bringing the loading material up to speed. Table 1 from *Hetzel* gives maximum safe speeds, under the considerations listed.

Table 1. Maximum advisable speeds for belt conveyors

Horizontal

Belt width, in.	12	14	16	18	20	24	30	36	42	48
Belt speed, feet per minute	300	300	300	350	350	400	450	500	550	600

Inclined

Angle of rise, degrees	5	10	13	16	19	22
Percentage of normal horizontal speed	91	83	78	73	67	61

Apart from the physical limitations stated, a good rule is to run the belt at as low a speed as it can be run to carry the load. In this way the percentage of the total load that comes into contact with the belt surface is least, the number of times that any given point on the

belt is subject to the abrasive action of the oncoming stream is a minimum and power consumption, and internal belt strain are least.

Slope. The maximum allowable slope varies with the size and shape of material, method of loading, speed of belt and moisture content. Coarse, rounded material requires a flatter slope than fine material or flat slabs; mixed sizes can be raised on a steeper slope than sized material and uniform feed permits steeper slope than intermittent feed. At normal speeds a slope of 18° is safe for −3 or −4-in. material; −¼-in. dry material can be run at 22° and at 25 or 26° if the conveyor is speeded to 350 or 400 ft. per min.; sand tailing with considerable moisture (15 to 20°) may run backward at 15°, but Delano (*102 J 27*) says that −2-mm. tailing containing 28 to 30 per cent. water was readily carried at a slope of 13° 10′ at the Bonne Terre mill (St. Jos. Lead Co.)

Power consumption depends upon the load carried, the inclination and speed of the belt, the spacing and kind of idlers and size of pulleys. The general formula is $Hp. = PS/33{,}000$, where P = pull on belt in pounds and S = speed in ft. per min. P is made up, in horizontal conveyors, of idler friction due to the empty belt plus that due to the load and may be written as $P = Lfd(X + Y + Z)/D$ where L = length in ft. center to center of tail and head pulleys; d and D are the diameters, respectively, of the idler bearings and the idler pulleys; f = coefficient of idler-bearing friction; X = weight of revolving part of idlers per ft. of length including troughing and return, Y = weight of 2 ft. of empty belt (carrying plus return) and Z = weight of material on 1 ft. of belt. By experiment, $f = 0.35$ for ordinary grease-lubricated idlers. $Z = 2000T/60S = 33.3T/S$, where T = tons per hour. Clearing and substituting, $Hp. = \frac{LSd}{100{,}000D}\left(X + Y + \frac{33.3T}{S}\right)$ (approximately). For an inclined conveyor the weight of the down-going belt balances that of the rising belt, so that the added power consumption is only that due to the load of material. This may be written $Hp. = 2000TH/60(33{,}000) = TH/990$, where H = lift in ft. In short conveyors the additional friction losses at the end pulleys require allowance. Jeffrey Manufacturing Co. recommends adding 20 per cent. to the above figures for conveyors less than 50 ft. in length, 10 per cent. for conveyors 50 to 100 ft. in length and 5 per cent. for those 100 to 150 ft. long. For belt trippers add according to the formula $Hp. = \frac{W^2}{432} + \frac{2}{3}$. In the drive add 5 per cent. for each speed reduction, except that with rough-cast gears this addition should be 10 per cent. An approximate rule, frequently used for horsepower of the conveyor alone is: $Hp.$ = 2 per cent. of the tons per hr. for every 100 ft. of length plus 1 per cent. of the tons per hr. for each 10 ft. vertical lift, or $Hp. = (0.02L/100 + 0.01H/10)T$.

Laboratory tests indicate that the coefficient of friction for oil-lubricated idlers is about 60 per cent., and for roller-bearing idlers 25 per cent. of that for grease-lubricated idlers. This does not mean, however, that 0.21 and 0.09 respectively can be substituted for 0.35 (= f above), on account of the fact the 0.35 takes into account many things beside actual idler friction. *Hetzel* gives the following empirical formula for long conveyors with ball-bearing idlers: $Hp. = (0.0087L/100 + 0.01H/10)T$.

Belt tension may be derived from horsepower as follows: If T_t = tension in the tight side of a belt as it goes onto a driving pulley and T_s the tension in the slack belt leaving the pulley, the driving pull = $T_t - T_s$. If f = coefficient of friction between belt and pulley and a the angle of contact between belt

and pulley in degrees, $T_t/T_s = 10^{0.00758fa}$. Experimental values of f are 0.25 for bare cast-iron pulleys and 0.35 for rubber-lagged pulleys. Table 2 gives values of ratio T_t/T_s for a wide range of conditions.

Table 2. Ratio of T_t/T_s. (*After Hetzel*)

Angle of belt wrap, degrees	T_t/T_s	
	Bare iron pulleys	Lagged pulleys
135	1.8	2.3
150	1.9	2.5
165	2.1	2.7
180	2.2	3.0
200	2.4	3.4
220	2.6	3.8
240	2.8	4.3
270	3.2	5.2
300	3.7	6.2
330	4.2	7.5
360	4.8	9.0
420	6.2	13.0
500	8.9	21.2
600	13.7	39.1
700	21.2	72.0

For a simple horizontal drive (a = 180°) on a bare iron pulley, T_t/T_s = 2.2. Effective pull = $T_e = T_t - T_s = T_t - 0.45\ T_t$, *i.e.*, the total pull = 1.8 times the effective pull. By using a rubber-lagged pulley, T_t/T_s = 3.0 and the total pull is reduced to 1.5 times the effective tension. By increasing the wrap on the driving pulley, by the use of a snub pulley, to say, 220°, the total pull is further reduced to 1.35 times the effective tension.

There is an additional tension on the belt due to its weight, when the belt is inclined at anything more than a very small angle. In Fig. 5, if B = weight of each run of the belt and i is the angle of inclination from the horizontal, the tension in the belt at the head pulley due to each run of the belt $= B \sin i$. The load on the idlers is $B \cos i$ and their resistance to turning under this load, *i.e.*, their resistance to a downhill run is $(fdB \cos i)/D$. The added tension on each run is, therefore, $T_i = B\left(\sin i - f\frac{d}{D}\cos i\right)$.

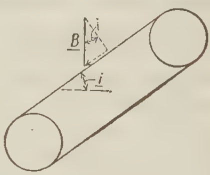

Fig. 5.

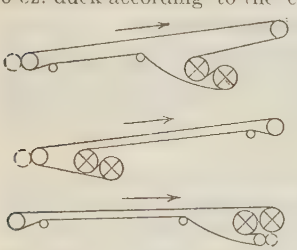
Calculation of belt weight. Determine Hp., then effective pull $T_e = 33{,}000Hp./S$ and from this and the ratio T_t/T_e, calculate T_t. Assign a safe value t for the working tension per inch, according to the weight and quality of duck used in making the belt. Figures used for t vary from 20 to 30 lb. for 28-oz. to 36-oz. duck according to the conservatism of the designer and the duty to which the belt is to be subjected. For long life, if the belt is well covered, use a low value for t; if the expected life is short, either by reason of hard service, light cover, or other reason, use the higher figures. The number of plies $= n = T_t/tW$.



The crossed pulleys are the driving pulleys and should be geared together. The third form should be used for the heaviest service. Driving pulleys should be lagged with rubber belting.

Fig. 6.—Drive arrangements for heavily-loaded conveyors.

Drive is ordinarily and best through the head pulley. Tail-pulley drive causes the loaded belt to run crooked. When the load is so heavy that insufficient wrap is obtained by simple head-pulley drive, some form of snubbing arrangement is necessary. (See Fig. 6.)

Feed to conveyors should be so delivered that at the point at which it reaches the belt it will be moving in the same direction as the belt and as nearly as

possible at the same velocity. This is accomplished by use of an inclined bottom in the feed chute at such an angle that the horizontal component of velocity of the feed passing from the chute will be about the same as the speed of belt travel. As the force due to the vertical component of motion of the feed must be withstood by the belt, the slope of the chute is generally a compromise to avoid this strain, or special arrangements are provided to relieve the belt of vertical shocks. Large pieces falling directly on the belt are liable to cut it. At a Rand crushing station one belt a few days old fed with lump material over a 40° grizzly had three holes 3 to 4 in. long (*122 P 313*).

Special feed chutes are sometimes used, which have a screen or grate in the bottom so that finer material falls on belt first and acts as a cushion for larger pieces which will not pass the grate. Clogging of the grate makes this device ineffective and it will not be satisfactory for all materials. A V-notch in the feed-chute bottom acts similarly and does not clog. The end of the chute may be made in a long curve ending at a tangent parallel to the belt and thus present the feed with little vertical force. This requires giving the feed sufficient velocity to pass along the curved part; considerable wear will take place on the chute. Specially-shaped chutes designed to keep the finer material near the bottom are also used.

The feed should be so delivered that it makes first contact with the belt just beyond an idler pulley; the belt then yields sufficiently to take up impact gradually and avoid cutting. To bring the material up to speed, especially if the belt is traveling fast, results in considerable slipping and tumbling with corresponding wear; this is more pronounced with inclined belts.

Skirt boards should always be provided to keep material from running off the belt before it has become settled on it. They are made of wood or steel and have a strip of belting nailed or bolted onto their lower edges, to close the space between the boards and the belt. On level conveyors skirt boards need be only 3 or 4 ft. long but on rapid or inclined conveyors they should be longer; on steep inclined conveyors carrying coarse material they are sometimes provided the entire length to prevent spill of any pieces that slide or roll back.

Discharge of conveyors may be by fall at the head pulley or by some device which removes the load before the head pulley is reached. The most satisfactory device of this sort is a tripper (Fig. 7). The tripper is usually mounted on wheels running on tracks so that the load can be delivered at several points, as over a long bin or into several bins; the discharge chute delivers to one or both sides of the belt. Trippers may be moved by hand or mechanically or may be automatic, traveling backward and forward and thus spreading the load uniformly. Ploughs or scrapers to remove the load cause extra wear on the belt and when scraping to one side only cause the belt to run out of line.

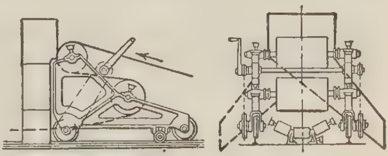


Fig. 7.—Tripper for belt conveyor.

Cleaning the belt of material that sticks is done by scrapers or revolving brushes placed under the head pulley; water sprays are used in some instances.

Support for a conveyor usually consists of wood or steel bents with longitudinal stringers across the caps on which the idlers are mounted; short conveyors are readily supported on the stringers alone. A walkway of light flooring (⅞-in. boards) is generally placed across the stringers between the upper and lower run of the belt to prevent material from falling onto the return side and possibly cutting the belt as it passes around the tail pulley.

Performance of a very large installation at H. C. Frick Coke Co. Colonial mine, East Roscoe, Pa. (*71 A 1123*) is shown in Table 3. All of the conveyors were 48-in. except No. 20,

which was 60-in. The duty was transportation of run-of-mine bituminous coal from underground loading chutes to barges 4.3 miles distant. For conveyors at Reploglе Steel Co., see Sec. 2, Table 61; at New Jersey Zinc Co., Sec. 2, Table 84.

Cost of construction. At Arizona Copper Co. smelter, Clifton, Ariz. (*49 A 3*) the conveyors described in Table 4*a* were built according to the cost schedule in Table 4 (1912–1914). The costs given include all labor and material for installation, feeders, etc., but not the steel frames to which the idlers are attached. The cost of wooden supports and walkways is included in case of conveyors 9^1, 9^2, 9^3, 10^1 and 10^2.

2. Pan conveyor

Pan conveyors are used for lump material that would cut a belt, or for finer material when loading pressures would be excessive for belts, or when, on account of low speed imposed by other conditions, belt tension is excessive. They consist of articulated steel pans carried on chains; the chains run over head and tail sprockets and are supported on the run by wheels or rollers running on tracks on the supporting frame. Different types of pans are shown in Fig. 8.

The shallow V-shaped pan (*a*) has the advantage that it discharges higher at the head sprocket than the other types, but the stiffness is not so great on wide conveyors as that of the deeper pans and it cannot be used on as steep slopes (15 to 20° max.). Pan (*b*) can be used up to 25° slope; it is stiff and well suited for hardwood lining, as shown. With such lining the conveyor becomes substantially of the apron type and should not be used on slopes greater than 15°. Pan (*c*) can be used on slopes up to 30°.

Pans are made of $\frac{1}{4}$- to $\frac{3}{8}$-in. steel; they are replaceable on the chain links, but if wear is great they should be lined with metal or hardwood.

Chains are subject to great tension on account of the slow speeds at which the conveyors are usually run; working loads may run as high as 25,000 lb., but it is better to keep down to 8000 to 10,000 lb. per sq. in. pin pressures, if possible. For light service, malleable roller chain is used (Fig. 14, *D*); for heavy service, steel-bushed roller chain; and for heavy feeder service, heavy all-steel roller chain.

Apron conveyors (Fig. 9) are essentially very shallow pan conveyors;

Table 4a. Conveyors referred to in Table 4.

a Fines from sample mill.

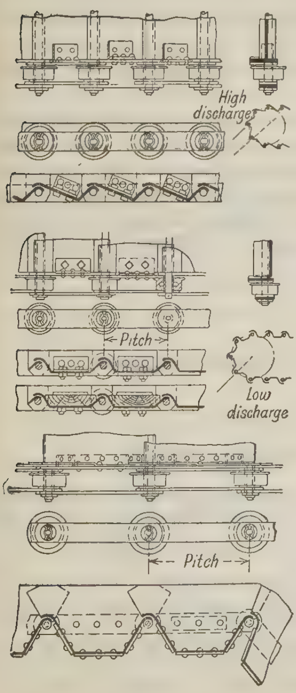

FIG. 8.—Pan conveyors.

in some cases the pans are without ends and spill is prevented by skirt boards. They are used for horizontal transport or inclinations up to 10 or 12°. Their principal application is in heavy feeder service. The lighter type (*a*) has the rollers at the side of the pans; in the heavy type (*b*) the rollers are underneath in order to cut down the unsupported span.

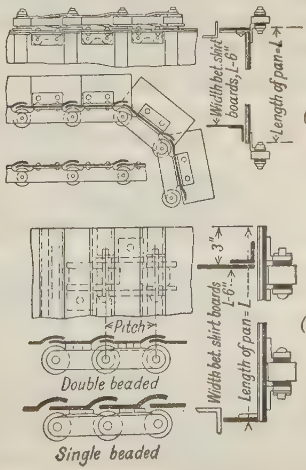

FIG. 9.—Apron conveyors.

Speed of pan and apron conveyors in metal-concentration plants rarely exceeds 50 ft. per min. and when they are used as feeders, speed usually ranges between 2.5 and 10 ft. per min. In the latter service they should be driven by some variable-speed device capable of ready speed change and convenient stopping and starting. In coal handling, the usual speeds are from 50 to 100 ft. per min.

Capacity may be estimated from Table 5. Ordinarily actual capacities will be below the tabular figures on account of irregularities in feeding; these irregularities are greater the greater the speed of the conveyor.

Table 5. Capacity of pan and apron conveyors at 20 ft. per minute.(*a*)
(*After Stephens-Adamson*)

Effective width, inches	Depth of material on conveyor, inches

a Based on material weighing 100 lb. per cubic foot. For other specific weights and for other speeds capacities are in direct proportion.

Power consumption. Stephens-Adamson Co. (*Catalog* 25) states that the chain pull at the head sprocket with machined bushed-roller chain, well lubricated, is 12 per cent. of the combined weight of load and conveyor for level conveyors; with rough, malleable roller chain, the corresponding figure is 24 per cent.; inclination lessens the frictional resistance in proportion to the cosine of the angle with the horizontal. They give the following formulas for chain pull P and horsepower $Hp.$:

For steel-bushed roller chain:

$$P = (4L + 33.3H)T/S + 0.24LW,$$
$$Hp. = (TL/8250 + SLW/137{,}500 + HT/990)(1 + 0.1N).$$

For rough malleable chain:

$$P = (8L + 33.3H)T/S + 0.48LW,$$
$$Hp. = (TL/4125 + SLW/68{,}750 + HT/990)(1 + 0.1N),$$

where L = horizontal projection of conveyor in ft.; H = total vertical lift in ft.; W = weight per ft. of conveyor in lb.; T = tons of material carried per hr.; S = speed in ft. per min.; N = number of gear-speed reductions.

Skirt boards for apron conveyors should be placed about 3 in. in from the edge of the pans (see Fig. 9) and should clear the pans just enough to insure against rubbing; this excludes entry of any material underneath the boards that cannot be broken without stalling the conveyor. Heavy angles lined with plate or heavy timbers lined with longitudinal steel straps are the usual skirt-board material; they must be stiff enough, as above indicated, to crush small particles between them and the pans, if necessary, without any noticeable deformation.

3. Bucket conveyor

Bucket conveyor (Fig. 10) consists of a continuous line of buckets attached by pivots to two endless roller chains running on tracks and driven by sprockets. The buckets are so pivoted that they always remain in an upright position. The carrier can transport either horizontally or vertically and thus is both a conveyor and an elevator. The path need not be rectangular but may be made almost any desired polygonal shape. Buckets are dumped by means of a cam placed to engage a shoe on the bucket, thus turning it into dumping position; the device can be placed anywhere on a horizontal or slightly-inclined run. The buckets have overlapping edges to avoid spilling when fed from a continuous stream; a special tripper reverses the overlap on the return trip so that it will not interfere as the buckets start rising. The carrier has been used most in coal handling but it is a most satisfactory device for use at custom mills and smelters where several varieties of material must be moved in and out of separate bins; thus mixed charges can be made up with one carrier fed simultaneously from a number of chutes.

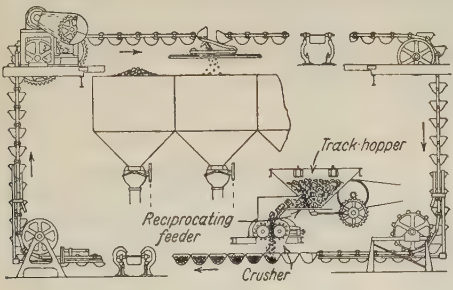

Fig. 10.—Bucket conveyors.

Table 6. Size, capacity and speed of Peck carriers. (*Link-Belt Co.*)

Bucket dimensions, inches: Pitch × Width	Pitch of chain, inches	Carrying capacity of bucket, cubic feet	Speed, feet per minute
18 × 15	18	0.68	30–40

30 × 30	30	4.37	45–60
30 × 36	30	5.25	45–60

Sizes and usual speeds of Peck carriers (Link Belt Co.) are shown in Table 6.

4. Flight conveyor

Flight conveyors (Fig. 11) consist of chain-drawn scrapers or flights running in a trough through which they drag the material to be transported. The trough may be placed on either the upper or lower or on both runs of the chain. Flights are usually made of malleable iron or steel and the troughs of steel, lined with steel or cast-iron wearing plates. Troughs may be placed at any angle from the

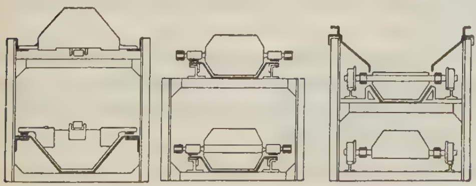

Fig. 11.—Flight conveyors.

horizontal to about 30°, but capacity is very much lowered as inclination increases.

Speed. The usual range is from 50 to 100 ft. per min.

Capacity may be estimated from Table 7.

Table 7. Capacity of flight conveyors. Tons of coal per hour at 100 ft. per minute
(*After Stephens-Adamson*)

Size of flight, inches	Horizontal				Inclined

8×24	....	....	135	90	120	96	72
10×24	....	....	172	115	150	120	90

Power consumption. L. D. Moss (*Peele*) states that for level conveyors anthracite requires about 3 hp.-hr. per ton-mile; bituminous coal, 3.5 to 4; and ashes, 4 to 6. Additional horse-power required for elevation may be obtained from the formula: hp. = tons per hr. × ft. lifted ÷ 990. Add to the total for horizontal transport plus elevation 10 per cent. for each gear speed reduction at the head sprocket.

Applicability. Flight conveyors are rarely used in metal-concentrating mills on account of excessive wear but are frequently used in coal washeries, where the material handled is less abrasive than ores. They are sometimes very useful for transporting short distances in confined spaces where no elevation may be lost or even slight elevation must be gained.

5. Screw conveyor

Screw conveyor consists of a spiral blade attached to a shaft which revolves in a horizontal or inclined trough. Material fed into one end of the trough is pushed toward the other end by the rotating spiral. The shaft is mounted on bearings at each end and also in the middle, if the conveyor is long. Spirals used for ores must be extra-heavy steel or cast iron.

Drive is through a pulley or sprocket mounted on one end of the shaft.

Power consumption is high. Horse-power required may be approximated by the formula: Hp. = $WLC/33{,}000$ (*S.-A. catalog*) where W = weight of material in pounds per min., L = length in ft., and C = 2.5 for cement, fine coal, etc.; 4.0 for ashes, sand, etc. For sand, gravel, ashes or similar materials screw conveyors may be obtained with diameters of 9, 12, 16 or 18 in.; running at speeds of 55, 50, 45, 40 r.p.m., respectively; with capacities of 230, 510, 1100, 1360 cu. ft. per hr. respectively. Higher speeds with greater capacities are used for lighter and less abrasive materials.

Screw conveyors are useful to transport dry or moist sandy material short distances where space for other devices is lacking, *e.g.*, to deliver return sands from a classifier to a ball mill or as a distributing feeder for vibrating screens but wear is great both on the blade and the trough.

6. Bucket elevator

A bucket elevator (Fig. 12) consists of a number of buckets (d) fastened to an endless chain or belt (a) running respectively on two sprockets or pulleys (b, c) at different elevations. Material is fed at (c) directly into the buckets or

is scooped up from the BOOT (*f*) and carried up and discharged into a receiving hopper (*g*) as the buckets pass over the upper (HEAD) wheel. The line joining the centers of the pulleys or sprockets may be inclined at any angle between 65 or 70° and the vertical. Bucket elevators are called CONTINUOUS if the buckets are spaced practically touching and CENTRIFUGAL-DISCHARGE if the buckets are spaced say one or more bucket-depths apart. The height of lift in concentrating mills is seldom over 75 ft. but there is no definite limit in the ordinary range of requirements.

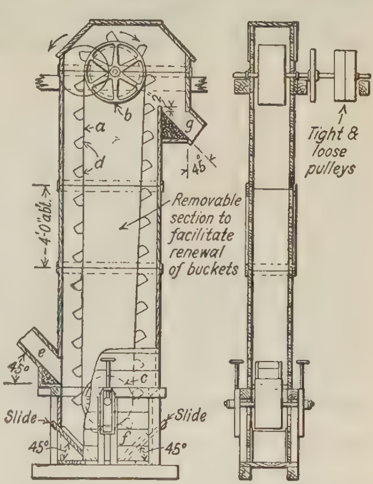

FIG. 12.—Belt-bucket elevator.

Drive is usually by a spur gear on the head shaft and pinion on a jack shaft belt-driven from a motor or line shaft. Direct belt drive from a line shaft to the head shaft is sometimes used; also direct connection of a motor to the pinion shaft. Gear drive is better than belt drive because it permits higher drive-belt speed and belt drive is better than direct connection because the belt will slip in case of a sudden jam and possibly save breakage of the bucket line.

Head shaft should be extra heavy and as short as possible. The greatest stress is due to the weight of the loaded bucket line and to sudden shocks arising from obstruction to the free motion of the line; a shaft strong enough to support this loading is more than large enough to transmit the necessary power. A light shaft that bends under load causes uneven and excessive wear on bearings.

Size of head shaft. Let w = total load in lb. of shaft, pulley, bucket line and ore; l = length in inches of the shaft between bearings; d = diameter of shaft in inches; z = section modulus = $\pi d^3/32$; s = permissible working stress in lb. per sq. in. = say 5000 lb. Then $wl/4 = sz = 5000\ \pi d^3/32$ and $d^3 = wl/1963.5$.

Bearings may be of standard pattern but preferably ball-and-socket, grease lubricated. Special COLLARS with an interlocking rim to cover the end of the bearing are sometimes used to exclude grit; closed ends aid exclusion. Shafting is frequently turned down on the ends to permit the use of smaller-sized bearings.

Rubber belt is the usual medium for carrying buckets in American concentrating-mill practice; BALATA BELTS have been widely used in South Africa. Rubber elevator belts are usually made with 32-oz. duck; for heavy work, 36- or 42-oz.; with a $\frac{1}{32}$- to $\frac{1}{8}$-in rubber cover on the pulley side for protection against pulley slip and some cover on the bucket side also, to provide for the wear of entering feed; for wet materials the cover on the pulley side is usually twice as thick as on the bucket side and ranges up to $\frac{1}{8}$-in. The edges usually have extra-heavy covering. The belt should be two to four in. wider than the bucket to prevent the buckets from catching on the housing or any other projection. Elevator belts are subject to heavy loads; surface wear is severe both on account of loading conditions and slip and creep at the head pulley; the perforations for bolts allow access of grit and water, and this in conjunction with acute bending around small boot pulleys, and frequent bending due to short length disintegrates the internal bond (FRICTION). (CREEP is change in belt length, due to difference in tension on the two sides of the head pulley, so that the belt shrinks in passing from the up side to the down side and this causes relative movement between the surface of the pulley and the belt).

Belt replacement is the most important item of upkeep in elevator operation so that precautions to extend belt life pay for themselves in short periods. Table 8 gives life of belts under various conditions. On elevators with buckets spaced some distance apart and run at low speeds, triangular strips of wood are sometimes fastened to the belt between buckets to prevent material from running along the belt and getting caught behind the buckets; this practice is reported to have greatly increased the life of belts (*59 A 225*).

Splicing belts. Various methods are shown in Fig. 13. The JACKSON FASTENER (*d*) consists of stamped steel plates each with two counter-sunk bolts, two oval cup washers with prongs and two sleeve nuts. The bolts with cup washers are inserted into holes in the belt from the pulley side, the steel plate put on and the sleeve nut tightened. The cup washers cause the belt to be drawn up into the concave parts of the steel plate and the sleeve nuts wedge the warp threads of the duck together and a tight joint is made. BUTT-STRAP JOINT (*c*) is usually twice as long as the width of the belt or, with continuous buckets, the length of two buckets on each side of the joint. The lap-joint (*c*) is simple and easily made. With butt-strap and lap-joints on heavy belts (over 6-ply) the extra thickness caused by the double layer of belt at the joint causes movement between the belts when passing over the pulleys and tends to loosen the bolts and allow sand to enter between the layers. When a lap joint is used the direction of motion of the belt should be as indicated by the arrow to prevent turning over the end when slipping occurs at the head pulley.

Head pulley should be large enough to prevent undue internal strain between the plies of the belt; a diameter in inches at least four, better five, times the number of plies in the belt is satisfactory. The diameter is also limited by the belt speed and discharge requirements.

Width of face should be 2 to 4 in. greater than the width of the belt. The pulley face is usually crowned but high crowns must be avoided unless the buckets are placed in two rows. A solid cast pulley with split hub and one or two keys and set screws is best; as

belt-bucket elevators

a further precaution against loosening a heavy band may be shrunk around the split hub or a keyed, solid-hub pulley pressed onto the shaft. Head pulleys are generally made extra heavy with two rows of arms on wide-face pulleys and long hubs extending almost the entire width of face.

Lagging increases traction between the pulley and belt and decreases wear on both. The most satisfactory lagging is 3- or 4-ply rubber belt or 2- or 3-ply belt with a 1/16- or 1/8-in. rubber cover, fastened by 1/4-in. flat-head bolts; the bolt holes in the rim should be countersunk outside so that the heads of the bolts are drawn down below the outer edge of the lagging, and thus prevented from wearing the belt.

Chains or link-belts running on sprocket wheels are commonly used for elevating broken stone. They have the great advantage of positive drive,

and are good for hot materials that might damage rubber belts. Their chief disadvantage is the great wear at the articulations, where lubrication is difficult or impossible; notwithstanding the use of special wear-resisting alloy steels, chain is unsatisfactory for wet pulps or dusty abrasive material.

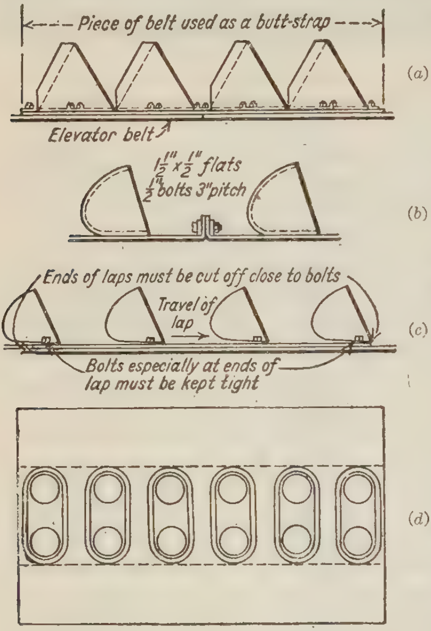

Fig. 13.—Methods of splicing elevator belts (*after Hetzel*).

The standard detachable chain Fig. 14, *A* is cheapest and is widely used; the links are easily replaced but no provision is made for lubrication or exclusion of grit; it can be obtained in manganese steel. Fig. 14, *B* shows interlocking riveted pintle chain, usually made of malleable iron; most of the strain comes on the links rather than the pins and grit is excluded to some extent. Ley bushed chains (Fig. 14, *C*) have malleable-iron links with case-hardened steel pins and bushings which are easily replaced. Special links (Fig. 15) carry the buckets.

An elevator may have one or two chains. Single chains are attached to the back of the buckets; double chains may be attached either to the back or sides. With elevators inclined at any considerable angles from the vertical, the chains are usually placed on the sides of the buckets and provided with rollers which run on a track, thus supporting the loaded side. Fig. 14, *D* shows link for malleable iron roller chain. For details of the numerous types of chains and link belt see catalogs of Stephen-Adamson Co., Link Belt Co., Jeffrey Mfg. Co., C. O. Bartlett and Snow, etc.

Housings. No housing is needed with coarse and nearly dry material except to guard against possible spill of material on men or machines near the

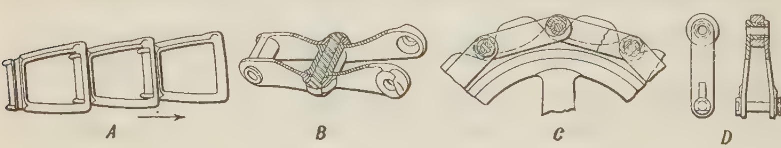

Fig. 14.—Chain-links for elevators.

elevator. If wet pulps or fine dusty materials are being elevated a housing should be provided to confine splash or dust. Wood is commonly used, steel

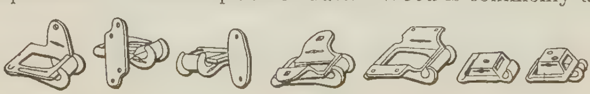

Fig. 15.—Links with attachments for holding buckets.

and concrete less frequently. The front of the housing (upcoming side) is made in removable sections and doors are provided to allow access to the boot.

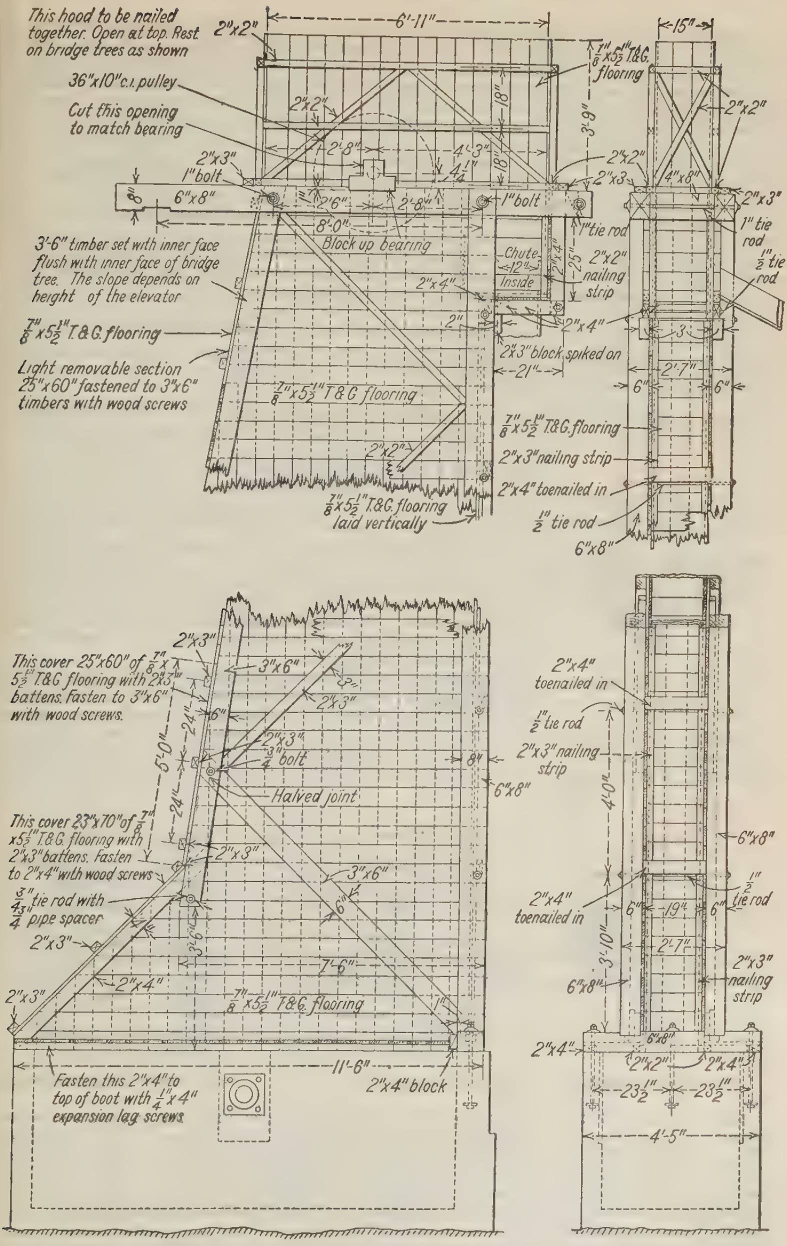

Fig. 16.—Wooden elevator housing.

The simplest WOOD HOUSING consists of 1- or 1½-in. matched boards nailed vertically to the inside of an outer framework. Fig. 16 shows details of a wooden elevator housing made up of two layers of matched boards; the outside layer is placed horizontally and nailed to the framework and the inside layer is nailed vertically to the outside layer. Building paper painted both sides with asphalt paint laid in wet between the two layers of boards prevents leakage. CLEARANCE between the belt and buckets and the housing should be not less than 4½ in. on the sides, better 6 to 8 in., and from 8 to 12 in. or more front and back. Boards running parallel to the belt are sometimes nailed on the inside of the housing to take any wear if the belt runs out of line. The joints on such boards should run in the direction of travel of the belt. The housing is usually light and is supported when possible on the floors of the mill building. SUPPORT FOR HEAD-PULLEY shaft and bearings is provided by special girders in the building frame. STEEL HOUSINGS are made in sections of light sheet steel with light angles riveted to the edges; sections are bolted together through the angles. REMOVABLE SECTIONS should be conveniently placed to allow access for observation and repair. A crane rail should be provided above the head pulley.

Boots for elevators may be small or large. Small boots are used for elevators lifting coarse material so that, if there is any spill, the material will be readily moved by the buckets.

Boots of cast iron or steel can be obtained from makers (Fig. 17). The bottoms are smooth and rounded to permit easy sliding of accumulated material in front of the buckets; removable liners are usually provided. Bearings for the boot-pulley shaft are sometimes supported on the boot with a take-up as shown in Fig. 17. CLEARANCE between the bucket tips and the bottom of the boot should be sufficient at the lowest position of the boot pulley to prevent the buckets from jamming against accumulated material; at least three times the diameter of the largest pieces handled should be allowed. For fine wet pulps the boots should be large to reduce wear on the sides and bottom. Such material is frequently fed directly to the boot and is scooped up by the buckets. The boot then may be either a concrete sump or a large wooden box 2 or 3 times the width of the housing and of greater length (see Fig. 16).

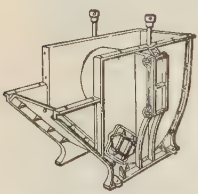

FIG. 17.—Cast-iron elevator boot.

Boot pulley is usually smaller than the head pulley, ranging from 6 in. less to two-thirds the diameter of the head pulley, but never less than 24 in. diameter. BOOT PULLEY SHAFT is usually lighter than the head shaft. BEARINGS are supported on the boot or better, independently outside. Proper lubrication of boot bearings is difficult and is usually neglected. Fig. 18 shows a bearing with flanges for bolting to the boot walls. Grease from cup at end moves in opposite direction from any entering grit and tends to keep the bearing clean. TAKE-UPS are necessary on vertical elevators to compensate for belt stretching. The usual form is supported on the boot and consists of a screw moving the bearing in guides. Special weighted automatic take-ups can be procured. A simple device in which the boot-pulley shaft is supported on wooden slides operated by levers is shown in Fig. 19. The amount of take-up is necessarily small and when the limit is reached the belt must be shortened. Take-ups can be omitted from inclined elevators; if the boot pulley shaft is placed behind the head pulley a horizontal distance equal to the diameter of the head pulley, the sag of the loaded belt is sufficient to allow as much stretch without loss of "wrap" on the

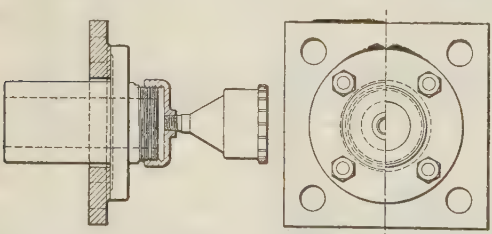

FIG. 18.—Special bearing for boot-pulley shaft.

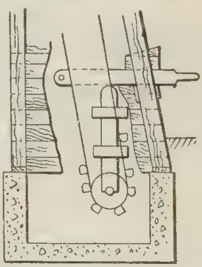

FIG. 19.—Lever take-up.

boot pulley as would be provided by a take-up. With inclined elevators extra tension is put in the belt, if the hang of the loose side is within the line of the catenary between the head and boot pulleys.

Head housing. A removable housing should be provided around the head pulley, extending a distance above the head shaft equal at least to the diameter of the head pulley. It should make a tight joint with the receiving hopper and be provided with a light, easily removable cover.

Receiving hopper is provided with a receiving iron (*a*) Fig. 16, to catch material as it discharges from the buckets. The receiving iron is placed as close to the buckets as possible (rarely more than 1 in. away from the edges of the buckets) and at a point low enough so that all material will be discharged from any bucket before it passes the lip of the iron. The best position to avoid too great a loss of lift varies from a few inches below the center of the head shaft for high-speed centrifugal-discharge elevators carrying a freely-flowing material to a point below a 45° line drawn tangent to the circumference of the head pulley for slow-speed elevators or those carrying sluggish material. The receiving hopper is usually made with rectangular bottom and material is allowed to bank up to its own angle of repose thus avoiding the use of liners. If discharging material strikes the sides of the hopper, liners are provided. The receiving iron in inclined elevators may be placed closer under the head pulley than in vertical, but the housing will be somewhat more complicated, greater floor space required, and if the inclination is great, rollers must be provided to support the loaded belt. Material discharges from the hopper through a chute or launder let into the side or end a few inches above the bottom.

7. Continuous-bucket elevator

This type is used for elevating coarse and comparatively dry material. They are usually run at low speeds so that the discharge takes place by dumping of the buckets as they pass over the head pulley, with little aid from centrifugal force. As the buckets dump, their load slides over the bottom of the preceding bucket and is caught in the discharge chute. Speed should not be so great as to cause excessive spilling at the feed chute and with material containing a large percentage of freely running fine material it should be fast enough so that enough throw will be given as the buckets pass over the head pulley to prevent the fine sand from running out the sides of the buckets and falling back down into the boot. With continuous chain-bucket elevators the speed is seldom greater than 100 ft. per minute; continuous belt-bucket elevators run at higher speeds; Table 9 gives proper speeds for various head-pulley diameters.

steel plates riveted together (a, b), with or without ears for lapping adjacent buckets. The transverse section depends upon the material carried and the slope of the elevator.

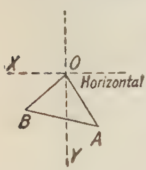

FIG. 21.

In Fig. 21, AOB represents a bucket in dumping position. Angle XOB should be 40 to 50° so that material dumped from the following bucket onto OB will slide freely; angle BOA should be 50 to 60° to prevent lumps of rock from wedging and lessen sticking of damp fine material. $BOA = 90 - XOB + YOA$. Setting $XOB = 50°$ and BOA at 60°. YOA, the inclination of the down-going belt, is 20°. The carrying capacity for any given inclination of elevator and length of bucket front depends upon angle BOA; for elevator slopes of 10° to 30° from the vertical, buckets with angle BOA between 60° and 70° have maximum carrying capacity.

Fastening buckets to belts is done by means of bolts. Other methods have been proposed but have not worked out satisfactorily. One or two rows of bolts may be used, the latter for all but very small buckets; two rows are spaced 1 to 2 in., and pulleys should be at least 30-in. diameter, if two rows are used. Buckets work loose readily and an elevator should be inspected at short intervals to tighten the buckets before they fall into the boot and tear off others. Double rows of narrow buckets set staggered on a wide belt are better than wide buckets because they allow the belt to conform to the crowned head pulley without undue strain on belts and bucket bolts. The gap between bucket and belt in passing over a pulley depends upon the length of the back of the bucket, the place of attachment and the diameter of the pulley. If the buckets are bolted along the upper edge of the back the gap at the bottom is large and in passing over the head pulley material will be spilled into the gap unless extraordinary precautions are taken; if bolted near the bottom, the large gap picks up material in passing through the boot and the buckets will probably be torn away. Center bolting is the compromise adopted. The gap $= g = \dfrac{(\sqrt{d^2 + l^2}) - d}{2}$, where d = diameter of head pulley and l = length of back of bucket; g should never exceed $l/8$.

Feed. A continuous-bucket elevator should be fed through a chute delivering to the rising side at a point such that the bottom of the feed chute is two bucket spaces above the foot shaft. This gives a chance to catch spill in a later bucket. CLEARANCE between the feed chute and the outer edge of the

bucket should be great enough to prevent a large piece of material from jamming.

Spill that falls into the boot must be dug out by the buckets, with consequent increase in wear and power consumption. Small accumulations in large boots may be removed manually through doors; Fig. 22 shows an ingenious method of removing large amounts mechanically. (*H. M. Roche*, Beach Glen Mine, Dover, N. J.)

Inclination is usually 10° to 30° from the vertical; this increases the chance of catching spill in succeeding buckets and also aids sliding discharge.

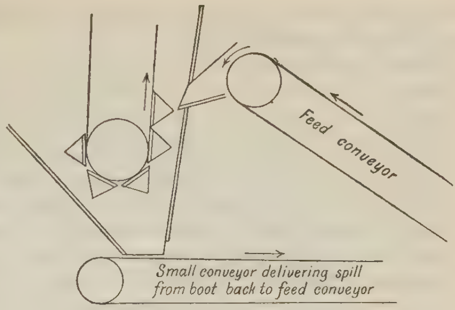

Fig. 22.—Arrangement for removing spill from elevator boot.

8. Centrifugal-discharge elevator

These elevators employ centrifugal force developed in passage over the head pulley to throw material clear of the buckets into the receiving hopper. As rising buckets reach the head pulley centrifugal force becomes effective and tends to push the bucket contents toward the lip. The force acting on the bucket loads is the resultant of gravity and this centrifugal force. Centrifugal force, $C = 2Wv^2/gD$ where v = peripheral velocity in ft. per sec., D = diameter in ft. of the circle described by the center of gravity of the load, W = weight of the bucket load in lbs., and g = acceleration due to gravity (32.2 ft. per sec. per sec.). Material should start to discharge from the bucket when the direction of the resultant of the forces becomes perpendicular to the front of the bucket; actually discharge begins somewhat later, the amount of lag varying with the fluidity of the load. Free-flowing material discharges close to the theoretical point; sluggish and sticky materials lag considerably.

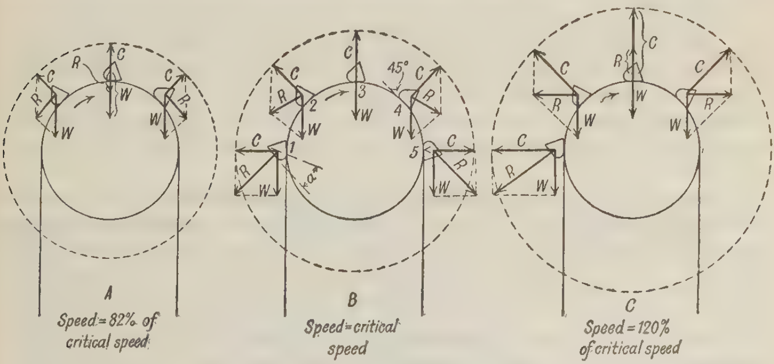

Fig. 23.—Forces at the head-pulley of centrifugal-discharge elevators.

Critical speed is that for which the centrifugal force is equal in magnitude and opposite in direction to gravity. At this speed the load is in equilibrium with respect to the bucket (see Fig. 23) and $C = W = 2Wv^2/gD$; $v^2 = gD/2$; $v = 4\sqrt{D}$ (approx.). To find the r.p.m. (N) for this condition: $v = \pi DN/60$; $\pi^2D^2N^2/3600 = .gD/2$; $N^2 = 1800g/\pi^2D$, and $N = 76.6/\sqrt{D}$. d (diam. of

head pulley) $= D - 2t - p$, where t = thickness of belt in feet and p = projection of the bucket in ft.

As a bucket starts onto the head pulley the sudden application of centrifugal force may, if the bucket is full of freely-flowing pulp, cause some spill as the load shifts to bring its surface perpendicular to the resultant force. As the bucket passes around the head pulley the resultant force decreases but it always has a component pointing towards the bottom of the bucket until the bucket is vertically above the pulley center. In Fig. 23, B, the buckets have a 45° bottom angle, and the resultant force at position (1) is perpendicular to the front of the bucket. The amount of material that the bucket will hold under this condition depends on the internal friction or fluidity of the mass; the load tends to take a position so that the angle (a) between the side of the bucket and the top surface of the load equals the angle of repose (Sec. 19, Table 2); with mobile pulps the carrying capacity of the bucket is distinctly limited, but with sticky or coarse dry material and buckets not too heavily loaded, practically no spill will occur; because the initial condition is instantaneous and is followed by more favorable conditions.

Free discharge occurs on the discharge side of the pulley when the direction of the resultant is within the parallels to the front and back drawn through the center of gravity of the load; in such cases there is no friction between the load and walls of the bucket. For the 45° buckets shown in Fig. 23, free discharge at critical speed extends over the full quadrant from the top to the point at which the belt leaves the pulley. For a bucket with bottom angle of 30°, free discharge extends only to a point 60° from the vertical; a bucket with 15° bottom angle will discharge freely only to a point 30° beyond the vertical. The bucket may still discharge beyond the point at which free discharge ends but discharge will be retarded by friction due to the component of the resultant perpendicular to the front of the bucket. Thus while a bucket with a small bottom angle has the greater carrying capacity its period of free discharge is so limited that net capacity is ordinarily less than that of buckets with more flare.

For belt speeds below the critical speed (Fig. 23, A), the bottom angle is unimportant except that material packs and holds back more with small angles. Under the conditions pictured in (A), while the bucket is moving from the top position to a point about 45° beyond, the resultant lies inside the tangent to the circle of rotation of the center of gravity of the load and the load tends to run out onto the belt; free discharge occurs between 45° and 90° beyond the vertical.

Overspeeds. Fig. 23, C, shows the effect of overspeed; 20 per cent. is probably the limit for efficient work. With 45° bottom angle, the resultant on the rising quadrant is always in a direction tending to push the load out; it reaches a minimum at a point 45° up from the horizontal. With a bottom angle between 35° and 40° the tendency to discharge is delayed until the bucket reaches 15° to 25° from the vertical. On the discharge side the resultant favors discharge over the whole quadrant; with a 45° bottom angle free discharge takes place after the bucket passes the 45° point; with smaller bottom angles free discharge starts later and *vice versa.*

The usual bottom angle for buckets handling ores or mill pulps is about 40°; this gives good capacity with a good range of free or nearly free discharge. Overspeeding usually causes incipient discharge in the rising quadrant but if overspeed is not excessive, most of the load is thrown well over into the receiving hopper. Excessive overspeed causes excessive discharge on the rising

side and much of the load falls back into the boot. Slow speeds cause delayed discharge, and the load may not be thrown clear, and there is considerable spill back into the boot, but the wear on the receiving hopper is not so great and friable material is not broken up as much as with the more violent ejection of higher speeds.

Loading conditions are affected by belt speed, if the elevator is boot fed. High speeds, especially with boot pulleys of small diameter, may produce such great centrifugal forces that material is prevented from entering the buckets in the lower portion of the run and it is then necessary to carry a deep bed of material in the boot to get proper loading; with heavy pulps and coarse material this causes excessive power consumption and damage to buckets. Table 11 gives speeds for various head-pulley diameters; critical speeds should

be used for freely flowing materials, the lower speeds for coarse or dusty materials.

Material coarser than ¼-in. should not be boot fed.

Buckets for centrifugal-discharge elevators are usually of malleable iron; various styles are shown in Fig. 24. Corresponding dimensions, capacities and weights are shown in Table 12. Styles *A* and *AA* are most used; *AA* is heavily reinforced on the front edge and corners. Style *B* is used for elevators inclined over 30° to the vertical; the high back prevents spill. Wear is greatest at the corners, especially when the buckets dig material from the

boot. Replaceable wearing edges are sometimes used. LIFE of buckets under varying conditions is shown in Table 8. Sheet-steel buckets are rarely used. Buckets are fastened to the belt by special flat-head bolts in one or two rows near upper edge of the back of the buckets; Table 13 gives standard spacing.

Bolt holes 9/32-in. diameter for ¼-in. bolts.

Soft-rubber washers on narrow strips of belting placed between the buckets and the belt protect the belt from cutting by the upper edge of the buckets or by gritty material caught behind buckets.

Spacing of buckets should be such that discharging material from one bucket will clear the preceding bucket. *Hetzel's* recommendations for closest spacing are given in Table 14. Increase in speed causes discharge in a more nearly radial direction and therefore permits closer spacing. Sluggish material requires greater spacing to allow free pick-up in the boot. A rough rule

is to space the buckets a distance equal to twice their projection; usual spacings are from 12 to 24 in.

Load in buckets is rarely more than half the theoretical capacity. Buckets full of free-flowing pulps will spill on reaching the head pulley, causing waste of power. In design, buckets are calculated one-third full in determining capacity and full in estimating power requirements.

Table 14. Bucket spacing, centrifugal-discharge elevators. (*After Hetzel*)

Discharge of packed or sticky material is aided by punching holes or slots in the bottom of the buckets; by attaching short lengths of chain loosely in the bottom; or by a U-shaped wire with the ends bolted to the belt outside the bucket and the bottom of the U projecting to the bottom of the bucket so that as the belt bends around the head pulley, the wire moves and breaks up the packed mass in the bucket. Suspended boards or rods arranged to tap each bucket sharply as it comes over the head pulley are also used.

Power for elevators

Driving power for elevator belts is transmitted by friction between the face of the head pulley and the belt. The friction must be sufficient to overcome a force equal to the difference in tension between the tight and loose sides of the belt; if it is less, the belt will slip. Slip may be prevented by lagging the head pulley, or by decreasing the difference in tension between the two sides of the belt by light loading or tightening the belt. Excessive tightening overstrains the belt and brings an excessive load on the head-shaft bearings. The angle of wrap on the head pulley is about 180° for vertical elevators and slightly less for inclined elevators where the down side of the belt hangs loosely. The proper relation between the tensions on the tight and slack sides of the belt can be found from the formula $T_1/T_2 = 10^{0.00758fa}$ in which T_1 = tension on the tight side in lb., T_2 = tension on the slack side, f = coefficient of friction, a = angle of wrap in degrees. Table 15 gives safe

Table 15. Coefficients of friction and values of T_1/T_2 for rubber belts on elevators with wrap angle = 180°. (*After Hetzel*)

values to use under various conditions. Dust or water between belt and pulley decreases the coefficient of friction.

Tension in the rising belt (T_1) is the sum of the weight of material in the buckets, the weight of the empty buckets and belt, the pull due to digging the load or filling the buckets and friction losses in the boot shaft. WEIGHTS OF MALLEABLE-IRON BUCKETS are given in Table 12. WEIGHT OF BELTING may be approximated as the product of the width in inches $\times$ number of plies $\times 0.03$. The PULL DUE TO LOADING AND PICK-UP from the boot can be taken as equivalent to the pull of the load of material in the buckets for a length of belt in feet of from $2D$ to $12D$, where D is the diameter of the boot pulley in feet. The most favorable condition arises in a slow-speed continuous-bucket elevator, which is front fed with practically no spill; for this a value of $2D$ may be used. For a continuous-bucket elevator for coarse material, picking up a large part of its load from the boot, $12D$ should be used; for front feeding of damp sand with little spill, $3D$; for thick pulps, 40 to 50 per cent water, $3D$ to $4D$; ordinary dilute mill pulps, boot fed, which do not settle readily, $4D$ to $6D$; and for boot-fed pulps which pack, $10D$. PULL DUE TO FRICTION LOSS at the boot is covered by adding 1 or 2 per cent. of the total calculated pull from other causes.

Tension on the down side of the belt (T_2) is equal to the weight of the empty buckets and belt.

If the ratio T_1/T_2 thus found is greater than $10^{0.00758fa}$ the tension must be increased by take-up and allowance must be made for the added tension in determining the size of belt needed. WORKING STRESSES in elevator belts should be kept below 35 lb. per in. per ply for 32-oz. duck and 40 lb. for 36-oz. duck; in most cases the stress can be kept below 25 lb. Extra plies are usually allowed when external wear is great.

Horsepower to drive the belt $= (T_1 - T_2) \times$ *belt speed in ft. per min.*/33,000.

To determine the horse-power to be delivered by the motor or line-shaft add 5 per cent. for each speed reduction through belts, chains or cut gears and 10 per cent. for each reduction through cast gears.

Design of a continuous-bucket elevator

To raise 50 tons per hr. of 2-in. material weighing 100 lb. per cu. ft. 50 ft. vertically, the elevator to slope 10° from the vertical.

As the slope angle is small it may be disregarded in calculation. The volume to be delivered per min. $= \dfrac{50 \times 2000}{100 \times 60} = 16.7$ cu. ft. Assume the buckets one-third full, then bucket capacity should be $16.7 \times 3 = 50$ cu. ft. per min. $= 86{,}400$ cu. in. per min. From Table 10 a $15 \times 7\frac{1}{2} \times 12$-in. bucket has 450 cu. in. capacity. Number of buckets per min. $= 86{,}400/450 = 192$. As the length of the bucket along the belt is 12 in. a belt speed of 192 ft. per min. will be necessary, and from Table 9, a 36-in. pulley will be needed. Gap $= \dfrac{\sqrt{d^2 + l^2} - d}{2} = \dfrac{\sqrt{36^2 + 12^2} - 36}{2} = 1$ in., which is less than $l/8$ and therefore satisfactory. If slower speed is desired, a $16 \times 8 \times 13$-in. bucket with capacity $= 555$ cu. in. gives $86{,}400/555 = 155$ buckets per min. or a belt speed of $\dfrac{13 \times 155}{12} = 168$ ft. per min. and the gap will be 1.13 for a 36-in. pulley or within the limit $l/8$. Using the latter size of buckets, the number of buckets on the upcoming side $= 50 \times 12/13 = 48$ (approx.). The load due to empty No. 10 steel buckets $= 48 \times 21 = 1008$ lb. The load in these buckets, assuming them full, $= 48 \times 555 \times 100/1728 = 1541$ lb. The belt width will be 18 in. Assuming 9-ply belt, the weight per ft. of length is approximately $18 \times 9 \times 0.03 = 4.86$ lb. and the weight on the loaded side $= 4.86 \times 50 = 243$ lb. Using a 30-in. boot pulley and assuming fair loading conditions, the pull due to digging in boot = the load carried on $6D$ ft. of belt $= \dfrac{6 \times 2.5}{50} \times 1541 = 462$ lb. The total tension on the loaded side $= 1008 + 1541 + 243$

+ 462 = 3254 lb. Add for friction between 1 and 2 per cent. say 46 lb. and T_1 = 3300 lb.

The tension per in. of width = 3300/18 = 183 lb. and with a working tension of 25 lb. per in. per ply, 183/25 = 7.32 or 8-ply belt will be needed. The head-pulley diameter in inches is 4.5 times the number of plies, which is satisfactory. The exact weight of 18-in. 8-ply belt with 36-oz. duck is within the value assumed above.

Tension on the down side of the belt will be 1008 + 243 = 1251 lb., hence T_1/T_2 = 3300/1251 = 2.64 and the coefficient of friction should equal 0.309 (from the formula $T_1/T_2 = 10^{0.00758fa}$). A rubber-lagged head pulley should be used (see Table 15). Since a wide allowance was made in taking the tension on the rising side that due to full buckets, there should be no slip under normal working conditions.

Horsepower to drive the belt = (3400 − 1251) × 168/33,000 = 11 hp. Add 10 per cent. (= 1.1 hp.) for reduction by cut gears and 5 per cent. (= about 0.6 hp.) for belt drive from motor to pinion shaft; the motor power required will be 12.7 hp.; a 15-hp. motor that will operate at high efficiency over a wide range should be chosen.

Size of head shaft. The total weight to be supported = the load due to belt, buckets and load on the loaded side, 3400 lb., + belt and buckets on the empty side, 1251 lb., + a 36 × 20-in. pulley, 660 lb., + the shaft (assumed), 200 lb., = 5511 lb. Assuming 4-in. clearance on each side of the pulley the thickness of the housing as 2 in., and placing 16-in. bearings just outside the housing, l = 20 + 8 + 4 + 16 = 48 in. d^3 = 5511 + 48/1963.5 = 134.8; d = about 5.12 in. The nearest standard size of shafting is 5$\frac{3}{16}$ in.

Design of centrifugal-discharge elevators. Similar procedure should be followed except that in addition belt speed and bucket spacing must be such as to give satisfactory discharge.

Performances. For elevators at Replogle Steel Co., see Sec. 2, Table 62; at New Jersey Zinc Co., Sec. 2, Table 85. See also elevators in the various flow-sheets in Sec. 2.

Cost

The principal item of cost other than power is belt and bucket replacement.

Table 16 (*52 A 116*) gives details of the cost for elevating fine thick pulp 55 ft.

Table 16. Cost of elevating pulp at Tonopah, Belmont

149 ft. of 20-in. Balata belt @ 2.80	$392.70
36 buckets @ 2.90	104.40
220 elevator bolts	20.24
7½ lb. washers	0.83
4$\frac{15}{16}$-in. shaft	22.22
2$\frac{15}{16}$-in. shaft	4.36
Babbitt	12.30
Labor to install new belt	193.41
Repair labor	107.12
Power at $8.82 per hp.-mo. (7.3 hp.)	772.56
Chain drive (replacement)	104.85
Total	$1,734.99
Wet tons elevated	1,045,162
Cost per ton	$0.00166

At Chino Copper Co. (*112 J 806*) the cost of elevating tailing during the sixteen months prior to Dec., 1920, was $0.01954 per dry ton. The lift was about 40 ft.; average tonnage, 5000 dry tons per 24 hr. in a pulp containing about 15 per cent. solids; dry tons elevated in 16 months, 2,459,300.

At Miami Copper Co., in 1915, two 24-in. bucket elevators in the coarse-crushing plant handled 1,348,122 tons of −¾-in roll product. The cost of maintenance per ton was as follows: Belt, $0.00104; buckets, 0.00025; miscellaneous supplies, 0.00044; labor, 0.00031; total, $0.00204.

Automatic skip hoists, which are used to a considerable extent in feeding iron blast-furnaces and in raising water from shallow mines, have been used at one plant, viz.: Alaska Gastineau (Sec. 2, Fig. 75) for elevation in the roll-screen circuit. For performance see Sec. 23, Art. 6.

Bibliography. F. V. Hetzel, *Belt conveyors and bucket elevators*, John Wiley & Sons, New York, 1922, contains a very complete discussion of belt elevators. See also A. O. Gates, *102 J 4*; *96 J 725*; and E. S. Wiard, *The theory and practice of ore dressing*, McGraw-Hill Book Co., New York, 1915.

9. Chutes

Chutes are steeply-inclined rectangular troughs used for transportation of dry or nearly-dry ore by gravity; they may or may not be covered. Vertical chutes are usually equi-dimensional and are closed on all four sides. Round-bottom chutes are sometimes used for transportation of coal to lessen breakage. Chutes are usually made of wood, lined with some wear-resisting material. Steel is frequently used for vertical or nearly-vertical chutes.

Chutes must be well supported and rugged enough to stand the shock of material passing through; they must be large enough to pass the desired tonnage, and slope enough to keep the material moving. Covered and vertical chutes should be made with removable covers to allow access for replacing lining or relieving stoppages.

Liners are always placed on the bottom and frequently on the sides of inclined chutes; vertical chutes are lined on all four sides. Materials used for lining are sheet steel, cast iron, chilled cast iron, manganese steel, steel rails, old iron or steel, wood, rubber or concrete. In some cases chutes are built in steps and material is allowed to build up; no lining is then needed.

Chute linings in anthracite breakers have commonly been sheets of blue annealed iron, (*66 A 422*) but these are rapidly corroded by acid water. Galvanized sheet resists corrosion and permits lower sliding angles. Vitrified clay pipe makes excellent lining and wears indefinitely. Glass has been found too brittle. HUDSON COAL Co. has used Corrosiron (cast iron with about 12 per cent. Si). It is made up in flanged U-shaped sections, 18 in. wide and 2 to 3 ft. long, both straight and spiral. AT the LOREE breaker this material had, in 1920, already outlasted ten sheet-steel linings and bade fair to last indefinitely. When new the surface is rough, hence the minimum angle is greater than after the chute has worn smooth. This difficulty is overcome by setting the chutes on the final slopes, lining with sheet iron, and removing the lining a sheet at a time, beginning at the lower end.

Size. The WIDTH of a chute should never be less than three times the size of the largest piece which it is to carry, if free running is desired. No definite rule can be set for the cross-section of a chute to carry a given tonnage. The width is usually fixed by the size of opening from which the chute takes or to which it delivers its load; DEPTH is usually made much greater than the depth of the stream both to prevent bounding out and for convenience in construction.

The minimum slope at which material will flow freely in a chute depends on the coefficient of friction between the chute lining and the material.

Holbrook & Fraser (*Bul. 234 USBM 42*) found that sliding angles on smooth steel surfaces varied not only with hardness and specific-gravity but also with the shape of the fragments. See Sec. 5, Tables 18, 19, 21 and 22. Cubical or rounded pieces slide at smaller angles than flat or wedge-shaped pieces. The distribution of pieces of different sizes in the materials is important, especially if moisture is present; very fine material tends to cake and retard motion; in general, sized material will flow on a flatter slope than unsized. SAFE SLOPES are greater than the angle of repose of the material; if smooth liners are used, such slopes are greater than those necessary for sliding on the lining, but the chutes will not clog if the lining becomes rough and uneven. General practice is to make slopes for dry material at least 40 to 45°. Too great slope causes excessive bounding with resultant breakage of material and excessive wear on liners. Convergence of the sides of chutes is to be avoided; if unavoidable, the chute must be designed so that the inclination to the horizontal of the line of intersection of the side and bottom is equal to or greater than the angle of repose of the material or the sliding angle, whichever is adopted as the minimum slope. Table 17 gives performances of various chutes.

Chutes for coal breakers are designed to reduce breakage of coal. This breakage may amount to as much as 10 or 12 per cent. of the total material reduced from domestic to steam sizes in the passage from jigs and screens to and through the loading pockets. For vertical drops, spiral chutes (Fig. 25) are commonly used. An automatically controlled box chute (Fig. 26) is also frequently used. So long as coal is traveling freely in the upper inclined chute, the counterweight keeps the hinged chute in the position shown and the bottom gate closed. When the vertical shaft is filled and coal begins to back up in the upper inclined chute, the weight of the coal depresses the hinged chute and opens the bottom gate

Table 17. Chutes in various mills

Ore	Size of pieces	Dimensions of chute		Slope, degrees and minutes
		Width, inches	Depth, inches	
Magnetic iron ore	−4-in. +2-in.	24	24	45–0

a Occasional clogging. *b* Clogs when moisture is over 6 per cent. *c* Bottom made in steps; material piles up between the steps and protects the bottom.

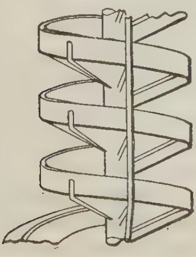

FIG. 25.—Spiral chute.

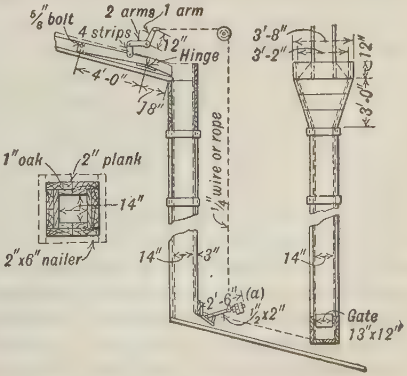

FIG. 26.—Telegraph chute (*after Ashmead*).

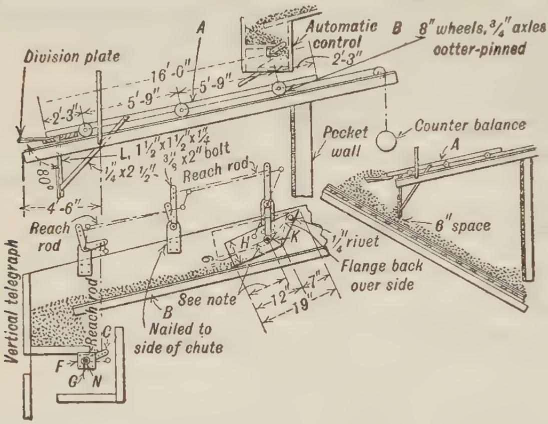
and flow starts again. If the vertical shaft is round, breakage is least. WHITE CHUTE (Fig. 27) is an automatic device for regulating the flow and fall into loading pockets. The counterweighted traveling carriage *A* is placed in position over the chute as shown. It is fed by an automatic control chute *B*, the control mechanism consisting of a balanced float *H* which connects by means of link rods with a tilting lip *C*. When coal is flowing down chute



Rod *N* is adjusted by moving *F* to desired position before nailing. Position of gate *G* is adjusted to suit conditions by moving lever *C* to any desired position and holding with set screw. Hole for rod *K* is located by trial so that float *H* balances with front on chute and back $1\frac{1}{2}$ to 3 in. off bottom, according to size of coal.

FIG. 27.—White automatic chute control and bin loader.

B the float lifts and thereby depresses the lip *C* and coal flows into the loading pocket. In the pocket the pressure of coal against the board *L* backs the movable chute *A* up slope and thereby permits complete automatic filling of the pocket with but little breakage. According to Ashmead (*66 A 422*) tests have shown 5 per cent. reduction in pocket-loading breakage due to this type of chute. It is to be noted that the control mechanism is adaptable to any chute.

10. Launders

Launders are narrow, inclined troughs used for transporting mixtures of pulverized solid and water by gravity flow. The solid is carried either by suspension, by sliding or rolling, or by a series of leaps or jumps, termed SALTATION. To obtain free motion of material in a launder, the slope must permit sufficient water velocity to overcome the inertia of the solid material and frictional resistance. The inertia of the solid particles varies with their size and density. Frictional resistance varies with velocity, the kind of lining, shape of launder, amount of material, proportion of solids in the flowing stream and the size, shape and density of the solid particles. Where particles are carried either by sliding or rolling the roughness of the lining may have important effect; if very smooth, angular pieces will probably slide and friction increase, while, if the lining is somewhat rough, the same pieces may roll or progress by leaps, with less friction loss. Very fine material is carried in suspension even at low velocities and with increasing velocity coarser material is held in suspension due to the more violent eddy currents. When velocity is low and the solid particles coarse, most of the movement is by rolling or sliding; as velocity increases, the movement is more by leaping with the finer particles going into suspension. Increase in the amount of very fine material in sus-

pension causes increase in density of the mass and the larger particles transported by rolling or jumping are more easily moved because of the buoyant effect of the denser medium. The velocity of the water is least at the bottom of the launder and increases, in a given cross-section, to a maximum at the surface of the stream.

Where solid material is carried only by rolling, the large pieces (extending higher in the stream) benefit by the higher velocity of the upper levels and tend to be carried faster than the finer particles. However, the path of a single small mass of liquid is not a straight line parallel to the axis of the launder but really sinuous, curving up and down and in and out from the sides. In this respect the flow may be considered different from that of a comparatively thin stream on a gradual slope, not narrowly confined. Roughness of the lining increases sinuosity of the stream by causing eddy currents.

When material fed to a launder starts practically from rest, the velocity at which it travels increases due to the component of gravity acceleration parallel to the bottom of the launder, reduced by frictional resistance both within the mass of flowing material (viscosity) and between the flowing material and the sides and bottom of the launder. Velocity will increase to the point where frictional resistance equals the gravitational force, thence onward the velocity will remain constant provided slope, shape, lining, etc., remain the same. Experimental evidence indicates that maximum velocity is quickly reached in launders on moderate slopes, and it is probable that in most cases launders are so fed that the initial velocity is close to or even greater than the velocity that would be reached starting from rest. If a launder of even slope is capable of holding solid material in suspension over the period of acceleration, it is capable of carrying a larger load after constant velocity is reached. Practice recognizes this by increasing the slope for a short distance at the head end; velocity is thus quickly increased and full advantage may be taken of the carrying capacity of the stream at constant velocity.

Calculation of minimum slope and proper size for a launder to serve under stated conditions is difficult because of the number of empirical constants needed. Considerable experimental work has been done, but the materials handled have been different in all cases and the variety limited in each instance, consequently widely divergent results are presented. Reports on working launders are not easy to analyze, since the slopes used are generally on the safe side and there is no clue as to the minimum slope. Tabulation and study of information available on about 150 launders carrying almost every variety of ores, concentrates and tailings failed to reveal more than broad generalities as to the influence of the various factors.

Velocity of the stream furnishes the force to move the solid which is to be transported. Velocity is either initial or that imparted by gravity. Retardation is due to frictional resistance or obstructions. Frictional resistance is decreased by making the cross-section of the stream such that the wetted perimeter is least per unit area of cross-section; by using a smooth lining; by varying the proportion of solid and the character of the solid. In general coarse material requires greater stream velocity than fine; heavy material greater than light; thick pulp greater than thin; angular material greater than rounded. Very rough lining and breaks at joints in the lining obstruct free flow by causing irregular movement in the body of the stream; their effect decreases with increase in depth of stream.

Slope. Figs. 28 and 29 show the recommendations of various experimenters.

Fig. 28 curves (*A*) and (*B*) are the minimum slopes determined by Blue (*8 J 536*); curve (*A*) is for beach sand and curve (*B*) for angular mill tailing with some slime present. Curve (*C*) gives slopes found suitable by Caldecott (*14 JCM 486*) for launders carrying sand containing about 4 per cent. pyrite, 10 per cent. of the sand being retained on a screen with 0.01 in. aperture; these values were calculated from the empirical formulas: $W = 12/(G - 1)$; $P = 100W/(W + 1)$ and $G = (W + 12)/W$, in which W = ratio by weight of water to solids, P = per cent. by weight of water, G = slope of launder, per cent. Curves (*D*), (*J*), (*K*) and (*L*) were plotted from results obtained by Browning (*29 M & M 300*); (*D*) is for $-10 + 30$-mesh limestone tailing

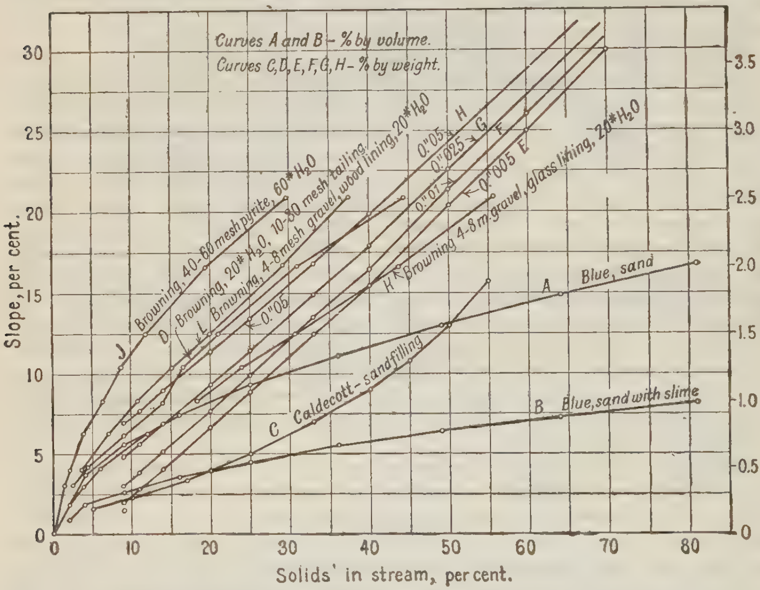


FIG. 28.—Relation between percentage of solids and slope of launders.

(40 per cent. +20-mesh and 60 per cent. $-20 + 30$-mesh) in a rectangular wooden launder 2½-in. wide; (*J*) is for $-40 + 60$-mesh pyrite table concentrate in a wooden launder 2½-in. wide.; (*K*) and (*L*) are for $-4 + 8$-mesh ordinary rounded pebbles, (*K*) with glass lining and (*L*) with wood. Curves (*E*), (*F*), (*G*) and (*H*) were plotted from a table by Julian, Smart & Allen (*Cyaniding gold and silver ores*), for sand of predominating size of 0.005-, 0.01-, 0.025- and 0.05-in. respectively. Caldecott and Powell (*14 JCM 121*) state that sand pulp will flow slowly with 30 per cent. water on a 30 per cent. slope, with 40 per cent. water, on 20 per cent. slope and with 60 per cent. water on a 10 per cent. slope.

The wide divergence of the curves is due to the variety of materials and conditions. The largest size investigated was 4-mesh rounded gravel. Fig. 29 (*2 RMP*) shows that the slope varies approximately as the square root of the particle size. The values from the curve are said to give velocities of 7 to 10 ft. per sec. The points off the curve are plotted from actual operations; most of them fall on the safe side above the curve; most of those below were dilute pulps (under 15 per cent. solids) but three ranged from 25 to 33 per cent.

Use of Curves. Bear in mind the characteristic of the particular material to be carried and err on the safe side; if insufficient slope is provided water must be added, which may be wasteful or undesirable in subsequent treatment.

GILBERT (*PP 86, USGS*) summarizing experiments on the carrying capacity of water in flumes, stated that much of the movement is by rolling or sliding, especially when the current is slow and the solid coarse; that with a swift current or fine solid the particles travel by saltation and the finest material is suspended. When the principal movement is by rolling or sliding, the capacity of the current increases with coarseness of the solid material, up to the point at which the current is barely able to start the particles. When the principal movement is by saltation, the capacity increases with fineness of solid up to and probably beyond the critical fineness at which the solid goes into suspension.

BLUE's experiments (*84 J 536*) were carried on in a U-shaped sheet-iron launder, 50 ft. long, 5 in. deep, with semi-circular bottom of 2-in. radius. Two classes of solid material were used, (*a*) beach sand (77 per cent. −40- +80-mesh; 1 per cent. −100-mesh; average size about 60-mesh), (*b*) sharp quartz sand containing varying amounts of clayey slime, in the proportions of about 10 per cent. of slime and 90 per cent. of sand; the sand averaged about 80-mesh, 90 per cent. −40 and 10 per cent. −200-mesh. Various mixtures of

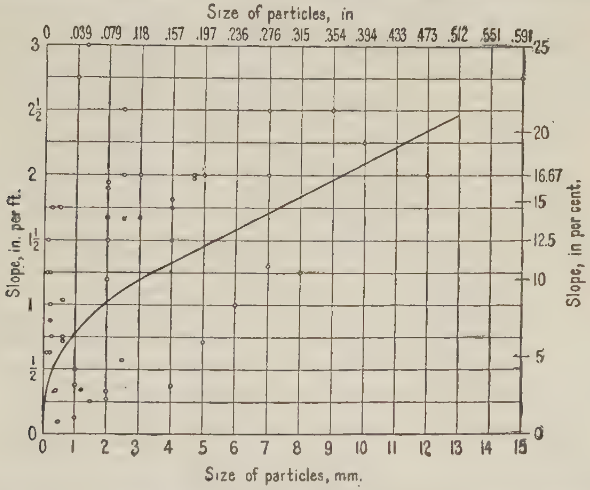

FIG. 29.—Relation between size of particles and slope of launder (*after Schmitt, 2 RMP*).

each of these solids with water were fed and observations made at the slope when the "least perceptible quantity of sand just began to fall to the bottom." Depth was measured to 1/16 in.; rate of flow and the proportion of solids by volume were determined by time samples taken at the discharge end and average velocities were calculated from these data. The results with beach sand indicated that the proportion by volume of wet solids in suspension, q, varied as the square of the slope S or, $S = k\sqrt{q}$. The sand-slime results were similar but less concordant; they indicated that with slime present more solid could be carried on a given slope with a given amount of water.

The value of k in above equation was determined to be 0.186 for the beach sand and 0.091 for the sand-slime mixture. Blue also used his results to calculate values of the COEFFICIENT OF ROUGHNESS, n, in Kutter's formula by solving for values of the constant C in the Chezy formula (Sec. 27, Art. 28) and substituting in Kutter's formula (Sec. 27, Art. 30). The values of n obtained indicated the relation, $n = 0.0125q^{0.055}$ for beach sand and $n = 0.0105q^{0.02}$ for the sand-slime mixture. These values of n can be used only when the roughness of the launder is about the same as that of the sheet-steel channel used. In the case of beach sand, an ill-defined relation exists between v and q, *e.g.*, $v = 8.148\sqrt[6]{q}$. The experiments covered slopes varying from 0.107 to 0.008, proportions of solids by volume from 0.0022 to 0.350; and depths from ⅝ in. up to 3¾ in. Calculated values of C varied from 72.2 to 135 and of n from 0.0080 to 0.0123. For the sand-slime mixture the slopes varied from 0.052 to 0.009, proportion of solids from 0.277 to 0.013, depths from ⅝ in. to 3¾ in., C from 70.0 to 128.0 and n from 0.0090 to 0.0118.

Julian and Smart (*Cyaniding gold and silver ores, J. B. Lippincott Co., 1921*) calculate the size of launders by use of the Chezy formula ($v = C\sqrt{rs}$) assuming a relation between width and depth to obtain the minimum wetted perimeter (for rectangular launders width = twice the depth) and making $C = 80$, which is an average value obtained from actual measurements of flow in launders carrying slime overflow and average stamp-battery pulp. Then if w = depth of the stream in ft., $2w$ = width, $2w^2$ = area of cross-section, $4w$ = wetted perimeter, $r = w/2$, and $v = C\sqrt{ws/2}$. If Q = cubic ft. per sec., $Q = 2vw^2 = 2Cw^2\sqrt{ws/2}$ or $Q^2 = 2C^2w^5s$, whence

$$w = \sqrt[5]{\frac{Q^2}{2C^2s}} = 0.151\sqrt[5]{\frac{Q^2}{s}}.$$

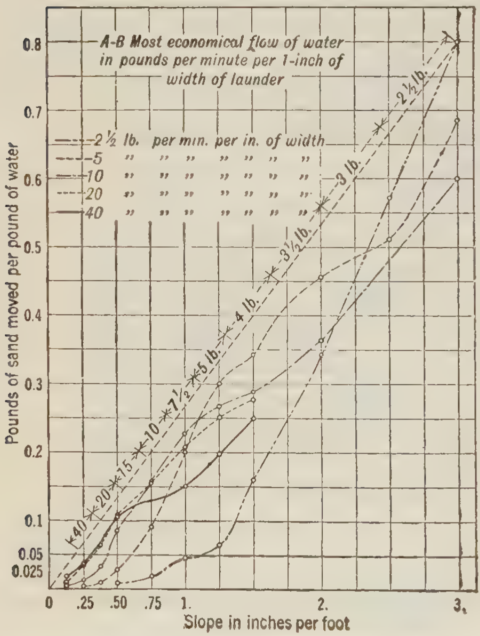

Fig. 30.—Launder flow (*after Overstrom and Richards*).

Any relation between the width and depth of the stream may be assumed; various assumptions should be tested until the size determined is best for the conditions at hand. In the construction of small wooden launders the width is influenced by the widths of good lumber available without ripping or making a longitudinal seam down the center.

Table 18 (*Gilbert, PP 86 USGS*) is of value in determining dimensions, using Julian and Smart's method for calculating launder size.

Richards (*3 OD 1592*) gives Fig. 30 from Overstrom's data. The most economical water quantity is determined by following the ordinate for a given slope to its intersection with the inclined straight line on which weight of water is indicated. The weight of sand that 1 lb. of water will transport is then found by following the same ordinate to its intersection with the curve for the economical water quantity and reading on the left-hand scale. To find the width of launder in inches divide the total weight of sand to be moved by the product of lb. of water per in. of width and lb. of sand moved per lb. of water.

Table 18. Depth of water in a rectangular wooden trough (planed and painted) 12 in. wide

The diagram was plotted from experiments with quartz from 40- to 150-mesh flowing in a wooden launder 2½ in. wide. It indicates that the amount of solid carried is independent of the wetted perimeter. The curves indicate that there is a certain quantity of water for each slope that will carry a maximum amount of solids per lb.

Launder performances are given in Tables 19 to 22. Table 19 shows limiting values of slope for each class of material. CANANEA ore (Table 20) consists of copper sulphides, native copper, garnet, sphalerite, galena and oxides and carbonates of copper in gangue of limestone, quartzite, quartz porphyry and diorite country rock. ANACONDA ore (Table 21), see p. 82. The slopes given are not necessarily minimum but were considered safe; extra headroom was utilized when available. LUCKY TIGER ore is a complex sulphide (Table 22).

Shape of launder. Frictional resistance can be reduced in flumes or conduits for water by making the shape of the channel such that the wetted area is the smallest possible for the volume flowing. This is accomplished by making the bottom semicircular which gives the smallest wetted perimeter for a given cross-section. The same thing is true in transporting pulp in launders, when the solid material is practically all carried in suspension, but when the solid material is carried wholly or in great part by rolling, a semi-circular bottom restricts the area available for free motion of the particles, and a rectangular cross-section is better. Gilbert found that rectangular or box flumes can carry more coarse solid than semi-cylindrical flumes of similar width and the same flow of water. Reduction of wetted perimeter to a minimum leaves minimum area exposed to the abrasive action of solid material in the stream and liner consumption is thus decreased. But the condition of least wetted perimeter may not always be most desirable. Where comparatively coarse material is transported, chiefly by rolling or sliding, it may be advisable to use a shallow stream, only slightly deeper than the size of the largest pieces of solid; increase in depth beyond this point increases the amount of water used but only slightly increases the effective velocity in the lower zones of the stream. Gilbert, dealing with relatively coarse material in flumes, found that up to a certain limit, varying with conditions, the carrying capacity of the stream increased with increasing relative width of channel and concluded that the ratio of depth to width for highest efficiency under such conditions would rarely be greater than 1 : 10 and often as small as 1 : 30, but that on large operations the width would usually represent a compromise between efficiency and cost of construction and maintenance.

The use of wood for launders leads naturally to rectangular cross-section. Triangular-shaped cleats nailed into the corners of wooden launders make the shape of the bottom approach semi-circular. V-SHAPED LAUNDERS of wood are used to a limited extent; the advantage lies in the simplicity of construction. The shape may be easily made whatever is desired when sheet steel or cement is used.

Reinforced-concrete launder (Fig. 31) (*96 J 22*), was designed to carry overflow water 400 ft. It was cast in 16-ft. sections. The concrete mixture was 3 parts of ⅝-in. jig tailing, 3 parts ordinary mill tailing from ¼-in. to 10-mesh, one part fine sand and one part cement; the bottom was 2½ in. thick; the sides 3 in. at the top, increasing to 5½ in. at the bottom; a 4 × 1-in. ridge was carried along the bottom on each side; strands of worn hoisting rope were used for reinforcement. Single ½-in. strands were run along the top and two double ½-in. strands were placed along the bottom on each side. These were wrapped with wire about 5 ft. from the ends and two single strands, one from each pair, were taken up to the top of the side (C to A) while other two strands continued to the end of the section. Hooks (A) of ⅜-in. rod threaded at one end were used to draw the strands tight. Pieces of 1 × ⅛-in. strap, (B) were put in at 18-in. intervals; at every other strap a

piece (*C*) was run across the bottom with a slight turn-up at each end. The bottom was reinforced longitudinally by three ½-in. strands above the straps. Forms of 1-in. board were built up as shown; the bottom form (*D*) was supported on wedges (*F*), made by ripping

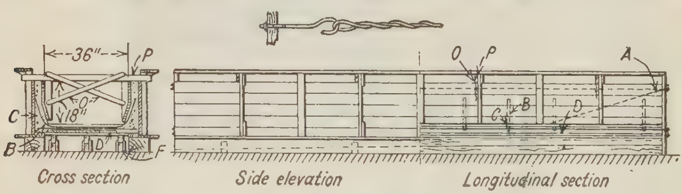

Fig. 31.—Reinforced-concrete launder.

2 × 10-in. hardwood planks, 16 ft. long, diagonally; it was easily removed by knocking out these wedges. The inside forms were held in place by ¼ × 1-in. iron braces (*O*), so arranged that the forms could be swung in and held in place away from concrete when removing by use of extra holes in the braces. The cost was $0.75 per ft., compared with $2.40 per ft. for iron pipe of equivalent capacity.

Turns and bends should be avoided, if possible; sharp turns cause clogging on flat slopes and bends cause excessive wear of linings. The slope at turns is generally increased to avoid clogging. Schmitt (2 *RMP 88*) recommends bend radii not less than 10 times the width of the launder and increase of from 1 to 2 per cent. in slope. Junctions should be made so that the direction of flow in each launder is approximately the same. Boxes or small sumps are frequently used at junction points and sharp turns; the exit should be raised a few inches above the bottom so that the bottom may fill with settled solid and decrease wear and splashing.

Depth of launder should be sufficiently greater than the depth of the stream to take care of splashing and of any sudden surges. *Julian, Smart and Allen* recommend making the launder 50 per cent. deeper than the stream for steady flow and 100 per cent. deeper where fluctuations are expected. Launders in practice show a much greater allowance in most cases. Of 53 launders, 45 had depths more than three times the wetted depth, the range was 1.3 times to 20 times and the average about 7.6 times.

Liners are important not only from the standpoint of frictional resistance but also because of the wearing quality and cost of different materials. Wood is usually the most easily available material but its life is short, except where only fine material in dilute suspension is flowing. Small wooden launders carrying material less than 1 mm. maximum size are generally left unlined; larger sizes are sometimes wood-lined. The life of wood in such service is long, it is easily replaced and its lightness saves in the amount of support necessary. The life can be increased indefinitely by placing cleats of wood or angle iron across the bottom at short intervals; solid material banks behind the cleats and makes a natural lining; frictional resistance is increased, however, and slope must be increased.

At the YMIR MINE, West Kootenay, B. C. (*34 A 602*) a 6 × 8-in. box-launder with 1-in. transverse riffles spaced 5 in. had a satisfactory life even when using soft hemlock or cedar lumber; the material was vanner tailing; the minimum slope was slightly under 5 per cent. (0.6 in. per ft.). At ALASKA GASTINEAU a 2-in. fir lining in a 22 × 44-in. launder carrying 5000 tons per 24 hr. of − 1-mm. material in a pulp containing 15 per cent. solids on a slope of 0.38 in. per ft. lasted 187 days.

RUBBER BELTING is a light and long-wearing lining, flexible and easily applied to wooden launders, but unless unfit for other service the cost is high.

At U.S.S.R. & M. Co. (Midvale) old ⅝-in. rubber belt used in 10 × 8-in. launder, sloped 3¾ in. per ft., carrying 25 tons per day of heavy − 1.0-mm. concentrate in a 1 : 1 pulp lasted two years. Similar belt in a 10 × 10-in. launder sloped 2¾ in. per ft. and carrying 85 tons per day of sand-table tailing of the same size in a pulp of 18 per cent. solids lasted over three years.

CANVAS BELTING is also sometimes used but the rougher surface increases frictional resistance. SLAG LINING was used at PHELPS DODGE CO., Morenci, Ariz. (*102 J 644*).

The slag castings were channel-shaped sections 12 × 12 × 2-in. weighing about 40 lb. each, reinforced with 1- or 1½-in. hexagonal 26- or 28-gage poultry wire. The slag was poured into metal molds standing on end with two pieces of reinforcing wire placed in each side; when the slag had chilled slightly, the molds were removed and the hot castings buried in a sand bed to allow slow solidification of the center and thus avoid shrinkage strains. The cost was not over 12 cents per ft. as compared to $0.90 to $3.00 per ft. for white-iron castings. Their use in the 1500-ton concentrator showed a saving in liner costs of $6000 per year over a period of 2½ years. In a two-mile tailing flume the cost in 1912 for cast-iron lining was $7015 or $0.01397 per ton. In 1914 cast iron and slag were both used; the combined cost was $1873.50 or $0.00407 per ton. From Jan. to July, 1915, slag lining cost $498.13 or $0.00197 per ton. In a launder taking roll product to an elevator, cast-iron liners lasted 90 days compared with 180 days for slag; cast-iron liners in launders carrying Wilfley-table feed lasted 60 days while slag liners were still in use after 240 days. In the tailing flume the slag lining had an estimated life of 6 years compared with yearly re-lining with 2-in. plank. Slag lining in chutes running dry was satisfactory for material up to ⅝-in. Such utilization of slag is a useful outlet for a product ordinarily waste; its use, however, is limited to plants where slag is readily available.

SHEET IRON OR STEEL, old boiler plate and discarded crusher steel and similar material are frequently used for launder linings. Table 23 shows the life of sheet-steel liners under various conditions.

CAST-IRON LINERS are usually made in short channel-shaped sections. The useful life of such lining is shown in Table 24.

The life of ⅝-in. cast-iron liners at FEDERAL LEAD CO., Flat River, Mo., in launders varying from 6 in. to 13 in. wide and carrying different materials, was from 8 to 10 months.

CONCRETE lining is readily made in convenient lengths and sizes and makes a very satisfactory and cheap lining.

At CONSOLIDATED MAIN REEF mill (*19 JCM 77*) U-shaped sections of concrete lining were cast in 18-in. lengths, 9 in. deep and 11½ or 13½-in. outside widths. The thickness

at the bottom was 2 to 2¼ in., tapering to 1 in. on the sides at the top. The average weight of an 18-in. length was 75 lb. Bend blocks for the turns were made of the same cross-section. Concrete slabs, 2½ in. thick and of various lengths, were also used. The mixture was one part quartzite dump waste crushed to ½-in., one part of the − ¼-in. fine material from the above crushing, 1 part of washed drift sand and 1 part of Portland cement. After concrete was poured into the molds it was allowed to set for two days, then submerged in water for 6 or 7 days, when it was ready for use. The joints between lengths were sealed with quick-setting magnesia cement or with mill blanketing. Cost for U-shaped blocks, including labor, material and installation, was about $0.40 per running foot, which was little more than the cost of 1-in. pitch pine with 3 × 3-in. fillets and much less than the cost of lining with belting. Except at bends the concrete had a very long life (see Tables 25 and 26).

Steel bars set in concrete (*19 JCM 77*). Discarded Osborn-liner bars in 7-ft. lengths were set on edge and laid in cement on the bottom and sides of a 14 × 12-in. launder having triangular wooden fillets nailed in the corners. The lining was from ⅝ in. to 1 in. thick and could be placed and dried for use within 9 hr. Quick drying was accomplished by slowly burning old bags soaked in kerosene on top of the cement lining. Slope was 8.5 per cent; pulp was 74 to 61 per cent. +60-mesh, 14 to 20 per cent. +90-mesh and 12 to 19 per cent. −90-mesh. Life was 4½ years, except at points of division and at the feed intake where replacement was made at the end of 2 years. A similarly lined launder carrying stamp-mill discharge showed little wear after 2 years. The cost of lining 100 ft. of a 12 × 14-in. launder and using 3600 lb. of discarded steel was estimated at $19.50 for labor and material; this was about one-seventh of the cost of new belt lining which was estimated to last only 6 months.

Glass is sometimes used in launders carrying fine material. The smooth surface reduces frictional resistance so that a flatter slope than otherwise can be used. Wear is long but the glass tends to crack.

Resistance of different lining materials to flow. Schmitt (2 *RMP*) says that cement, wood, and rubber belt give practically the same resistance and that canvas belt decreases velocity.

Browning (*29 M & M, 300*) found that a given flow of water carried more angular tailing and pyrite on flat slopes in linoleum-lined and wood launders than in glass-lined ones. The capacity for rounded gravel was greater in every case in the glass-lined launder, probably due to absence of eddy currents and ease of rolling the rounded particles on the glass surface. In general, high velocities cause increased wear on lining.

Splitting the stream cannot be done satisfactorily by taking the laterals off directly; the best method is to use vanes to split into parallel streams and subsequently lead the streams apart.

Pipe launders. Pipes running partially full are sometimes used as launders. Ordinary iron pipe is most common, but wood-stave and vitrified clay pipe are also used. Large-sized iron pipes are sometimes lined with wood. When worn, a new surface is presented by turning the pipe.

At Guanajuato (*95 P 78*) 8-in. pipe was used for transporting −30-mesh, sharp, granular quartz-calcite tailing 5440 ft. The pipe was ⅝-in. thick; bell-and-spigot joints were calked with tarred hemp rope loosely driven; the outside was asphalted for protection against rust; curves were mostly 14-ft. radius; slope was 3½ per cent. for the first 800 ft. and 2¼ per cent. for the remainder. The pulp was reduced to 25 per cent. solids before entering the pipe; occasional increase in thickness caused some deposition of sand; delays due to clogging totaled four hours in 13 months. At full mill capacity, 250 tons per day, the pulp ran 1¾ in. deep, and traversed the pipe in 12 min., equivalent to 7.5 ft. per sec. The pipe could carry 1000 tons per day. No appreciable wear was noticed after 13 months (100,000 tons transported) and the life was estimated at 50 years. At about 500 tons per 24 hr. with 5 : 1 dilution the pipe ran a little less than half full (*95 P 457*). A 12-in. pipe running partially full carried sandy tailing at Homestake (*22 IMM 87*). Joints were made with a loose sleeve coupling held in place by wedges, which permitted turning without shutting down; pipes were turned 120°, so that three different wears were obtained from the same length of pipe by turning twice.

11. Centrifugal pumps

Single-stage centrifugal pumps are limited, in general, to lifts under 50 ft. but in several instances these pumps work against heads of from 60 to 80 ft.

Multi-stage pumps are used for larger lifts. Lifts greater than 50 ft. are rarely encountered in handling mill pulps so that very few multi-stage centrifugal pumps are found in mill work. The open-runner single-suction volute pump (Fig. 32) is most generally used. Material enters through a suction pipe and is delivered to the center of the revolving impeller, whence it is thrown by centrifugal force imparted by the blades to the periphery of the pump chamber and is discharged through the vertical pipe. Pressure to lift the fluid is obtained by the conversion of a large part of the velocity head produced by the rotation of the impeller to pressure head. The direction of motion of the fluid at the instant it leaves the impeller is the resultant of motions tangential to the periphery of the impeller and to the surface of the impeller blade. The volute chamber is designed so that the change from velocity head to pressure head shall take place with the smallest possible loss; thus in Fig. 32 the size of the chamber increases gradually towards the discharge pipe. The head which the pump must develop equals the difference in head between the intake and discharge levels, plus the velocity head required to give motion to the fluid, plus losses in the pump and losses due to friction in the pipe lines. The shape and curvature of the impeller blades are important considerations in design for any given service. Fig. 33, *A*, shows charac-

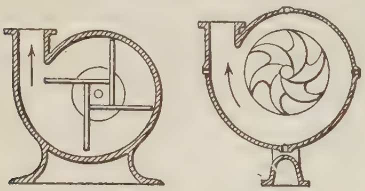

Fig. 32.—Centrifugal pump.

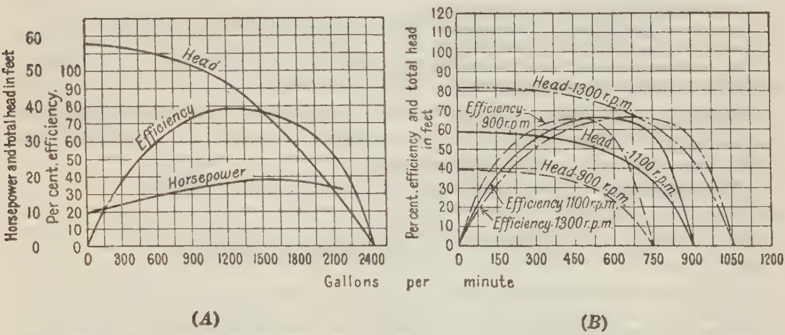

Fig. 33.—Characteristic curves of centrifugal pumps (*Morris Machine Works*).

teristic curves of a single-stage centrifugal pump operating at constant speed. Fig. 33, *B* shows the effect of change in speed. The general shape of the curves is the same for all speeds; it is determined by the design of the pump and especially the inclination and position of the vanes of the impeller. The curves for any given pump explain the changes which occur with changes in the conditions under which the pump operates. The size of a pump is usually designated by the size of the discharge pipe. Table 27 gives sizes and dimensions of one make; Table 28 gives the speed at which a pump should be run to deliver its most economical capacity against any required head.

Impellers may have 4, 6 or more blades; the shells may enclose liners or the shell itself may be designed to take the wear. Impellers and liners are generally made of cast-iron or

a Refers to low-lift pumps.

manganese steel. For special work with hot, acid or corrosive liquids, brass, rubber or other resistant materials are used. The greatest wear is on the impellers and liners and varies with the material being pumped; it varies with the size of particles in the pulp, hardness of the ore, shape of pieces, and, with the dilution; coarse material causes greater wear than fine; very dilute and very thick pulps wear less than those of intermediate density.

Table 29 summarizes data on life of impellers and liners of various sizes of centrifugal pumps at 16 different plants; the short life of the smaller-sized pumps raises a doubt as to their economy. LOST TIME varies from 0.5 per cent. to 5 per cent. of the possible running time; the chief cause is replacement of worn impellers and liners; in larger pumps several hours may be consumed in this work. Where pumps are to run continuously duplicate units should be installed to prevent shut-downs for repairs.

a Dilution of pulp varied from 60 per cent. water to 95 per cent. water. Lifts varied from 18 ft. to 80 ft. Speeds varied from 350 r.p.m. to 1200 r.p.m.

Drive may be either by belt or direct connection to a motor or steam engine. A direct-connected motor makes a compact, independent unit but is not advisable if the pump is located in a wet place or where there is danger of flooding. Belt drive is preferable in wet stations or where a line-shaft is convenient. If the drive belt is too tight, excessive wear of bearings results; if the pump turns hard, the cause should be sought in the pump itself.

Feed may be either suction or gravity; the latter is better. If suction feed is used, the pump must be primed when starting. Priming is best done by introducing water into the discharge pipe just above the level of the top of the pump; the water should be supplied through a separate water line with a valve. A tee in the discharge line with nipple, elbow and removable plug furnishes manual means of priming. Steam ejectors are sometimes furnished for priming large pumps. Priming is complete and the pump ready to work when the suction line and the pump itself are completely filled with water. Provision of a pet-cock let into the top of the pump allows the escape of any air which may be pocketed there during priming or accumulate during running. The SUCTION PIPE is usually one or two sizes larger than the discharge pipe and should be as straight and free from bends as possible. Bends should be of long radius to decrease friction losses. FOOT VALVES and STRAINERS are usually provided on the suction pipe; the free area through these should be about twice the inside cross-sectional area of the pipe. All joints in the suction pipe should be made carefully to prevent leakage of air, which would reduce or destroy suction.

Stuffing box. Leakage of air into the pump or leakage of fluid from the pump where the shaft passes through the shell is prevented by a stuffing box and gland. Water at a pressure slightly higher than that developed by the pump (about 1 lb. for every ft. of lift) is forced in to the bearing through a small hole tapped in the top and connected to the water line; this keeps gritty or acid material from getting into the bearing and also aids in keeping the packing in the stuffing box from hardening and cutting the shaft. Square flax PACKING treated liberally with oil and graphite and cut in rings to go just once around the shaft is used in the stuffing box. The GLAND should be made just tight enough so that 5 or 10 drops of water per min. leak out; excessive tightening causes heating and wear on the shaft with loss of power.

Suction lift. Table 30 gives the approximate theoretical maximum suction lifts in ft. at 60° F. for various altitudes and fluid densities; actual lifts ordinarily will not exceed one-half the theoretical. Increase in temperature reduces the maximum suction lift, due to increased liberation of vapor at higher temperatures. Table 31 shows the effect on suction lift with increase in temperature; very hot fluids should be fed by gravity.

Table 30. Approximate theoretical suction lifts at 60° F. (*17 CME 629*)

Altitude above sea level	Specific gravity of fluid, thousandths

Discharge pipe layout should be carefully made; a level run may cause clogging; bends should be as few as practicable and of long radius; valves should not be placed in pulp lines, since closing may cause solid material to pack so that the line will not clear again when the valve is reopened; stopping the pump may cause similar trouble. Provision of a by-pass to be opened just before stopping the pump will clear the pipe; shutting off the pulp supply and substituting clear water before shutting down is also effective. The by-pass is the best arrangement, as the pipes can then be drained immediately, if the pump stops accidentally.

Velocities of 350 ft. per min. in discharge pipes and 200 ft. per min. in suction pipes will, in general, prove satisfactory.

Size of feed. Centrifugal pumps successfully handle pulps containing coarse particles. They are frequently used to elevate pulps containing up to ¼-in. particles; large pumps used in hydraulicking operations successfully handle gravels containing fair sized rocks.

A 12 × 24-in. pump in one mill was reported as handling 600 tons per 24 hr. of − 1¼-in. + 20-mesh material together with 4500 gal. of water per min.

Efficiency of well-designed pumps doing good work will vary from about 50 per cent. for the smaller sizes to about 75 per cent. for large sizes. These efficiencies are not always attained in practice as the pumps may not be working under the most favorable conditions. In handling pulps, the high velocity attained keeps the solid material in suspension. Possible dilution of certain pulps from the water admitted to the gland may make it desirable to choose some other means of elevation.

Advantages. The centrifugal pump is simple, requires little space and the attendance while running amounts to only a small portion of a man's time, to determine whether it is functioning properly.

Costs. Jones (*52 A 116*) [1915] gives the following figures covering the cost to operate a 4-in. solid-lined Krogh centrifugal pump elevating filter feed 55 ft.

	Cost, dollars	Per cent of total
Liners	482.57	37.97
Runners	126.72	9.97
Housings	81.00	6.37
Bushings	36.00	2.83
Shafts	22.84	1.80
Chain and sprocket	47.65	3.75
Gland	1.89	0.15
Strand	11.25	0.89
Labor	53.12	4.18
Power @ \$8.82 per hp.-month (39 hp.)	408.00	32.09
Total	1271.04	100.00
Wet tons pumped	755,255	
Cost per ton	\$0.00168	

Wilfley centrifugal pump (Fig. 34) has a centrifugal seal where the shaft passes out of the pump casing and thus avoids the need of a stuffing box. The success of the centrifugal seal in protecting the bearings from gritty and hot solutions permits the use of ball bearings on the shaft with consequent saving in wear and power. The pump has no suction; feed enters intake (*a*) thence through a passage to the enclosed-type impeller (*c*). The discharge pipe is screwed into the keeper (*l*), which is raised or lowered by bolt (*m*), when removing the case; the joint between the keeper and the case is made with a ring of square packing. The centrifugal seal consists of a revolving expeller (*d*) having radiating wings similar to an open runner and a stationary member having a projecting groove (*e*). Material leaking by the edge of the expeller encounters the groove (*e*) and is directed towards the wings of the expeller which eject it again. When the pump stops, an automatic check valve closes around the shaft, preventing any leakage. Wearing parts are easily and quickly removable by loosening two nuts which hold the shell (*f*), when the shell can be swung aside on arm (*g*), giving access to the impeller, the follower plate (*h*) and expeller. The joint between the follower plate and the frame is made with a ring of square packing (*i*), set in a groove in the frame; the joint

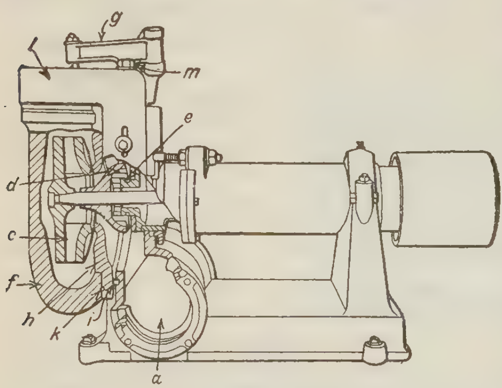

FIG. 34.—Wilfley centrifugal pump.

between the follower plate and the case is made with flat faces and a round rubber gasket (*k*), cemented into a groove in the follower plate.

This pump has been very successful in handling gritty or sandy materials. Tables 32 and 33 give details of capacity and speed of the various sizes.

12. Spiral pump

Frenier pump (Fig. 35) consists of a spiral wheel, (*a*) revolving in box (*b*) which contains the fluid to be elevated. Material entering the spiral through the opening (*c*) advances toward the center and is discharged through hollow shaft (*d*) and the stuffing box and gland connection (*e*) to discharge pipe (*f*). The weighted lever (*g*) takes up the thrust of the delivery pipe. With each revolution of the wheel, fluid is scooped into the spiral and air enters during the remainder of the revolution so that a portion of each succeeding turn of the spiral is filled with the fluid to be lifted. The lifting force results from the difference between the sum of the hydrostatic heads resulting from the fluid in the spiral and the pressure induced as the fluid enters the spiral, and the head of aerated liquid in the discharge pipe. The lifting force is independent of the speed of revolution; it can be increased only by an increase in the number of turns of the spiral or diameter of the wheel. The makers recommend 20 r.p.m. as the most satisfactory speed. The radial distance between suc-

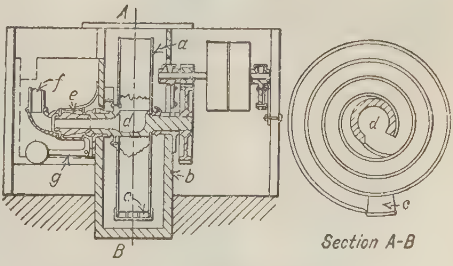

FIG. 35.—Frenier pump.

cessive turns of the spiral is generally 2½ in. Table 34 shows maximum capacities and lifts for the various standard sizes of pumps.

The Frenier pump is suitable for elevating solutions, sand or slime pulps to heights ordinarily not greater than 10 or 12 ft. but in several instances lifts as great as 16- and 20-ft. have been made. The pump will not operate satisfactorily under changing conditions. The level of fluid in the FEED box should be 7 in. below the shaft. If the pump is overloaded, it will stop working; it does not work well when under-fed; frequently it is fed at a rate slightly in excess of capacity and an overflow is provided on the feed box; the material overflowing is then handled by an auxiliary air-lift with float-control valve. The greatest WEAR takes place between the rotating tube at the end of the hollow shaft and at the bend of the discharge pipe. For most efficient operation the discharge pipe should be vertical and have a vertical discharge opening with free fall to allow the escape of air. The construction is simple and little attendance is required.

13. Diaphragm pump

DIAPHRAGM PUMP (Fig. 36) (*18 JCM 95*) consists of a hollow chamber with a valve in the bottom and a movable diaphragm, also valved, which closes the top of the chamber. The diaphragm is given an up and down motion by a connecting rod from an eccentric on a pulley- or gear-driven shaft. To start, the pump is primed by completely filling the chamber and the space above the diaphragm with water. On the up stroke of the diaphragm the lower valve opens and admits fluid to the chamber from the suction pipe; displacement of the fluid in the space above the diaphragm causes some of it to overflow the lip shown. At end of the up stroke the lower valve closes and on the down stroke the upper valve opens and allows fluid to flow from the underside of the diaphragm to the space above it. At end of the down stroke the lower valve again closes and the cycle is repeated. The DIAPHRAGM is made of a rubber sheet about ⅜ in. thick with a single ply of loosely-woven duck imbedded in it. The working surfaces of valves and seats are best made of high-grade rubber; this wears well and gives tight closure even when small

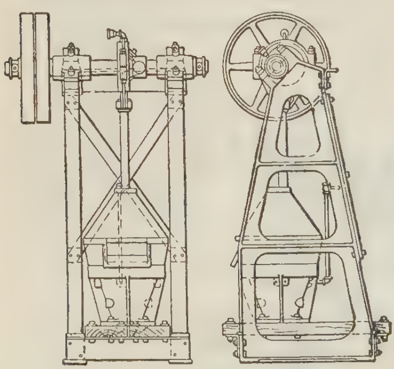

FIG. 36.—Diaphragm pump.

chips get between the valve and seat. The floating type of valve allows complete washing of the seat at each opening.

Height of lift of diaphragm pumps is limited by atmospheric pressure and also by the strength of the diaphragm; lifts should never exceed half the theoretical lifts of Table 30; ordinarily lifts are less than 8 ft. SPEED may be from 15 to 100 strokes per minute but the most satisfactory operation is with less than 40 strokes per min.; higher speeds cause splashing. STROKE may be lengthened as much as the diaphragm will stand. CAPACITY may be varied by changing the speed or length of stroke or it may be controlled by admission of small quantities of air into the chamber through a pipe with a needle valve.

The diaphragm pump has found its greatest application in elevating and controlling the underflow from thickeners. It is simple to operate and requires little attendance and repair. Pulps containing as much as 50 per cent. solids are easily handled.

At HOLLINGER (*57 A 150*) a No. 4 Goulds diaphragm pump with 3-in. stroke performed as follows:

No. strokes per min.	Vol. per stroke, cu. ft.	Sp. gr. of pulp	Per cent. solids	Tons solids pumped per day	Per cent. increase in speed	Per cent. increase in volume per stroke	Per cent. increase in tonnage
14.5	0.139	1.54	54.5	76.3			
23.0	0.148	1.48	50.5	114.5	58.5	6.5	50.0

The life of a diaphragm was more than one year when operating at from 14 to 18 strokes per min. while rubber valves and seats showed no perceptible wear in six months.

14. Tailing wheel

Tailing wheel (Fig. 37) consists of large rotating wheel with projecting buckets on one or both sides of the rim. When at the bottom the buckets scoop up pulp from a pit and at the top deliver it into a receiving trough or launder. The old type wheels were constructed of wood but newer ones are of steel, either rigid or of bicycle-spoke construction. Wood is best, even on steel wheels, for lining the rim flanges and the vanes forming the buckets. Tailing wheels have been most used on the Witwatersrand to elevate stamp-mill tailing. Wheels up to 60-ft. diameter have been made. The net lift, *i.e.*, the distance between the level of the feed launder and that of the receiving launder, is less than the diameter of the wheel to an extent determined by the inclination of the bucket vanes to the wheel radius. Julian and Smart give the RATIO OF DIAMETER TO NET LIFT is about 1.3 : 1 and recommend an angle of 65° between the radius and the bucket vanes. Usual SPEED is about one-third the critical speed at which centrifugal force would prevent bucket discharge. Table 35 gives critical and practical speeds for wheels of various diameter. The time required for buckets to discharge is given by Wood and Laschinger (*77 J 482*) as not less than 3 sec. on 40-ft. wheels or 5 sec. on 60-ft. wheels. DRIVE may be by belt and pulley mounted on the shaft or by pinions and gear, or by a sheave built into or around the outside of the wheel itself. Manila-rope drive on sheaves has been most favored.

The first COST of tailing wheels is high; large wheels require heavy construction and massive supports for the shaft bearings. Maintenance and repair costs are low. Reliability and durability are high. POWER EFFICIENCY is usually from 40 to 50 per cent. Centrifugal pumps and bucket elevators cost less, require less space, and are generally more desirable than tailing wheels.

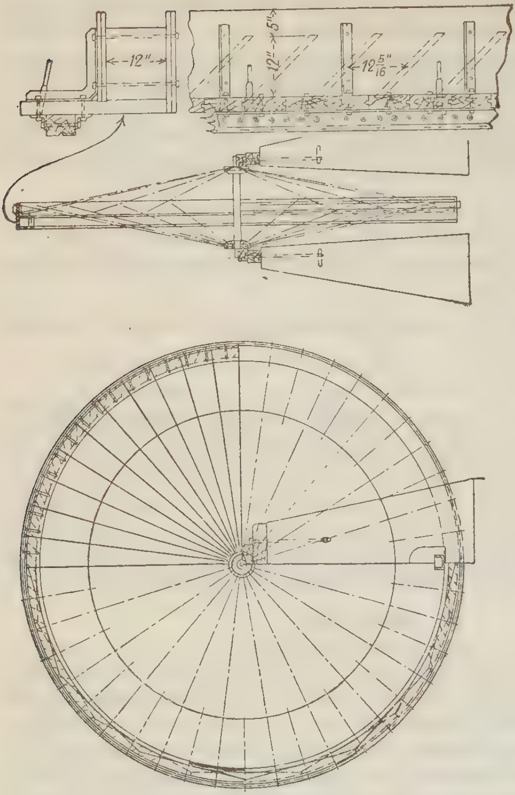

FIG. 37.—Tailing wheel.

At CALUMET AND HECLA plants (*90 J 218, 12 MH 308*) five tailing wheels, one 40-ft. diam., three 50-ft. and one 60-ft. elevate coarse mill tailing to launders running out over Torch Lake. The 60-ft. wheel at HECLA weighs 500 tons with base plates and columns; it is bicycle-type with a hollow shaft, 32 in. outside and 16-in. inside diameter by 27 ft. long; 4-in. spokes radiate from two 10-ton hubs to the outer rim upon which are mounted two spur gears with 12-in. face and 4.7-in. pitch. The buckets are 3 ft. wide × 4 ft. 6 in. long and are mounted on each side of the rim. A 37-in. pinion on the counter-shaft is driven by ropes from a 700-hp. motor. The speed is about 4 r.p.m., equivalent to about 12 ft. per sec. at the inside edge of the buckets. The buckets dip into a trough under the wheel and deliver to two troughs above, making a total lift of about 50 ft. CAPACITY is about 5500 gal. per revolution. The KENNEDY MINING AND MILLING Co., California, used four 56-ft. tailing wheels in tandem to elevate stamp-mill tailing to flumes (*97 J 517*). A wooden flume delivered to the first wheel about 1500 ft. from the mill; the second wheel was 100 ft. distant, the third, 820 ft., and the fourth, 200 ft. The LIFT was about 35 ft. in each

Table 35. Critical and actual speeds of tailing wheels

Diameter of wheel, feet	Critical speed		Actual speeds (⅓ critical speed)	
	Revolutions per minute	Peripheral velocity, feet per minute	Revolutions per minute	Peripheral velocity, feet per minute
10	24.218	761	8.07	254
20	17.125	1076	5.71	359
30	13.983	1318	4.66	439
40	12.110	1522	4.04	507
50	10.830	1701	3.61	567
60	9.887	1863	3.29	621
70	9.154	2013	3.05	671

wheel; the flumes were set on 2½ per cent. grade. The mill capacity was about 400 tons per day. At the old Belmont Mill, Millers, Nev. (*106 P 282*), stamp-mill pulp was lifted 48 ft. to classifiers by a tailing wheel. Operation was reliable and upkeep low; 87,952 tons were elevated in one year at a cost, including classifying, of 3.6¢ per ton. The Tonopah Mill, Millers, Nev. (*106 P 282*), had two wheels. No. 1 was 30-ft. diameter and elevated 500 tons of dry ore and 3500 tons of solution per day with a 7½-hp. motor. First cost was high but the wheels were efficient and maintenance was low compared to bucket-elevators. The cost of elevating and separating was 8¢ per ton. At the City and Suburban Mine, Witwatersrand (*77 J 481*) a 25-ft. wheel lifted 5549 lb. of tailing pulp per min. 19 ft. 1 in. The theoretical power requirement was 3.205 hp.; the actual power, including two intermediate countershafts was 6.635 hp.; total efficiency, 48.35 per cent. At Henry Nourse mine, Witwatersrand (Julian & Smart) a 60-ft. wheel was operated at 45 per cent. efficiency and consumed 15 hp. The drive sheave was 55-ft. diameter, driven at 3 r.p.m. by 1¾-in. manila rope from an 11-ft. sheave on the countershaft. The wheel axle was 20 ft. × 14 in. with bearings 2 ft. 6 in. × 12-in. diameter. The life of the rope was 3.5 years (*77 J 481*). At the Bullfinch Proprietary mill, W. A. (*13 CME 331*) a tailing wheel elevates the product of stamp mills to hydraulic classifiers. Diameter of wheel, 40 ft.; 112 @ 720-cu. in. buckets; peripheral speed, 400 ft. per min.; driven by manila rope, 6 in. in circumference, which lasts 60 days; power consumption, 7.3 hp.; about 2500 tons of ore and solution lifted per day.

15. Air-lift

The air-lift (Fig. 38) is used to elevate solutions, slime and, in certain cases, sand pulps. It consists of a delivery pipe (*a*) submerged for a part of its length in well or sump (*b*); compressed air is introduced into the delivery pipe at the foot-piece (*c*) through an air pipe (*d*). The air causes a decrease in the density of the fluid in the delivery pipe and consequent elevation by hydrostatic pressure and discharge at (*e*). Efficient operation depends on proper design of the lift and regulation of the air pressure. The known factors in any particular case are the amount of fluid to be elevated and the height to which it must be raised; the important items to be determined are the volume of air required, the pressure at which it must be delivered, the size of delivery and air pipes and the depth to which the delivery pipe must be submerged below the normal level of the liquid in the well or sump.

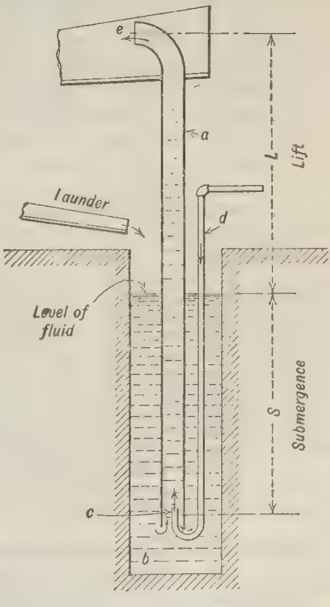

Fig. 38.—General arrangement of air-lift.

The depth of submergence (S) (Fig. 38) for most efficient operation at any lift (L) cannot be exactly determined in advance; if the air-lift is to handle large quantities of material so that a slight improvement in efficiency will cause considerable saving, provision should be made to vary submergence after operation is started. The figures in Table 36, based on average practice, may be used for calculation in design.

Air pressure. The pressure at which air must be delivered to the foot-piece is governed solely by the depth of submergence (S) and should be just sufficient to force air into the delivery pipe; $P_1 = 0.434gS + P$, where P is the atmospheric pressure in lb. per sq. in., P_1 is absolute pressure of air entering the foot-

piece and g the sp. gr. of the fluid to be elevated. A slightly higher pressure will be required in starting up. The pressures at which air is supplied at the foot-piece in operating lifts conforms closely to the theoretical pressures thus calculated. Excessive pressure causes air to escape from the bottom of the delivery pipe into the well; this reduces the density of the fluid therein and may stop the lift; at any rate, to keep the lift in operation under such circumstances will require a large excess in volume of air and so reduce efficiency.

Table 36. Submergences for air-lifts. (*Sullivan Machinery Co.*)

Lift in feet (L)	Submergence, per cent. $\left(\frac{100S}{S+L}\right)$
Up to 50	70–66
50–100	66–55
100–200	55–50
200–300	50–43
300–400	43–40
400–500	40–33

Volume of free air required may be calculated by the following formula: $V_a = 0.8\ L/C \log [(S + 34)/34]$ (**1**) in which V_a = cu. ft. of free air per gallon of fluid (at normal pressure, P_a, 14.7 lb. per sq. in. and 60° F.) and C = a constant varying with height of lift, L. Values of C are given in Table 37. Results obtained closely approximate actual values.

The size of delivery pipe required can be calculated from the amount of fluid to be delivered in a given time and the volume of air used during that time. Certain values for velocity have been found satisfactory in practice and by taking pipe of a size to keep within these limits losses due to friction will be kept within reasonable amounts. The VELOCITY OF THE FLUID in the discharge pipe increases as the top is neared due to expansion of the contained air. The velocity at the foot-piece may be taken at from 4 to 8 ft. per sec. and the velocity at discharge should be kept under 20 to 25 ft. per sec. Velocities should never be so low that solid material will settle out of the rising liquid or less than the velocity at which the largest air bubbles will rise in the fluid.

Table 37. Values of C in equation (1)

Lift in feet	C
10–60	243
61–200	233
201–500	216
501–650	185
651–750	156

Let V_1 = cu. ft. of air per min. at pressure P_1; P_1 = absolute pressure of air at the foot-piece, lb. per sq. in.; Q = cu. ft. of liquid per min.; v_1 = velocity in ft. per min. at foot-piece (assumed between 250 to 450); A = internal area of the delivery pipe in sq. ft.; q = gallons of liquid per min. Then $Q = q/7.48$ and $V_1 = qP_aV_a/P_1$. The total volume of air and liquid at the foot-piece equals $Q + V_1$ cu. ft. per min. and the required area of the delivery pipe = $A = (Q + V_1)/v_1$. Standard pipe nearest this size may be used.

The velocity of the air-liquid mixture at the discharge should be calculated to insure that it is not greater than 20 to 25 ft. per sec. Expansion of the air on rising may be considered isothermal since the air is in small bubbles surrounded by water.

Some authorities allow capacities of 10, 12 or 15 gallons of fluid per min. per sq. in. of cross-section of the delivery pipe and calculate the size of pipe on this allowance, but it is wise to check by calculating actual velocities at the foot-piece and discharge.

Size of air pipe can be found by reckoning air velocity at 20 to 30 ft. per sec.; velocities up to 70 ft. per sec. are sometimes used but friction loss is higher.

Foot-pieces are of various designs; the simplest is merely the projection of the air pipe into the lower end of the delivery pipe (Fig. 38). Other forms are shown in Figs. 39 and 40. The air should be dispersed as completely as practicable; large air bubbles rise faster than small with consequent greater slippage of the liquid past the bubbles. To reduce SLIPPAGE to a minimum, the more complicated foot-pieces introduce the air through many small holes, thus obtaining smaller bubbles and better dispersion.

Tests have shown that the efficiency of the system is increased appreciably by use of properly designed foot-pieces. At the East Rand Proprietary Mines, Ltd. (*105 EL 26*) efficiencies were 17.7 per cent. and 27.5 per cent. with a foot-piece with air admitted through a single 4-in. opening compared with efficiencies of 37.15 per cent. and 30.55 per cent. with the improved style shown in Fig. 40. These tests were made on lifts elevating slime mill pulps weighing 63.3 lb. per cu. ft. about 30 ft. A slight flare at the lower end of the foot-piece is advantageous in furnishing a gradual increase in velocity of entering fluid.

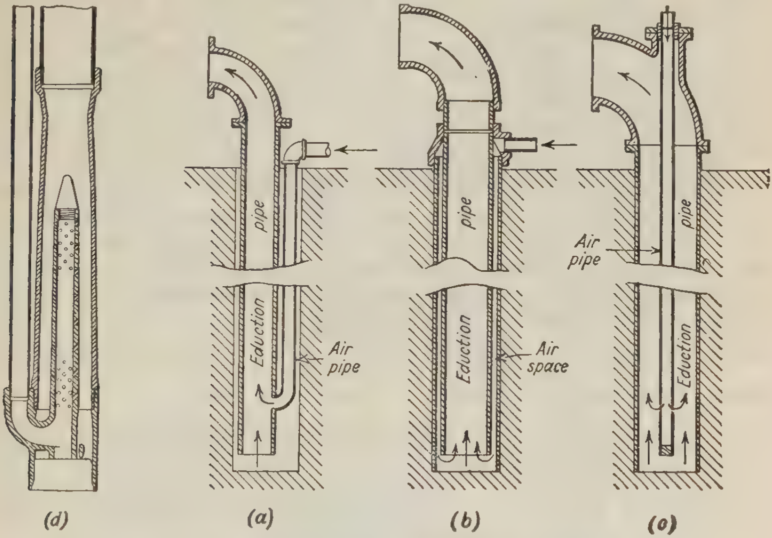

Fig. 39.—Foot-pieces for air-lifts (*Sullivan Machinery Co.*).

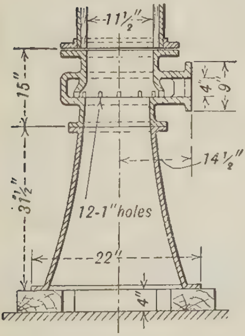

Diameter	Inches	
	No. 1	No. 2
Outside top flange	21	23
Inside pipe	11½	13½
Outside flange below air inlet	19	20
Inside bottom of bell	22	30

Fig. 40.—Foot-piece for sand and slime pulps (*105 EL 26*).

Discharge pipe is sometimes increased in size upward on long lifts to keep down the velocity. The advantages of changing to a larger size with ordinary reducers is questionable, as a sudden change of velocity with consequent eddy losses takes place; with a long gradual reducer eddy losses are cut down but gradual increase in pipe diameter is impractical except possibly for low lifts in agitating and aerating machines such as Pachuca or Parral tanks. The

best arrangement for discharge end is a vertical opening with a cusp-shaped umbrella (Fig. 41) to deflect the stream downward. The discharge may be turned horizontally by use of a long-radius elbow but it will not be as efficient; if the discharge pipe is turned and run any considerable distance horizontally allowance must be made for further losses.

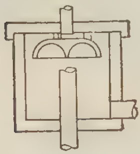

Fig. 41.—Umbrella top for air-lift.

Losses in an air-lift are friction in the pipe lines, slippage of fluid past rising air bubbles and velocity head lost at the discharge. Friction losses can be kept within reasonable limits and slippage can be reduced by increased dispersion of air. Ordinarily the velocity head lost is unavoidable on account of the necessity to keep the solid in suspension; some saving could be made by the use of increasing-diameter pipe, but this is generally impracticable.

Efficiency of the air-lift may be expressed as the ratio (multiplied by 100) of the theoretical horse-power needed to raise the liquid to the air horse-power required for adiabatic compression, or the indicated horsepower of the air-compressor cylinders, or the input horse-power to the compressor as determined from steam-indicator cards, or the motor power consumption. Water horse-power $= 62.5QgL/33{,}000$. Air horse-power with adiabatic compression $= \dfrac{144PVn}{33{,}000(n-1)}\left[\left(\dfrac{P_1}{P}\right)^{\frac{n-1}{n}} - 1\right]$, where $n = 1.406$ for single-stage adiabatic compression.

In making comparisons of air-lift efficiency with the efficiency of other systems, the work of the air-lift should not be condemned because of an inefficient compressor plant nor should the lost work occurring in the compression of the air be disregarded.

Efficiencies for good work in practice vary between 35 and 40 per cent.; instances of efficiencies up to 45 per cent. are claimed.

Advantages. The air-lift is easily constructed; lack of moving parts reduces wear, expensive repairs and shut-downs; attendance for the lift itself is insignificant but a proportionate part of compressor charges must be borne by it. Where aeration and agitation of the fluid to be elevated are desired it is especially suitable. Flexibility can be obtained by provision of a valve on the air line operated by a float on the surface of the liquid in the sump so that the air supply can be regulated to the amount to be lifted. When large variations occur for considerable lengths of time lift columns of various sizes may be provided so as to be easily interchanged. An air-lift can generally be easily cleaned out by shutting off the discharge and turning on the air at as high a pressure as possible thus forcing out and mixing any accumulations in the pipe lines; these will be removed readily on again opening the discharge. The first cost ordinarily will be less than for other devices. The greater power as compared to other systems may be compensated by savings in attendance and repairs. Air-lifts have been successfully applied to the elevation of sand and slime pulps. Where acid or other corrosive fluids are to be elevated the air-lift has a distinct advantage over pumps.

Disadvantages. Proper design is essential for operating efficiency. It is necessary to provide a sump or well of considerable depth; great depths can be avoided by compounding the lift, making it a series of short lifts, but this complicates and increases the piping. When compressed air is not already available, air-lifts would be of doubtful advantage unless large volumes were to be handled.

Application of air-lift to mill work is generally limited to lifts under 20 ft., due to the depth of submergence necessary. In such cases, especially where comparatively small tonnages are handled, little attention has been given to the refinements of design necessary for efficient operation, as the total power consumed is small. However, close attention to design and efficient operation have resulted in the installation of several plants for handling large tonnages of mill tailing at considerable saving over elevators, centrifugal pumps or tailing wheels. At Chino Copper Co. (*112 J 806*) an air-lift to elevate 12,000 dry tons per 24 hr. of mill tailing in a pulp containing about 15 per cent. of solids was installed in preference to a bucket-elevator system because of lower first cost and an estimated

operating cost of 72 per cent. of that with bucket elevators. Actual operation showed that operating costs were about 50 per cent. of those for bucket elevators. The general arrangement is shown in Fig. 42. Six well pipes were provided in a single shaft, with gates arranged to deflect the incoming pulp-stream to whichever one was being used. Three sizes of lift columns of standard, wrought-iron, flange-connected pipe were made as shown in Fig. 43 to be used with varying capacities and to determine which gave the highest efficiency. Details of the foot-piece are shown in Fig. 44, A. A traveling crane on a steel framework was installed to facilitate changing the lift columns; concrete umbrella deflectors on a mov-

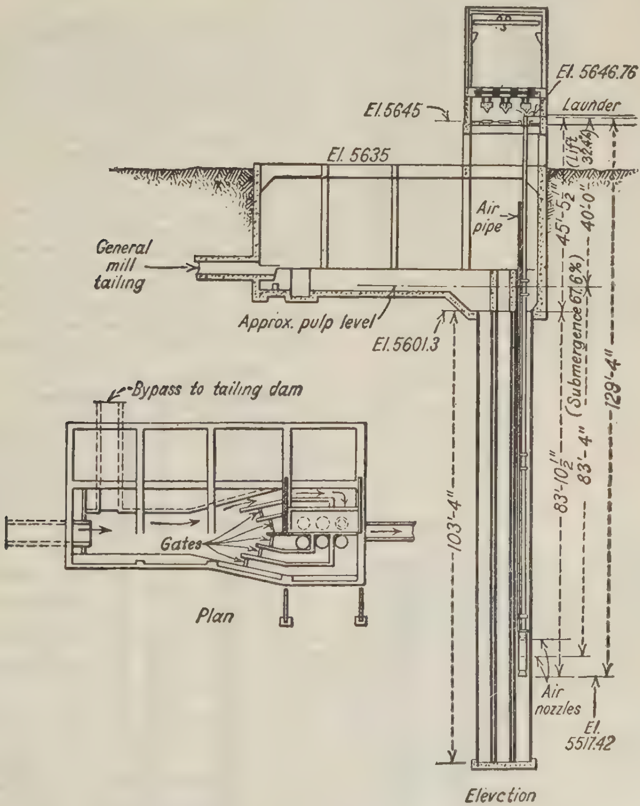

FIG. 42.—Arrangement of tailing air-lift at Chino Copper Co.

able carriage over the discharge ends of the columns caused the rising pulp to drop into a concrete box from which it flowed away in a launder. Air was furnished from the main power house, 530 ft. distant, by two Ingersoll-Rand, Imperial-type XPV-4 steam-driven compressors with compound steam cylinders 13- and 29-in. diameters and duplex single-stage air cylinders 22-in. diam. by 20-in. stroke. Special oil-pressure governors controlled the speed of the compressors so that with decrease of pressure or lowering of pulp in the well the governor caused the compressor to slow down until the wells filled again with pulp and the reverse action took place. Table 38 presents operating details for sixteen months of 1919 and 1920. For cost data see Sec. 23, Art. 3. The air-lift proved very successful in automatically taking care of fluctuations in feed rate, without change of lift-columns. Although ample provision was made for reserve wells and columns in case of clogging it was found that the lifts could free themselves and start up even after 32 ft. of sand had settled in the pit.

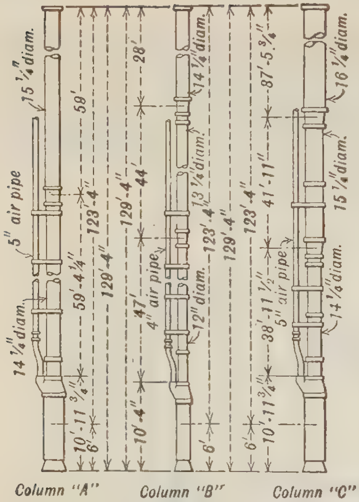

FIG. 43.—Lift columns for air-lift at Chino Copper Co.

Fig. 44, *B*, shows a foot-piece designed by Ingersoll-Rand to improve the efficiency of the CHINO lift. This foot-piece was attached to 43 ft. of standard 14-in. O. D. pipe followed by 76 ft. to the discharge of special welded pipe increasing uniformly from 14 to 16 in. outside diameter. With this column it was expected that power consumption would be cut 5 to 10 per cent. with a corresponding increase in efficiency of from 2 to 4 units per cent.

At another large copper mine in the southwest (*105 J 1177*), three air-lifts replaced three 10-in. centrifugal pumps direct-connected to 150-hp. motors to lift 7000 gal. per min. of tailing having 4 or 5 parts of water to 1 of solids. The air-lifts consisted of 10-in. discharge pipes in 20-in. wood stave pipes; a 40-hp. motor drove the compressor for each. Operating costs and repairs on the air lifts were a small fraction of those when pumps were used since excessive wear of sand in the pumps reduced the life of runners and liners to about 4 days, continuous running. At the Angelo and Cason mills of EAST RAND PROPRIETARY MINES, LTD., tests were made to determine best operating conditions. (*105 EL 26*.) The foot-piece used is shown in Fig. 40. The lower 35.4 ft. of discharge pipe

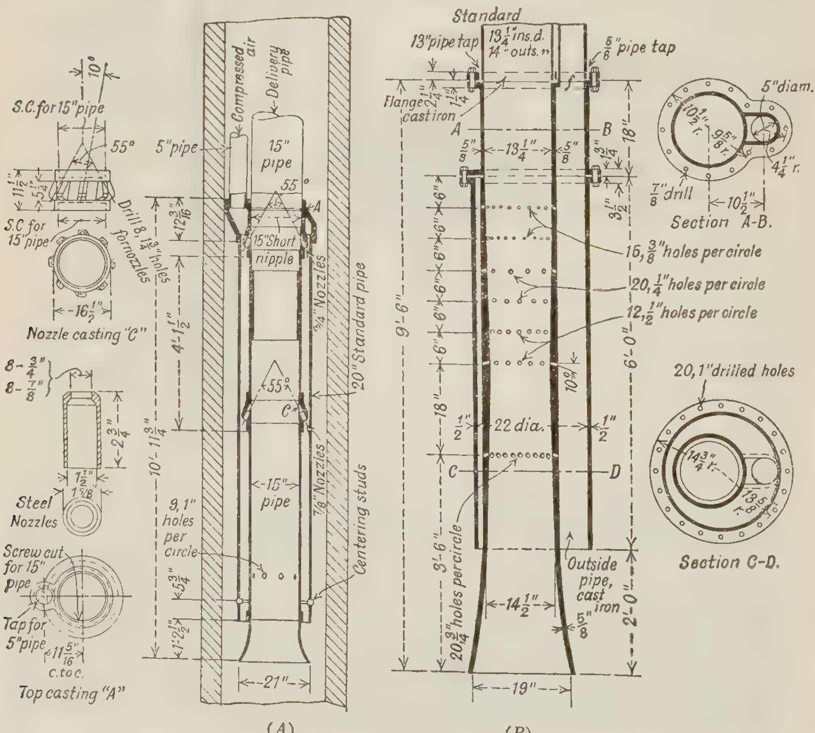

FIG. 44.—Foot-pieces for air-lift at Chino Copper Co.

was lined with wood, thus reducing the internal diameter of pipe on No. 1 from 14- to 11½-in. and on No. 2 from 16- to 13 ½-in. Table 39 gives results of some of the tests on slimes and sands. The slime pulp weighed 63.3 lb. per cu. ft. and the sand, 64.56 lb. per cu. ft. Columns 1, 2 and 3 show the effect of submergence on efficiency. Plotting the results of these and other tests gave a curve indicating a submergence of 1.83 to 1 for a maximum efficiency of 36.2 per cent. Column 5 on Cason slimes shows higher efficiency than this, but was attained with an increased amount of pulp.

16. Feeders

Feeders are necessary whenever it is desired to send a uniform stream of dry or moist ore to any kind of machine, since dry or moist ore, whether

coarse or fine, will not flow uniformly from a reservoir of any kind through a gate except when regulated by some type of mechanical feeding mechanism. The requirements of a satisfactory feeder are: (*a*) It must be positive (*b*) once set for a given rate it must deliver at that rate irrespective of the amount of ore ahead of it. (*c*) It must be readily subject to adjustment to vary its delivery rate. (*d*) It must start under load, and stop without spill. (*e*) It should be adapted to the size of material to be handled. The commonest types of feeders are: (1) traveling bands of articulated pans, called, APRON FEEDERS, or of belting, called BELT FEEDERS; (2) revolving pulleys or rollers with smooth or irregular surfaces, called ROLL OR PULLEY OR ROTARY FEEDERS; (3) shaking or reciprocating plates; (4) plungers; (5) screws; (6) revolving disks. Movable grizzlies (Sec. 5, Art. 4) are used for coarse-ore feeding and special forms of feeders are used with cylinder mills (Sec. 4).

Apron feeder (Fig. 45) is used for coarse ore. It consists of a short pan conveyor (Art. 2) set underneath the bin or hopper to be discharged in such a way that a part of the weight of the filling rests on the carrying surface.

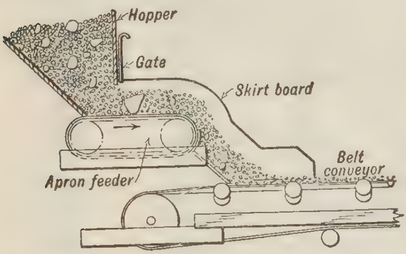

FIG. 45.—Apron feeder delivering to belt conveyor.

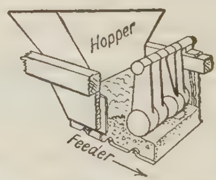

FIG. 46.—Swing-hammer feed regulator.

This surface should be sufficiently uneven to make the feeder positive. If the lumps are large and there is considerable pressure of material above the feeder tending to cause the material to pack, the pans should be deeply corrugated, but if the material is fine or does not tend to bridge at the hopper mouth, a smooth surface may be used. If desired, the bin gate can be eliminated and replaced by a swing-hammer regulator (Fig. 46). This device, as shown in the sketch, automatically adjusts itself to the passage of large lumps, while acting in general to maintain a layer of feed of even thickness on the apron. Heavy chains, steel rail and the like are used as substitutes for the swing hammer. A disadvantage of this device is the fact that if the swinging part breaks for any reason the broken steel is apt to go into the crusher. A device to prevent this contingency (*112 J 660*) consists of, say, three steel rods bolted at several places to the swinging part and fastened to the support; these will hold the parts of a broken hammer until it is discovered and removed.

Speed of apron FEEDERS ranges between 5 and 20 ft. per min. The usual widths are 24, 30, 36, 42, 48 and 60 in. and the distance between sprocket centers 36 to 42 in.

Capacity depends upon rate of travel, width, and size of material. The thickness of the layer must be at least as great as the size of the maximum lump, if a fixed slide gate is used on the bin; but if a swing-hammer regulator or its equivalent is used, the layer may be thinner. Tons per hour are approximately equal $3wts$, where w, t and s are width of the feeder in ft., thickness of the layer in ft. and speed in ft. per min. respectively. This assumes 20 cu. ft. of broken material as piled on the conveyor to weigh one ton, which is equivalent to an allowance of 56 per cent. voids.

Pan conveyors are used in place of apron feeders when it is desired to both transport and feed the material (see Fig. 47). At United Comstock a 48-in. pan conveyor with wood-cushioned pans was used to feed from the coarse-ore bin. It was driven at 9 to 15 ft.

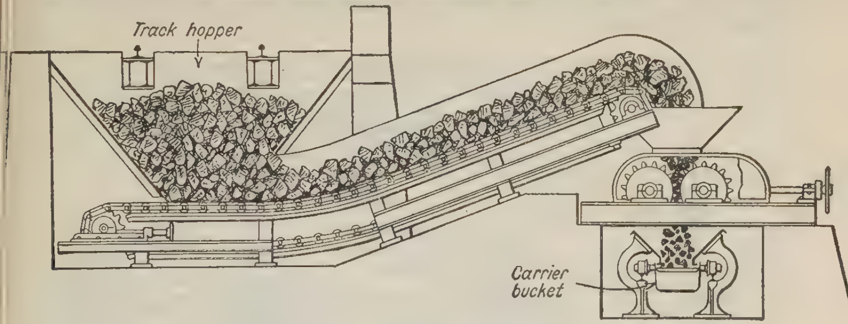

Fig. 47.—Pan-conveyor feeder from bin to crusher.

per min. from the head shaft by means of a direct-connected motor with double-gear speed reducer (*114 J 848*). This conveyor both fed and elevated to a grizzly preceding the primary crusher. At Ohio Copper Co. (*99 J 749*) stock apron feeders used for coarse ore worked well but the plates bent in time. At Inspiration (*121 J 726*) special feeders with manganese-steel plates (platens) of the form shown in Fig. 48 were used to feed run-of-mine ore from bins to the primary breakers. Instead of having rollers on the link pins to run on a track, the rollers were stationary and supported the links on the loaded run and the platen flange on the return. The platen width was 4 ft.; width between skirt plates, 42 in.; length between sprocket centers, 42 ft. 6 in.; maximum thickness of ore stream, 2 ft.; maximum load, 7 cu. ft. per ft. of length (= 0.35 ton); average maximum load delivered, 300 tons per hr., including many stops for picking waste and to prevent overloading the crusher. Motor input at 20 ft. per min., 5.36 hp. empty and 7.50 hp. loaded; at 10 ft. per min., 3.43 and 4.29 hp. respectively. Short feeders (7 ft. 6 in.), the same width drew 3.21 hp. empty and 3.75 hp. loaded when running 40 ft. per min. and fed about 12 tons per min.

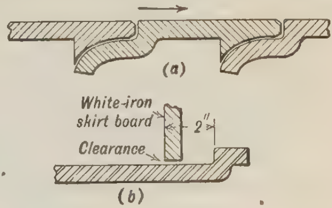

Fig. 48.—Transverse (*a*) and longitudinal (*b*) sections of manganese-steel platens on apron feeders at Inspiration.

Belt feeders are essentially short belt conveyors so placed under an inclined chute that they control the discharge of material therefrom. The method of placing relieves them from any part of the static load of the material in the bin. The head pulley must be placed so that the surface of the material at rest in the chute falls behind the vertical plane through the pulley shaft. Belt feeders frequently and properly replace apron conveyors for fine ore but are unsatisfactory for coarse ore since uneven loading by heavy lumps deforms them so that material spills, and because wear is excessive. Occasionally the belt surface is armored as shown in Fig. 49 (*111 J 63*). The material list for the feeder pictured follows:

Six common flat boxes, 1$^{15}/_{16}$-in. 12 bolts ½ × 7½-in. for same. 12 ½-in. mal. washers, for same. 1 shaft 1$^{15}/_{16}$ in. × 3 ft. 2 in.; keyseated for 10 × 15 pulley and ratchet wheel. 1 shaft 1$^{15}/_{16}$ in. × 2 ft. 6 in.; keyseated for 10 × 15 pulley. 1 shaft 1$^{15}/_{16}$ in. × 3 ft. 4 in.; keyseated for 14 × 4½-in. pulley and crank disk. 6 split safety collars, 1$^{15}/_{16}$-in. 9 ft. 3 in. of 4-ply rubber belt, armored as shown. 2 c. i. solid pulleys 10 × 15 in., 1$^{15}/_{16}$-in. bore. 1 c.i. solid pulley 14 × 4½ in., 1$^{15}/_{16}$-in. bore. 1 ratchet wheel (15½ in. outside diam.,

face 2½ in. ±), with arm; $1\frac{15}{16}$-in.-bore. 1 crank disk, 15 in. diameter, face 2 in. ±; $1\frac{15}{16}$-in. bore as shown. 1 crank pin $\frac{15}{16}$ in. × 4 in. ±. 1 connecting rod with ends, as shown. 1 pin, $\frac{15}{16}$ in. × 6 in. ±, with washers and keys. 1 pawl, 2 in. × 6 in. × 2½ in. with pin, washers, and keys. 1 pawl, 2 in. × 6 in. × 2½ in. with pin, washers, keys, and box. Armor plates and rivets for belt.

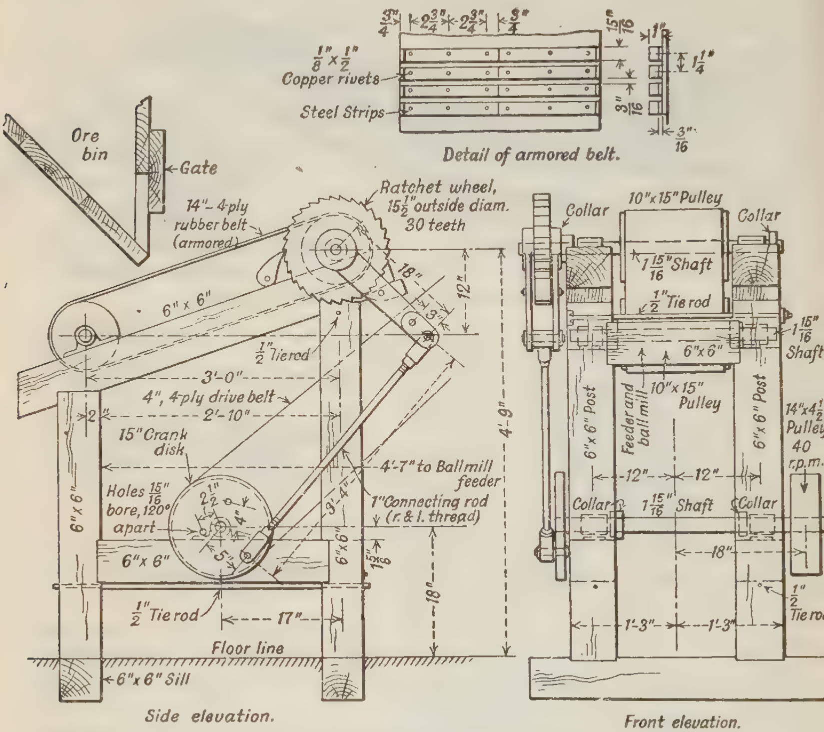

FIG. 49.—Belt-apron feeder.

The price in 1921 was $157 against $285 to $350 for plunger feeders and $300 for roll feeders of equal capacity.

Capacity may be calculated by the same formula as for apron feeders.

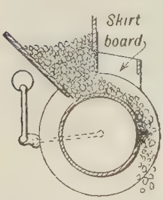

FIG. 50.—Roller feeder.

Roller feeder. (Fig. 50.) The diameter and setting of a feeder of this type should be such that a tangent to the front surface of the roll, drawn from the lower edge of the hopper gate, makes an angle with the horizontal less than that of the angle of repose (ϕ) of the material and less than the sliding angle (θ) of the material against the roll face, and at the same time the angle of the tangent to the roll face at the rearmost point of contact of the ore therewith should be less than θ. Skirt-boards must be used to confine material on the roller. Rolls from 12 × 12-in. to 48 × 48-in. are commonly used, the larger diameters for coarser feeds and the greater widths for larger capacities.

Advantages are simplicity of desigr, large capacity, low speed and low power consumption. Disadvantages are that delivery is almost directly below the feed point and there is considerable loss of head room.

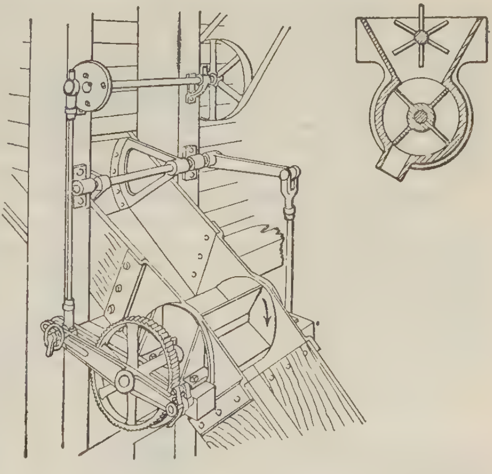
At Miami Copper Co., a 48 × 48-in. roller feeder had two spiders; face, 1½ in. thick, protected by ½-in. manganese steel plates bolted on. It was driven by ratchet and pawl with six possible speed changes.

Wear on drum surfaces can be materially lessened by grooving the surface transversely or by bolting on transverse angles, thus preventing sliding. Such provision is useful, also when material tends to pack and bridge at the nopper mouth. Rubber bands (see Sec. 13, Art. 5) should be useful in this service.

Peripheral speed of 5 to 20 f.p.m. is usual.

Capacity in tons per hr. is given approximately by the formula $T = 3\pi dwtn$, where d, w and t are diameter of roll, width of roll, and thickness of layer of material thereon respectively in feet and n = r.p.m. of roll.

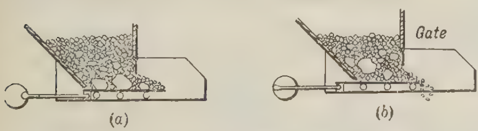
Rotary feeder (Fig. 51) is used where close regulation of fine feed is desired. It is usually placed in a hopper-discharge chute (*b*) and lacks the positive features of the apron and roller feeders but with a freely-flowing fine feed, or one that can be stirred by revolving prongs as indicated in (*b*) a remarkably close estimation of the quantity passed may be made by attaching a revolution counter to the feeder shaft and carefully calibrating the quantity delivered against r.p.m. The chute form (*a*) is less common. The figure illustrates the use of ratchet-and-pawl drive, which is probably the best for slow-moving feeder.



(*a*) (*b*)

Fig. 51.—Rotary feeder.

Reciprocating-plate feeder (Fig. 52). In moving forward into the position shown in (*a*) a layer of material is carried forward on the plate and more material settles from the hopper onto the rear portion of the plate. On the reverse stroke the plate slides under the material and that material at the forward end of the plate has its support withdrawn and falls. Widths range from 12 to 48 in. The plate may be supported on wheels, as indicated in the figure, or suspended by rods.



(*a*) (*b*)

Fig. 52.—Reciprocating-plate feeder.

The speed is usually below 30 r.p.m. Stroke length depends upon the size of material; it should be great enough to prevent bridging above the plate at the end of the forward stroke; usual lengths are between 4 and 12 in. Capacity may be estimated from the equation $T = 3ltwn$, where w, l and t are effective width of feeder, length of stroke and average thickness of layer on plate in front of hopper gate respectively, in feet, and n = r.p.m. This

feeder is suitable for both coarse and fine ore, provided there is no tendency to pack and bridge in hopper mouth. Wear on the plate is considerable and the hopper must be emptied in order to make renewals. The drive should be through a gear, and a flywheel to overcome the inertia at reversing is advisable.

When this type of feeder can be mounted so as to remove the static weight of the column of ore, *e.g.*, under the end of a chute, it may be run at higher speeds and becomes a shaking feeder. The operation is then the same as that of shaking screens (see Sec. 5, Art. 6) and, in fact, screen or grizzly bottoms are often provided. Such an arrangement is particularly desirable in loading a mixture of medium-coarse and fine material onto a belt conveyor, as it permits the fine material to load onto the belt first (see Fig. 53) and thus decreases wear and lessens slip and tumbling of the coarse lumps; material thus loaded is also excellently arranged for hand picking.

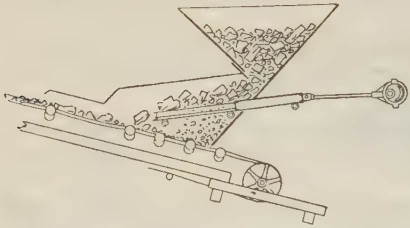


FIG. 53.—Shaking grizzly loading conveyor.

Vibrating-tray feeder is a form of shaking feeder; the feed trough, inclined slightly (5 to 10°) is hinged at the upper end and supported on an adjustable stirrup at the lower end so that it is just lifted by a projection on a revolving shaft, *e.g.*, a square corner or cam ear, and then dropped. The vibration thus set up is sufficient to move dry, pulverized material readily and if the number of vibrations is between 240 and 600 per min. will give substantially continuous, uniform movement. The feeder is not suitable for heavy loads nor coarse material.

Plunger feeder (Fig. 54) consists of an eccentric-driven plunger working in an open-top trough placed below the mass of ore to be fed, or replacing a side-draw chute; unless the hopper is shallow, the latter is the better position.

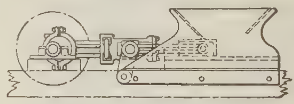

FIG. 54.—Plunger feeder.

SPEED is usually less than 30 strokes per min. and stroke length from 3 to 6 in. CAPACITY is estimated similarly to that of the preceding feeders.

Screw feeder (Fig. 55) is sometimes used for closely regulated positive feeding of fine, free-running soft material; it is useless for sticky material and wears rapidly with gritty substances. Screws range from 6 to 12 in. diameter, speed up to 80 r.p.m., capacity of a 6-in. screw at 80 r.p.m. is roughly 90 cu. ft. per hr. and of a 12-in. screw, 700 cu. ft.

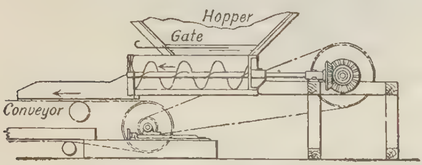

FIG. 55.—Screw feeder.

Challenge feeder (Fig. 56) is of the revolving-disk type; it consists essentially of an inclined circular plate or disk (J) forming the bottom of a chute or hopper (L) which is open at (M). Disk (J) is revolved slowly by bevel gears on shaft (I), which is driven by the friction pawl (D) attached to lever (B). When the feeder is used with gravity stamps, (B) is actuated by connecting rod (F) and lever (G) from a feeder tappet (H) on the center stem of the battery. The feeder may also be pulley driven, in which case a cam on the pulley shaft lifts (B). Speeds of (J), and hence feed rate, are varied by varying the down-

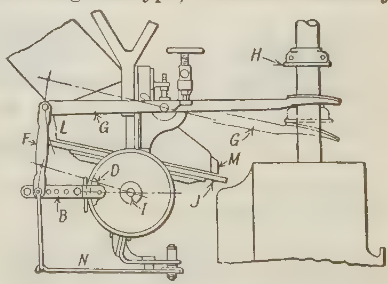

FIG. 56.—Challenge feeder.

ward return of (B) by means of the tension of spring (N). The pulley-driven form requires relatively little headroom, compared to other forms of feeders.

Stirrup feeder is essentially an undercut concave gate (Sec. 19, Fig. 29) eccentric-driven, with a transverse baffle placed centrally in the box above the swinging gate and clearing the latter sufficiently to prevent wedging. This baffle holds material that falls onto the gate in place so that the gate moves from under and drops it at each oscillation. It has been used frequently for fine-roll feeding.

17. Distributors

It is almost invariably necessary to split the stream of ore passing through a mill at some point or points in its flow in order to distribute the parts to parallel treatment processes; thus the product of a primary breaker must, frequently, be sent to two or more secondary breakers; the product of intermediate crushing to a battery of grinding machines and the product of one grinding machine to a battery of concentrators. The method employed for distribution of moving streams depends primarily upon accuracy required. CRUDE SPLITTING may be done by spreading the stream into a shallow and roughly-rectangular section and then inserting diverting vanes into the stream, at the central point, if halving is desired, etc. ACCURATE SPLITTING may be effected by the method employed in many mechanical samplers (Sec. 21) *i.e.*, by contracting the stream into a substantially equidimensional section and delivering it to a compartmented vertical drum, either the drum or the delivering mechanism being made to revolve on a vertical axis in such relation to the other that when the compartment-dividing walls cut the stream the stream is flowing substantially in the plane of the wall.

Coarse material. Except in sampling, distribution of streams of coarse material rarely requires accurate splitting; for crude work the stream from a chute, conveyor, or the like is allowed to fall freely onto the upper edge of vertical partition walls between fixed chutes. Only a two-way split makes any approach to accuracy owing to the fact that the center of the stream flows most rapidly and is coarsest. Bins with multiple gates are probably best for distribution of coarse dry material to a number of parallel machines.

Launder splitting is frequently employed for fine fluid pulps. The simplest arrangement is to fork the launder and place a hinged metal plate extending the partition wall upstream; this may be moved until the desired proportion passes down each fork before fastening into place. Multiple splitting is best effected by repetition of two-way splits.

Revolving distributors. The commonest form for fine pulp is typified by Fig. 57. The feed is led into the central compartment of the revolving tub (a), overflows at notch (b) (4 in. wide in the figure) into the annular launder (c) and thence through spout (d) successively into compartments (e) in the outer tub. Each compartment delivers through (f) to its proper pipe or launder. SPEED is 20 to 30 r.p.m.; pulsation of the resulting streams is lessened by making hole (f) small enough to prevent immediate emptying of its compartment.

Distributors with revolving compartmented drums are rare. They discharge through pipes at different radial distances into corresponding fixed annular troughs and thence to launders.

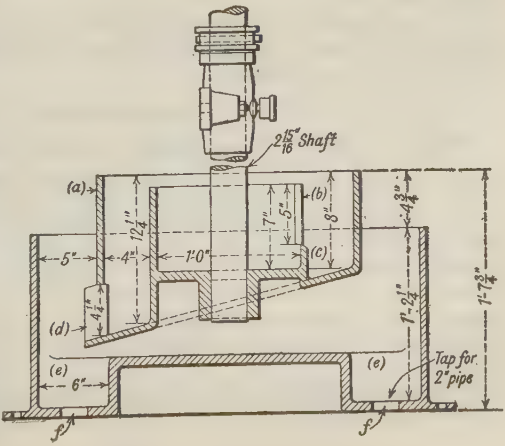

FIG. 57.—Revolving distributor.

SECTION 21

SAMPLING

BY

HENRY A. BEHRE, ASST. PROFESSOR OF MINING, SHEFFIELD SCIENTIFIC SCHOOL, YALE UNIVERSITY

Definition. Sampling is the operation of taking from a given lot of material a portion that is as nearly representative of the whole as is economically possible and is of convenient bulk for testing or analysis. It usually involves two operations, (*a*) crushing to reduce the size of particles, and (*b*) cutting down or dividing the lot into two parts, one of which is usually of much smaller bulk than the other and constitutes the sample. The scope of the present article is sampling of broken ore and various mill products. For sampling mines see mining texts and handbooks.

Factors affecting ore sampling. The principal elements in any sampling problem are (*a*) the weight of sample to be taken, and (*b*) the method of taking the sample.

The first question involves consideration of one or both of the following: the weight necessary to fulfill the purpose of the sample, and the minimum weight that will represent the lot.

1. Weight of sample

Weight necessary for assay sample will vary from a minimum of, say, 100 gm. to a maximum of 1 kg., the latter amount being sufficient to allow any necessary number of repeat or umpire assays. The amount actually weighed out for assay will vary from 0.5 gm. on high-grade base-metal concentrate to several assay-tons (29.166 gm.) on spotty gold ores. For SCREEN ANALYSIS the necessary weights range from 50 gm. for a single analysis of 100-mesh material or finer to 20 kg. for 1-in. material, and proportionately larger amounts for coarser sizes. For LABORATORY AND SMALL-SCALE MILL RUNS the necessary quantity will vary from a few pounds to many tons, depending upon the extent investigation.

Minimum weight of sample allowable in order that the sample may represent the lot depends upon (*a*) allowable error, (*b*) worth of valuable mineral,

(c) size of largest pieces in lot, (d) size and number of pieces of valuable mineral. Note that (b) and (d) are the elements of the grade of the ore.

Allowable error is determined by the purpose for which the sample is taken. The least error is allowed in taking samples for assay. Great error is allowable in the case of samples taken for preliminary treatment tests, and the like. The allowable error in sampling for assay is least when the assay is to form the basis for settlement between buyer and seller. The limit is practically fixed by the accuracy of the methods of assay used, it being, of course, unnecessary to carry refinement in sampling beyond the point reached by ordinary commercial methods of analysis. Accuracy of analytical methods on different products is presented in the following paragraphs.

Gold. Duplicate assays by the same assayer should check within 0.02 oz. on low-grade ores; the discrepancy should not exceed 0.05 oz. on 5-oz. ore, while a 0.1-oz. discrepancy is permissible on 5- to 20-oz. ore. (*Lodge, R. W., notes on assaying, John Wiley and Sons, 1919; Smith, E. A., The sampling and assay of the precious metals, Chas. Griffin & Co., Ltd., London, 1913.*) Two assayers working on the same pulp or on samples cut from a small, finely-pulverized lot should check within similar limits, according to most writers. Fulton (*TP 83, USBM*) states that differences of 0.02 to 0.05 oz. are usually split on 1- to 2-oz. ores and of 0.04-oz. on ores running above 2 oz. Barbour (*92 J 314*), gives 0.05 oz. as the splitting limit and Whitaker (*105 J 538*), 0.02 oz. Seamon (*A manual for assayers and chemists, John Wiley and Sons, 1910*) states that 0.01 and 0.2 oz. covers the usual splitting range, but recommends that umpiring be resorted to when the difference between buyer's and seller's assays on a 50-ton lot exceeds 0.1 oz. Table 1, arranged from Brunton (*40 A 567*), presents figures of actual mill results on a variety of ores. By comparison of the last four columns, the degree to which sampling checks assaying may be observed. Table 2 was prepared from data given by Woodbridge (*TP 86, USBM*) based on results obtained from shipments of one mine to various sampling plants. It shows the degree to which buyer and seller may be expected to check on the same samples of various grades of ore. The detail (not presented here) shows that buyer's assays are rather consistently lower than seller's which leads to the belief that deviations shown in this table are not due entirely to physical difficulties. Table 3, arranged from the same source as Table 2, is a comparison to indicate the degree to which duplicate samples may be expected to check. Note that, in general, greater difference exists between duplicate samples than between assays by buyer and seller.

The above figures indicate that sampling should be accurate to within at least 1 per cent. on a 5-oz. ore while an error of as much as 5 per cent. would be allowable on 0.5-oz. ore. A hard and fast rule as to allowable difference cannot be set for all cases. Many ores present physical difficulties in sampling and assaying which must be taken into account when setting a standard for accuracy. In any case, however, although individual assays may not check closely, an average of several or many assays on a sample should closely approximate the true value of the sample.

Silver. Duplicate assays by the same assayer, doing the most careful work, should check within 0.2 to 0.5 oz. for ores up to 50 oz. In ordinary work differences up to 1.0 or 2.0 oz. maximum may be expected (*Fulton, Seamon*). On high-grade ores duplicates should check within 1 per cent. of the total silver content. Assays on duplicate samples by different assayers should check within 0.5 to 1.0 oz. for average (10- to 20-oz.) ores (*Fulton*). On high-grade ores differences of 1 per cent. are allowable. The usual splitting limit between buyer and seller is 0.5 oz.

Tin. Ordinary cyanide fire assays by the same assayer should check within 0.2 per cent. metal for low-grade ores to 0.5 per cent. for high-grade ores. (*W. A. MacLeod and C. Walker, Metallurgical analysis and assaying, C. Griffin and Co., Ltd., London, 1903.*)

Other metals. Table 4 presents limits for commercial work using volumetric methods. Duplicate electrolytic assays for copper should check within 0.03 per cent. metal on 20 per cent. to 60 per cent. ores and 0.02 per cent. on ores less than 20 per cent. (*MacLeod and Walker*).

Worth of valuable mineral. The preceding text and tables show that on gold ores and concentrate the allowable error is, in general, under 0.05 oz.; on silver ores, under 0.5 oz.; on copper ores, from 1 to as high as 10 lb. per ton; and on zinc and lead, as high as 20 lb. per ton; increasing as the worth of the valuable mineral decreases.

Size of largest pieces in lot and size and number of pieces of valuable mineral present are interdependent in their effect on the minimum weight of sample allowable and affect this weight because of the fact that accuracy requires the inclusion in the sample of a certain minimum number of individual pieces rather than of any given weight of material. The significance of this statement will be seen from a consideration of the following possible and usual cases.

(a) **The lot is a mixture of individual particles of pure valuable mineral and pure gangue, all of the same size.** The valuable mineral may all be in one piece. In such a case nothing less than the whole lot is a correct sample. If, however, the lot contains a known large number of pieces of valuable mineral and after careful mixing is divided into parts. the probable number of pieces in excess or deficit in any part may be determined by experiment or mathematically. The part taken may then be said to represent the whole if the effect on its value of pieces in excess or deficit is within the allowable error for sampling operations. If the whole lot is now taken and crushed so that the diameter of each particle is reduced one-half, the number of particles then present will be eight times as many as originally. A sample portion of this crushed material, in order to contain the same number of pieces of valuable mineral as above and, therefore, to have the same probable error, need be only one-eighth of the weight taken above, *i.e.*, the sample weight varies as the cube of diameter of the particles. If w_1, w_2, w_3, etc., = the weights to be taken at sizes D_1, D_2, D_3, etc., respectively, then $w_1/w_2 = D_1^3/D_2^3$ or $w_1/D_1^3 = w_2/D_2^3 = w_3/D_3^3$, etc., or $w/D^3 = k$ (ore constant) and $w = kD^3$. Application of this formula for weight of sample cannot be made to usual cases met with in ore sampling, as the conditions obtaining in crushed ore are different from those assumed in deriving the formula.

(b) **The lot is a mixture of particles of different sizes, all of which contain both valuable mineral and gangue in varying proportions.** This is substantially the condition in all coarse ores. For any given ore there is a particle size above which no valuable mineral can occur as a separate piece and likewise a size above which no gangue can so occur. In this case the pieces containing the greatest amount of valuable mineral have the greatest effect on the value of the part taken for the sample. When in excess or deficit, the effect of such pieces is determined by the difference in grade between them and the pieces of average grade that they replace, or their effect is equivalent to that of smaller pieces of pure valuable mineral. The allowable number of pieces of highest grade in excess or deficit is greater than if these pieces were of pure valuable mineral, hence a smaller sample of material containing such pieces can be taken. With coarser and coarser pieces making up the ore mass, the difference in value between a piece of highest grade and pieces of average grade becomes less and less and the value of each piece comes nearer to that of the whole.

(c) **The lot is a mixture of pieces of pure valuable mineral, pure gangue and particles containing both valuable mineral and gangue.** This is the case most frequently met. If all the pieces are of the same size, the maximum error is introduced when a piece of pure valuable mineral replaces a piece of pure gangue or *vice versa*. However, the number of pieces of pure mineral is less than the total number of pieces containing valuable mineral and the probable number of such pieces in excess or deficit in the sample is, therefore, less, so that their effect on the value of the whole is less than if all pieces were of pure valuable mineral and pure gangue. Further, the probability that such pieces will replace pieces containing both valuable mineral and gangue is a factor that decreases their effect. If the material is composed of pieces of varying size, the coarser pieces are more likely to be those containing both valuable mineral and gangue while pieces of pure mineral and pieces of pure gangue are more likely to occur in the finer sizes and to have, therefore, small effect on the value of the sample. Consideration of the conditions discussed in (*b*) and (*c*) leads to the conclusion that if, at any given size, a sample is taken, the weight necessary to give the same degree of accuracy at finer sizes will be greater than that indicated by the rule ($w = kD^3$). Likewise at coarser sizes the weight of sample necessary will be less than indicated by the rule. Successive crushing operations on a lot of ore produce changes in the conditions in which valuable mineral and gangue occur. In the coarsest sizes practically all of the valuable mineral occurs together with gangue in all pieces. With decreasing size mineral is gradually freed from the gangue and in the finest sizes it is practically entirely free. Differences in friability of gangue and valuable mineral cause increase in the amount of one or the other in finer sizes at each stage as crushing progresses.

Relative specific gravities of the valuable and gangue minerals will determine the effect that one particle of a given size in excess or deficit will have on the value of the sample.

Table of sample weights. The difficulty of deriving mathematical formulas to take all of above factors into account is apparent. The usual way to determine the sample weight required at any size is to reckon on experience with the particular ore to be sampled or experience with ores in general. The tendency is to allow a sufficient factor of safety by taking a sample large enough to cover possible unforeseen sources of error. Variations in the weights taken in practice, on ores of same class are not always due to disregard or misunderstanding of the principles involved, but to local conditions and the facilities available.

Brunton (*25 A 826*) presents diagrams based on mathematical calculations to determine the weight of sample at different sizes when the specific gravity of the richest mineral and the ratio of grade of the richest mineral to the average grade of the ore is known. The diagrams are based on the reasoning that the allowable error is equal to the difference between the value of the probable number of pieces of valuable mineral and the same number of pieces of average value which they would replace if in excess or deficit. Results show that if such conditions remain the same throughout all sizes the weight of sample should vary as the cubes of the diameters. Full account is also taken of the fact that larger pieces than the theoretical cube are found in the undersize of a screen, due either to irregularity of the screen or the presence of elongated pieces. Use of these diagrams is limited to cases where conditions are known and where they remain the same throughout all sizes. This is not the case with ordinary ores.

Richards (*2 OD, Chap. 19*), reasoning from considerations similar to those discussed under (*b*) and (*c*) above, and noting that in several installations on a variety of different ores the weights at different sizes were taken proportional to the squares of the diameters, calculated a table for different grades of ore, using one figure from practice in each case and calculating the rest.

Columns 1–6 in Table 5 were prepared from Richards' table. Column 7 shows weights obtained by applying the rule that the sample weight should vary as the cube of the diameter. The calculation is based on the assumption that 0.1 assay ton (0.00643 lb.) is a correct sample of 100-mesh material. Column 8 gives figures presented by Philip Argall for sampling in successive cuts 200,000-lb. lots of 10- to 15-oz. gold ores from Cripple Creek. The weights in this column vary approximately as the squares of the diameters and lie somewhere between the figures in Columns 5 and 6 from Richards. The larger figures in parentheses are recommended for an added factor of safety for certain ores. Column 11 summarizes results obtained from examination of 55 flow-sheets of sampling plants. The weights are based on 100,000-lb. lots, the figures being averages for different sizes. In averaging, some excessively high or low weights for any one size were omitted. The results lie between columns 3 and 4 for medium ores as given by Richards. This is as might be expected and indicates that practice generally has followed the rule that sample weights should vary as the squares of particle diameters. Columns 9 and 10 give maximum and minimum figures from the flow-sheets used in averaging; figures in parentheses are highest or lowest figures.

Columns 12 to 15 inclusive, present sampling standards suggested by Demond and Halferdahl for base and precious metals. These data were set down in an attempt to obtain logical figures based on a combination of experiment and mathematics rather than on arbitrary application of the rule of squares. Their method is based on the assumption that the sample weight w should vary as some power a of the diameter D or $w = kD^a$ where k is a constant for any given ore. One gram for base-metal ores and one assay ton for precious-metal ores, the amounts usually taken for assays, were assumed to be correct sample weights for 150-mesh material. A portion of the ore at some larger size was divided into a number of equal parts and each part was crushed down and assayed. The probable error for any portion was then calculated and if larger than the allowable error the correct sample weight was calculated so as to obtain a probable error less than the allowable error in 90 to 95 per cent. of all cases. Substituting values of weights and sizes in the two instances in the formula $w = kD^a$, they solved for k and a, and then calculated the correct weights for other sizes. They demonstrated that values of a less than 1.5 should not be used, as the samples would be too small. The method is applicable to any given class of ores. With low-grade or very uniform ores a will have a low value and with high-grade or spotty ores a high value (see Table 5); for ores of intermediate grade or uniform value, a will lie between these extremes.

While the method of Demond and Halferdahl has much to commend it, it does not take into account the changes in relation between gangue and valuable mineral with change of

particle size, but uses the same power of the diameter over the whole range of sizes. Columns 17 and 18 use one assay ton for precious-metal ores and 1 gm. for base-metal ores as correct weights at 150-mesh and take the exponent a as ranging from 3 for material between 150-mesh and 65-mesh to 1.5 for material between 2-in. and 4-in. This method tends to give larger samples at the smaller sizes and smaller samples in the larger sizes. If the assay charges need to be larger than one assay ton or one gm., the weight of any size may be found by multiplying the tabular figures by the number of assay tons or grams needed to give correct assays.

Column 16 gives the minimum permissible sample weights suggested by Richards for GOLD ORES. For SILVER ORES take one-tenth of these values. Inspection of figures in this column shows that there is no constant or regularly changing ratio between weights and diameters. These sample weights are evidently based on no rule except experience and personal judgment as to what weights can be taken at various sizes.

Examination of sample-mill flow-sheets indicates wide variation in sample size. The most obvious relation noticed is the taking of successive 20-per cent. cuts after each reduction in size by one-half or the use of a value for a of about 2.13.

Weight of coal samples used and recommended by U. S Bureau of Mines (*Bul. 116, USBM*) based on an original gross sample of 1000 lb. is given below.

Largest size of coal and impurities in sample before division, in	Weight of sample to be divided, lb.
1	1000 (or more)
¾	500
½	250
⅜	125
¼	60
3⁄16	30

Two 5-lb. samples are taken from the 15-lb. sample obtained by division of the 30-lb. at 3⁄16-in., (p. 1139) so that 5 lb. is the sample weight really taken at this size. Further reduction of the sample yields 6 oz. after crushing to 20-mesh (0.0328-in.) and 3 oz. after grinding to 60-mesh. From the 60-mesh sample 1-gm. amounts are used in making the various analyses. The weights in the coarser sizes vary as the squares of the diameters of the largest pieces. Assuming this relation necessary and sufficient, a 5-lb. sample at 3⁄16-in. is too small; if the 5-lb. sample is sufficient 6 oz. at 20-mesh is larger than necessary and 1 gm. (0.002205 lb.) at 60-mesh is far too small. If, however, 1-gm. is enough, an undue allowance is made in the larger sizes.

Weight of samples for screen test should be great enough to give an accurate sample at the sizes that are important. The allowable error is influenced by the care with which the screen test is made. The weights ordinarily taken for screen-test samples vary from say 100-gm. for −65-mesh material to 5 or 10 kg. of 1-in. material. Larger weights may be necessary in special cases depending on the accuracy desired and the end in view.

2. Segregation

It is most desirable that the mass to be sampled be thoroughly mixed. Practical homogeneity is attained with solutions, and the maximum of uniformity, lacking homogeneity, with fine suspensions. In such cases, any part can be taken at random as an accurate sample. But in dealing with broken ore, uniform mixing is difficult. Ore as mined varies in composition from place to place and in breaking, loading and crushing segregation increases. In crushing, some of the minerals present, due to differences in hardness and friability, break into smaller pieces than others. Vibration of a car transporting ore tends to sift the finer and the heavier pieces down through the coarser, so that the material in the car is not uniform in value from top to bottom. If ore is transported by means of inclined chutes or launders, segregation takes place therein. Coarser pieces bound or roll down the chute while finer pieces slide slowly along the bottom. Heavier pieces tend to settle near the bottom

in the sliding mass. If a chute ends in a free fall, the larger and heavier pieces, due to their greater momenta, fall further away from the end than the finer and lighter pieces. If the ore is piled in a heap, the coarser pieces roll down while the finer remain near the top. Thus, in order to take an accurate sample, either the material must be thoroughly mixed or the method must be so applied as to take segregation fully into account.

HAND SAMPLING

Sampling is done either by hand or by machine. Hand sampling is usually expensive, especially on large lots; it is slow, and the personal element enters so largely that it is difficult to obtain accurate results. Machine sampling should be used where possible and hand sampling applied only where material is not suitable for treatment by machine, as with sticky ore, or where machinery is not available, or the expense of its installation not justified.

Hand-sampling methods. The more common methods of hand sampling are: (*a*) grab sampling, (*b*) coning and quartering, (*c*) shovel sampling, (*d*) pipe sampling.

3. Grab sampling

This is the simplest form of hand sampling. It consists in taking small, equal portions by scoop or shovel at random or at regular intervals from the mass of material to be sampled. The following variations illustrate practice.

(a) **Grab samples of large heaps of ore** are obtained by taking a shovel- or scoopful at different points on the surface of the heap. The points may be located by dividing the surface into squares or rectangles, or the location may be left entirely to the judgment of the sampler. If large samples are desired, pits are dug at various points and the whole or part of the material excavated is taken for the sample.

(b) **Ore in railroad cars or boats** may be sampled as in (a). In this case a net is frequently placed over the surface of the ore and the sample is taken at the knots in the net, or the sampler measures off sample intervals from the sides and ends of the cars with a shovel or measuring stick.

(c) **As ore is being loaded or unloaded,** grab samples may be taken at intervals along the working faces as excavation progresses.

(d) **Where ore is being transported in small lots** by wheelbarrows, tram buckets, wagons or small cars, a GRAB may be taken from each load and thrown into a box. The box is emptied at the end of each day or shift and taken as a sample of the ore transported for such period of time.

Methods (*a*) and (*b*), taking samples from the surface only, assume that the character of the ore does not change with depth in the heap. Correct results can hardly be expected on such an assumption on account of segregation. Method (*c*) is more likely to give results that are accurate, since samples are taken from all parts of the mass. Method (*d*) is also more commendable than (*a*) and (*b*) and should, over a long period, give a fair average with certain classes of ore. However, it is probable that the samples would run regularly high or regularly low.

E. H. Dickenson (*35 SMQ 55*) gives the following figures from a small ALASKA mine: Ore, medium-grade copper containing chalcopyrite and pyrite in greywacke and slate. A 2-lb. sample was taken by an experienced man from each one-ton car dumped into a boat for shipment. The ore was again sampled at the smelter in a mechanical sampling mill. Figures based on two years of work with shipments varying from 200 to 2000 tons each showed that the average difference in assay between grab and mechanical samples was 7.1 per cent. of the copper content and the maximum difference, 28.5 per cent. The percentage of cases in which the grab sample was high was 55 and results were more than 10 per cent. wrong in 30 per cent. of the cases. Applying these figures to three ores running 2 per cent.,

10 per cent. and 20 per cent. copper, respectively, errors and the expectation of errors would be as follows:

	2-per cent. Cu ore.	10-per cent. Cu ore.	20-per cent. Cu ore.
	Per cent. Cu	Per cent. Cu	Per cent. Cu
Average error of grab sample	0.14	0.71	1.42
Maximum error of grab sample	0.57	2.86	5.72
Minimum error to be expected in 30 per cent. of the results	0.20	1.00	2.00

In this ore values did not tend to segregate in the fines to any great extent as shown by the following sizing-assay test:

Screen, mesh	Per cent. of total weight	Per cent. of total Cu
60	30.6	24.8
80	9.5	8.7
100	6.6	7.0
100	53.3	59.5
	100.0	100.0

Usually more than 55 per cent. of the results would be high. It is general experience that grab sampling gives high results, due probably to the fact that the sampler avoids large lumps.

Advantages of grab sampling are that it is cheap and quick. **Disadvantages:** It is difficult, when taking a small portion such as a shovel- or scoopful, to get full representation of all sizes of particles, especially when lumps are present. Just what part of a lump or how much of the coarser and finer pieces should be taken at each grab is left to the judgment of the sampler, and either by over-zealousness or by carelessness on his part, more of some size than is proper is almost certain to be taken. It is also practically impossible to take such an amount of material at each grab that every part of the lot shall have proportionate representation in the final sample.

Applicability. The ore should be crushed to 0.5-in. or smaller before sampling. Grab sampling should be applied only to low-grade or very uniform ores, or in cases where approximate results only are desired, or in order to detect salting.

Examples of grab sampling

Mogollon district, New Mexico (*72 A 535*). The ore contains gold and silver, both native and in argentite, and pyrite in a gangue of quartz, calcite and andesite. Yearly averages of composite daily grab samples taken from cars at the scale seldom show a variation of more than 10 per cent., generally 3 or 4 per cent., from the value determined from addition of the metal produced to that lost in tailing. (See *25 A 82C*.) Comparison follows:

	Case 1	Case 2
Weight of ore, tons	51,862	43,993
Value, mill average	\$11.084	\$10.254
Value, grab sample	\$11.218	\$11.193
Percentage excess of grab sample above mill average	1.20	9.17

Iron ores in cars or boats are usually sampled by grab-sampling. The methods described below are those used by U. S. Steel Corporation (*1 IEC 107*).

Car sampling. Samples of about 2 oz. to 3 oz. are taken with a garden trowel or small scoop (3½ × 2¼ × 1¼-in.) at 12 places in a 25-ton car and 15 places in 50-ton car. Either the PARALLEL or ZIGZAG SYSTEM is used (Fig. 1, *a*, *b*, *c*, *d*). Lumps met at sampling points are sampled by breaking off a small piece about the size of the first joint of the thumb. Samples from ten cars are combined, making about 15 lb. for ten 25-ton cars and 20-lb. for ten 50-ton cars. With very lumpy ore the ROPE-NET SYSTEM is used. Knots are about 18 in. apart and the car is sampled in about 32 places. MOISTURE SAMPLE is taken at three places along the center of each car after removing several inches of surface.

Boat sampling. The size of boats varies from 3000 to 12,000 tons capacity, one or two decks, 6 to 36 hatches with widths from 12 to 24 ft. Ores vary from very fine to all lump. The sample may be taken by small scoop (¼-, ½-, or 1-lb. capacity) from grab buckets, while unloading. This method is expensive as one man is needed for each grab bucket.

Sampling of cones is the term applied to the following method: The sampler starts at point "A" (Fig. 1, *e*), directly under the edge of the hatch and midway between the center and side of the boat and takes samples at points 1 ft. apart (measured by the trowel, which is 12 in. long), up the side of the cone, over the apex and down on the opposite side. Then similarly along the other diagonal. The amount thus taken is equivalent to about one-tenth of the total sample for the hatch. After the grab bucket has removed all ore within reach, samples are taken in parallel vertical lines up the face of the ore at 1-ft. intervals. The first line is 2 ft. from the side of the boat and succeeding lines are spaced at 4-ft. intervals (Fig. 1, *f*). This is repeated on the opposite face.

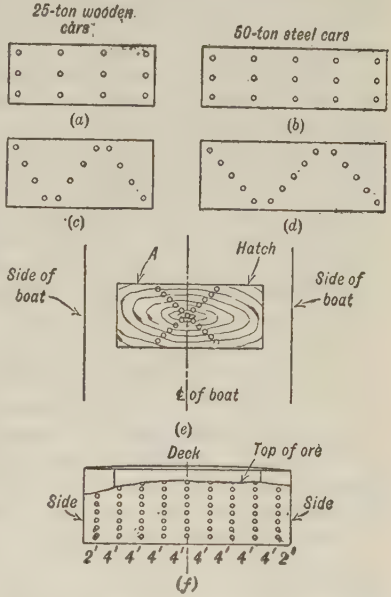

FIG. 1.—Sampling iron ores in cars and boats.

Round sampling is used when operation of the grab bucket makes sampling of cones impracticable or with boats with 24-ft. hatch centers and decks furnishing protection to samplers. When a 5- or 6-ft. face is exposed by the grab-bucket, the sampler takes samples of the face by the same method as in Fig. 1, *f*. The amount taken on this round is about one-third of the total. The second round is taken similarly after the grab bucket has removed all ore within reach; this comprises the remaining two-thirds of the sample.

4. Coning and quartering

This is one of the oldest forms of hand sampling. It was for many years the standard method of sampling throughout the western United States, especially for batches of ore whose value was to be determined between buyer and seller. It can be used on lots up to 50 tons. Where larger lots are to be sampled, the first cut is made by some other method and the sample thus obtained is further reduced by coning and quartering.

The method consists in piling the ore into a conical heap, spreading this out into a circular cake, dividing the cake radially into quarters, taking opposite quarters as sample and rejecting the other two. The ore should be crushed through 2-in. or smaller ring. The operation should be carried on in a room of sufficient size to allow convenient handling of material. The floor should be smooth and free from cracks, preferably made of concrete or steel sheets; it should first be swept thoroughly clean to avoid salting from

a previous lot. The ore is dumped on the floor in two or four piles, or in a circular ring. Shovelers then pile this ore into a right-conical heap conveniently placed, taking care to drop each shovelful directly onto the apex. The object of coning is to form a heap in which segregation shall be symmetrical with respect to the vertical axis. To insure this, successive shovel loads should be so taken as to contain similar sizes similarly segregated on the shovel and should be so dropped onto the cone that the segregation therein is symmetrical. This end is attained by having the shovelers take successive shovel loads from adjacent places around the periphery of the heaps from which they are shoveling and drop these loads from successively adjacent points around the cone that they are building. Each man should take a shovel load of the same size as each other shoveler, and shovel loads should be made smaller as the size of the heap being shoveled becomes less. When the material is placed in a ring the men move around the ring as they shovel onto the cone. When the ore is all heaped up into a cone, the floor is carefully swept and the fines collected are placed on the apex, not swept up against the bottom of the pile. The men then start at points near the bottom of the cone and, with their shovels held tangentially, drag the material down radially so as to form a truncated cone or flat circular cake. In this operation they should work around the cone. The cake is then marked off into quarters with a stick or board along diameters at right angles. Opposite quarters are shoveled out as reject. The remaining quarters, called the sample, are then shoveled into one or more piles or into a ring depending on the amount of material, and the coning and quartering operations are repeated until the sample is so small that further crushing is necessary before further reduction in bulk can be made. A cross made of sheet iron or wood with sharpened edges is often used to mark the truncated cone into quarters. This is placed on top of the cake with the center of the cross directly over the center of the cone and is then pressed into the ore until it touches the floor. Such an arrangement is preferable to marking off with a single board. Lines of division will be more exact and the cross can be left in place to hold the sides of the sample quarters vertical while the reject quarters are being shoveled away. Or the cross may be laid on the floor before starting the pile and each shovelful dropped over the intersection. The cone is then spread out to the thickness of the cross and the reject shoveled away as above.

Coning does not mix the ore uniformly. As material is shoveled onto the cone the coarser pieces roll down the sides and come to rest on the floor while the finest particles remain near the apex. Pieces of intermediate size arrange themselves on the slopes of the pile according to their size. The ultimate result desired is that the segregation be symmetrical with respect to the axis of the cone. If this condition is attained, any sector taken should correctly represent the whole.

Bench or cobbing system, sometimes used to get better distribution of the material in the cone, consists in first making a small cone of some of the ore and spreading it out into a cake, then making another cone on the center of the cake and spreading it out and repeating until all the ore is thus disposed of. This method tends to reduce the effects of accidental errors in flattening the cone.

Advantages of coning and quartering are few. Expensive equipment is not required, the only tools necessary being wheelbarrows, shovels and brooms. It can, therefore, be used in remote places where more elaborate sampling machinery is not available. It is applicable to practically all classes of ore and, in the case of small lots of high-grade material, there is no danger of such loss as might occur through leaks and hold-backs in a mechanical sampling mill. The fact that all ore is in plain sight throughout the period of sampling is probably the chief reason why this method has survived as long as it has, this being especially desirable

where ore is being sampled for sale. DISADVANTAGES. The method is expensive, requiring frequent handling of the ore by crude means, and much sweeping. The danger of salting is considerable. From the standpoint of accuracy the method is susceptible, either through accident or intention, to such manipulation during the operation that a true sample will not be obtained. As the men shovel from the piles of ore or ring onto the cone, they should all push their shovels either radially or at a tangent into the piles or ring. Otherwise the coarse material will be in a different position on each man's shovel and when the ore is thrown onto the cone the coarse material will segregate unsymmetrically. Further, it is difficult to keep the axis vertical. If the axis is inclined, more fine material will accumulate on the side toward which it leans. This is called "drawing the center" and it has frequently been brought about in order to make the sample of higher or lower grade, as the operator desired. To avoid "drawing the center" a vertical rod is sometimes placed to mark the axis of the cone. When spreading the cone into a flat cake, there is danger that more fine material from the apex will be spread over one part than another. During dragging out, coarser pieces are pushed along to the outside by the shovels while the finer particles sift through and tend to remain nearer the center. As spreading progresses the finer material from the center is spread out and the cake obtained tends to have a separation of the coarser particles on the bottom and the finer on the top. There is also difficulty in spreading the last small portion of fines evenly. For these reasons chances of error are great and the effect of carelessness or willful abuse is difficult to detect.

Time and labor required. The following data are given by Johnson (*53 J 111, 132*): EL PASO SMELTING WORKS. Mexican labor, coning and quartering a 2-ton sample taken by the tenth-shovel method:

4000-lb. lot.		
4 men, 1 on wheelbarrow from platform to crusher, 1 man at crusher, 2 men with wheelbarrows carrying ore from crusher and forming circular ring	45 min.	
4 men shoveling from ring to cone 6-ft. diam., 3.5 ft. high	20 min.	
4 men spreading to truncated cone 9 in. high at center, 5-in. at circumference	5 min.	
4 men cutting quarters and removing reject	10 min.	
Total, 4 men		80 min.
2000-lb. sample; 4 men.		
Shoveling to a ring	6 min.	
Making cone	9 min.	
Spreading	3 min.	
Halving	5 min.	
Total, 4 men		23 min.
1000-lb. sample; 4 men.		
Making ring and cone	12 min.	
Spreading	2 min.	
Halving	3 min.	
Total, 4 men		17 min.
500-lb. sample; 4 men.		
Re-crushed in rolls, 10 × 20-in.		35 min.
Total, 4 men		155 min.
500-lb. sample; 2 men.		
Piled in a heap, spread to a circle, pushed out to ring	15 min.	
Making cone (3 ft. diam., 1.75 ft. high)	5 min.	
Spreading (6.5 in. thick at center and 3 in. at circumference)	3 min.	
Halving	2 min.	
Total, 2 men		25 min.
250-lb. sample; 2 men.		
Ground in rolls to pass 10-mesh		35 min.
Making ring	2 min.	
Making cone	4 min.	
Spreading (5 ft. × 2 in.)	2 min.	
Halving	3 min.	
Total, 2 men		11 min.

125-lb. sample; 2 men.	
Making two heaps, coning, spreading, halving	8 min.
63-lb. sample; 2 men.	
Making two heaps, coning, spreading, halving	6 min.
32-lb. sample; 2 men.	
Coning and halving	5 min.
About 16 lb. sent to bucking room.	
Total, 2 men	90 min.

Total time, 4 men, 2 hr. 35 min. = 1.29 man shifts
Total time, 2 men, 1 hr. 30 min. = 0.38 man shifts

Total .... 1.67 man shifts

Total time to reduce 2 tons to a 15-lb. sample for delivery to assay office . . 4 hr. 5 min.

5. Shovel sampling

Shovel sampling, also called FRACTIONAL SHOVELING, or FRACTIONAL SELECTION, can be applied when ore is being loaded or unloaded, or moved from one place to another by shoveling, or it may replace coning and quartering for cutting down a given lot, with intermediate coning of the sample as previously described. Every alternate, or every third, fourth, fifth or tenth shovelful is taken for the sample, depending upon the size of sample permissible or desired. Common practice is to take the fifth or tenth shovels in unloading a car and to finish sampling by alternate shovels.

Advantages. Shovel sampling is applicable to larger lots than coning and quartering and when alternate shovel loads are taken, is more reliable and accurate; it is cheaper, quicker, and requires much less space. Accuracy is attained by making a large number of sample cuts, the number depending on the size of shovel used and the weight of the lot sampled.

DISADVANTAGES: Shovel sampling should not be used if large lumps, say greater than 2-in., are present. It is subject to manipulation by the sampler in choosing the shovelful to be taken for the sample, both as regards the amount taken and the kind of pieces. The cheapest kind of labor is commonly employed and when other than alternate shovels are taken, it is difficult for the shoveler to keep count of shovelfuls. When ore is piled in a heap in which segregation has taken place and is sampled by this method there is considerable danger of the sample shovelfuls being taken more from either the coarser or finer parts of the heap, so that every size of material is not represented in proper proportion in the sample.

Time required by four Mexican laborers unloading a 20-ton car and taking at the same time a tenth-shovel sample is given by Johnson as 2.5 hr. At EL PASO smelter four men take 4 hr. unloading a 50-ton car of Chino concentrate (15 per cent. moisture) and taking every tenth shovel for sample. (*117 J 13.*) In this instance, the sample is shoveled onto boards placed across the car above the load that is being shoveled; the sample remains in the car and is moved and dumped, samples from five cars being united.

Cost of shovel sampling varies with the character of material, moisture contained and facilities available for disposal of sample and reject.

The labor cost of the old method of sampling wet, sticky flotation concentrate at GARFIELD smelter, consisting in taking every 15th or 20th shovel for sample and cutting down further by alternate shovels, was from 6¢ to 8¢ per ton of concentrate before the war to 20¢ later. (*122 P 17.*)

A variation of shovel sampling used on high-grade silver ore from Cobalt follows. (*17 CMI 239.*)

Ore coming from a trommel with 0.25-in. openings is discharged into wheelbarrows and distributed in a long narrow ridge. The ridge is turned over once by shoveling and a new ridge formed, then divided by alternate shoveling into two ridges, the shovelfuls being carefully distributed over the tops of the ridges. These two ridges are each divided into two other ridges by the same method, four ridges resulting. Further reduction of each ridge

is then made by successive crushing and riffling. Table 6 gives the assays of samples from each of the four ridges with five different ores and indicates that this method gives good results even on ores as difficult to sample as these.

Table 6. Results of shovel sampling Cobalt silver ores

Ridge	Silver, ounces per ton				
	A	B	C	D	E
No. 1	2269.7	2082.8	1527.7	535.8	353.3
No. 2	2263.6	2079.2	1533.0	538.5	355.1

Maximum deviation, per cent. of total	−0.2%	−0.3%	−0.3%	+0.85%	+0.9%

Combination of hand-sampling methods is used by the U. S. Bureau of Mines in sampling coal. (*Bul. 116, USBM.*) The original or gross sample of 1000 lb. for ordinary lots (or 1500 lb. when large pieces of impurities are present, or 500 lb. with slack or smaller sizes of anthracite) is taken by grab sampling or shovel sampling during unloading. The amount taken at each grab or shovelful varies from 5 to 10 lb. for slack and smaller sizes to 10 to 30 lb. for run-of-mine coal. The sampling interval depends on the size of lot. When taking the sample from bottom-dump cars, while unloading, a special " ladle " is used having a handle 5 ft. long and bowl 1 ft. in diameter at top, 9 in. at bottom, and a depth of 9½ in. The " ladle " holds from 25 to 30 lb. of coal. Generally two ladlefuls are taken from each car by holding the ladle underneath the car when dumping. The gross sample is cut down by alternate shoveling to 250 lb. and coning and quartering to 15 lb. as follows:

1000 lb. gross sample. Crushed to 1-in.; mixed by shoveling into a conical pile, then shoveled into a pile 5 to 10 ft. long and alternate shovels taken giving a **500-lb. sample,** which is crushed to ¾-in. and treated as above, giving a **250-lb. sample.** This is crushed to ½-in., mixed, by shoveling, into a conical pile and then shoveled into another cone, flattened and quartered, giving a **125-lb. sample,** which is crushed to ⅜-in., placed on a blanket or canvas (6 ft. × 8 ft.), mixed by rolling, coned by drawing up the ends of the cloth, then flattened and quartered, giving a **60-lb. sample.** This is crushed to ¼-in., placed on the blanket and the preceding operation repeated, giving a **30-lb.** sample which is crushed to 3/16-in. and again subjected to rolling, coning, flattening and quartering, giving **15-lb. sample.** Two **5-lb.** samples are taken from the two 7½-lb. sample quarters, and are placed in sample containers.

Every precaution as described in Art. 4 is taken in forming the cones and shoveling from them. The first shovelful for forming the long piles is spread out in straight line, having a width equal to the width of the shovel and length of 5 to 10 ft. The next shovelful is spread directly over the top of the first but in opposite direction and so on, back and forth. The pile is occasionally flattened during this procedure. Alternate shoveling from the long pile begins at either end on one side and successive shovelfuls are taken the width of the shovel apart as the shoveler advances along one side and around the pile, always in the same direction. Crushing may be done mechanically or by hand with an iron tamping bar or sledge on a sheet-iron plate or solid floor. Flattening of the cone is accomplished by pressing the apex vertically with the flat of the shovel or a board.

Trench sampling (*Smith, loc. cit.*) consists in spreading the ore out into a flattened square or rectangle, about 2 or 3 ft. thick with 100-ton lots and from 1 to 2 ft. thick for smaller lots, and cutting trenches through the cake about 1 ft. wide, crossing at right angles at the center. All material thus excavated is taken for the sample or alternate shovelfuls may be taken. Sometimes all of the material from the trenches is rejected and samples are taken with a shovel from the sides of the four piles left. The accuracy of this method depends on the degree to which material is mixed before making the flattened rectangle. If the rectangle is made by spreading out from a cone, the sample will probably contain too great an amount of fine material, as the same width of cut is taken from the center as from the edges. (See Art. 4.) As the sides of the trenches take the form determined by the angle of repose of the material, it is difficult to be sure that the same proportion of ore is taken from the top as from the bottom, and if there is a difference between the top and bottom layers, the sample will not be accurate.

Quartering shovel (Fig. 2) is a shovel about 10 in. wide, with flanged edges and with two partitions on the blade dividing it into three spaces. The two outside spaces cover three-fourths of the area of the shovel blade and are open at the back. The center space, about 2.5 in. wide (one-fourth of the area) is closed at the back. The sampler pushes the shovel into an ore pile and then, with a quick rotary motion, swings the loaded shovel. The ore in the two outside spaces slides off the back of the shovel and goes to the reject, while the portion in the center space remains on the shovel and is thrown into a wheelbarrow or other receptacle as the sample.

This device does not give accurate results. There is a tendency for fines to be more in evidence in the central space and coarser pieces in the two outside spaces. The method is seldom used, as it offers no advantages over fractional shoveling and is less accurate.

Fig. 2.—Quartering shovel.

Fig. 3.—Split shovel.

Split shovel or U-shovel (Fig. 3) is made up of several troughs, generally about 12 to 18 in. long, 2 in. wide and 2.5 to 4 in. deep, with intervening spaces of the same width. Material to be sampled should be crushed to 0.5-in. or less. The shovel is laid on the ground or held by an operator and another man shovels the ore onto the split shovel with a square-end shovel. When the troughs are filled, the first man throws the split-shovel load to the sample heap. The troughs must not be allowed to overflow.

This method is slow, requires two conscientious and careful men, and is not as accurate as the alternate-shovel method.

6. Pipe sampling

Several varieties of pipe or gun samplers are used. The simplest form consists of a piece of pipe (0.5-, 1-, or 1.5-in. diam.) one end with sharpened edge, the other fitted with a tee and two short nipples to form a handle. The pipe should be long enough to reach the bottom of the heap to be sampled; it is thrust vertically to the bottom of the heap at regular intervals, and then withdrawn and pounded with a hammer, to release the sample.

Several forms are shown in Fig. 4. (*A*) consists of pipe and fittings made up as above, with a longitudinal slot cut out. It is pushed into the mass to be sampled, twisted around until filled, and then withdrawn. (*B*) is made up of two such slotted pipes, one smaller than and within the other. It is pushed into the ore with the pipes in position (*a*) until it reaches the bottom. The handle is then turned until the pipes take position (*b*) and is twisted back and forth until the inner pipe is filled with material. The pipes are then again turned to position (*a*) and withdrawn and emptied into the sample box or sack.

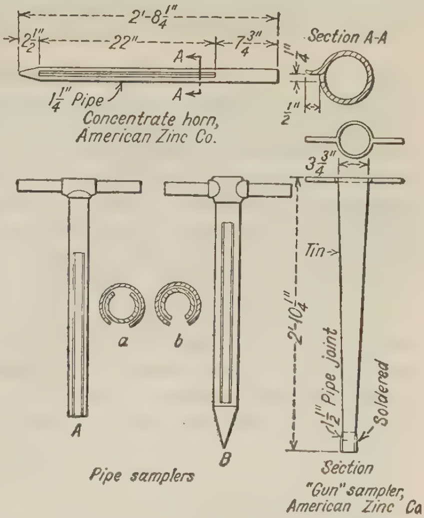

FIG. 4.—Pipe samplers.

Applicability. Pipe samplers are satisfactory for sampling fine concentrate in railroad cars or bins, provided the material has not packed down too hard. They are also used for sampling sand in vats before or after treating with solution in percolation extraction processes. They can be used on tailing heaps or on any finely-crushed ore. Small pipe samplers are used for sampling material in sacks or cans. Pipe sampling gives quick results, is cheap, and, for concentrate or vat charges, where the material is well mixed, results are as accurate as necessary. Pipe sampling of concentrate or other fine material in cars is usually done by taking samples at regularly spaced intervals.

In MONTANA (*121 P 866*) the usual method is to make insertions of pipe in parallel rows spaced at 2-ft. intervals. The pipes are 4 to 5 ft. long, 3 in. diam. at top and 2 in. at the cutting edge. About 250 lb. is usually obtained from 40 to 75 insertions of pipe. The expectable error is within 1 part in 100. Two men should sample the material in a 50-ton car in about 30 min.

Auger samplers, resembling ordinary earth augers, are also used in the same manner and on the same classes of material. They have the advantage that they can be used on material that has packed so hard that it is difficult to force a pipe or "gun" sampler into it.

MACHINE SAMPLING

Automatic machine samplers are devices designed to substitute mechanical processes for the undesirable human element in hand-sampling. By so doing they lessen or eliminate the accidental and intentional errors introduced by the personal factor, shorten the time required for cutting a sample and reduce the amount of operating labor. Against the reduction in labor and time are to be charged the consumption of a small amount of power, a capital investment with attendant interest and amortization, repair and maintenance charges. Further, in a custom sampling plant, cleaning out between different lots of ore is a tedious and difficult job. Machine samplers have difficulty in handling sticky ore.

The fact that ore being machine-sampled is not in sight throughout the operation in a custom mill, delayed the substitution of machine for hand methods, but at present practically all large custom mills use machine sampling and find marked advantages in the ease and uniform accuracy of operations.

Sampling machines require the ore in motion in order to present it to the cutters as a thin ribbon or stream. They are of two general types: (*a*) Those that take part of the stream all the time (stationary devices); (*b*) those that take all of the stream part of the time (moving devices).

7. Stationary machine samplers

Stationary cutters are designed and used on the assumption that there is no variation in the character of material in a transverse section of an ore stream. This is practically never the truth. Generally the material in a moving stream varies more irregularly and less gradually in a transverse section than along its direction of flow. In broken ore sliding down an inclined chute, the coarse pieces slide on top and toward the center, while the fines are on the bottom and against the sides. When such a stream changes direction, the coarser and heavier pieces are carried to the far side of the chute, due to their greater momentum, while the finer particles are not carried so far. The result is a stream made up of coarse on one side and fine on the other, which does not subsequently mix and become uniform. The following conditions may cause similar results (*A. W. Warwick, Notes on sampling, Industrial Print. and Pub. Co., Denver, 1903*): (*a*) Two elevators throwing ore into the same chute, one elevator raising low-grade ore and the other richer ore; if the streams do not cross, little mixing takes place. (*b*) Feeding an elevator from the side instead of from the front. (*c*) Irregular feed of coarse and fine material to a crusher, or coarse material on one side and fine on the other; (*d*) anything that produces an eddy causes segregation between different sizes in an ore stream. Stationary cutters can not be expected to deliver an accurate sample unless ore is presented thoroughly mixed.

Whistle-pipe sampler in its simplest form consists of a vertical iron or steel pipe with notched openings cut halfway through the pipe, each opening spaced 90° horizontally from the preceding. Rectangular steel plates are placed in the notches so that top edges coincide with a diameter of the pipe. Above each notch is placed a hopper-shaped cast-iron liner which gathers the ore into a compact stream before presenting it to the dividing edge. Ore is poured into the pipe at the top. When the stream reaches the first splitter, half is deflected outside the pipe and falls into the enclosing bin or housing as reject. The remainder continues down the pipe and is halved by each succeeding edge. The portion passing the last cutter constitutes the sample. With five dividing notches, *e.g.*, the sample is $\frac{1}{32}$ of the weight of the total material fed to the pipe.

Fig. 5 (*Warwick*) shows details of an improved type of whistle-pipe sampler, in which material is fed at each cut to a splitter (*m*) that divides the stream into quarters. Opposite quarters are rejected, the other two continue and are again split in the same manner. In this design deflectors are spaced at 45° horizontally.

Advantages of whistle-pipe samplers are cheapness of installation and operation, simplicity, and quick reduction of bulk. No power is needed. Disadvantages are such as to preclude their use when an accurate sample is desired. In the simple type first described, wear on the cutting edges causes displacement thereof so that a changing proportion of the stream is taken as wear progresses. The improved design with vertical cutting edges dividing the stream in quarters avoids this disadvantage. Fuse, waste, rags, wood and similar materials catch on cutting edges and cause improper splitting and may clog the openings. Clogging cannot be detected during operation. The general objections to machines that cut part of the stream all the time also apply. Uneven wear of cast-iron liners may cause segregation. No opportunity is afforded for re-crushing between cuts hence the whole lot must be reduced to a size commensurate with the bulk of the final sample. Expense of such crushing would be out of the question in a custom sampling mill, and would not be justified in any mill where the ore could be treated in a coarser state than sampling demanded.

Single-split samplers consist of a splitter or divider placed in such a way in a stream of material issuing from a launder or chute as to continuously deflect a portion of the stream into a sample hopper or container. They are more inaccurate than the whistle-pipe samplers and have little to commend them.

Bank or combination riffles are usually made of five sets of riffles arranged as shown in Fig. 6 (*TP 86, USBM*), each riffle made up of a number of troughs of equal width, separated by cutting edges, adjacent troughs discharging in opposite directions. For detailed description of single riffles see Art. 11. Material is fed in a uniform sheet over the first riffle and split into many streams. Half of these discharge one side and half

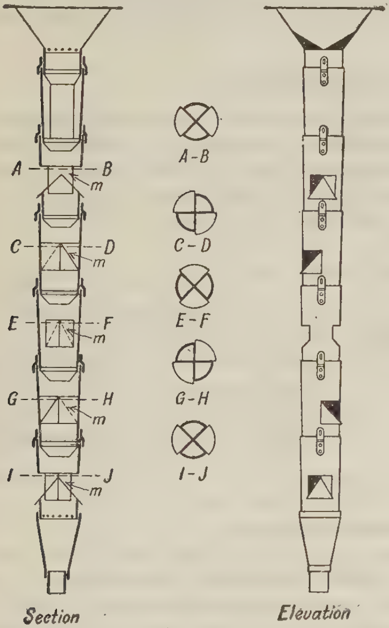

Fig. 5.—Whistle-pipe sampler.

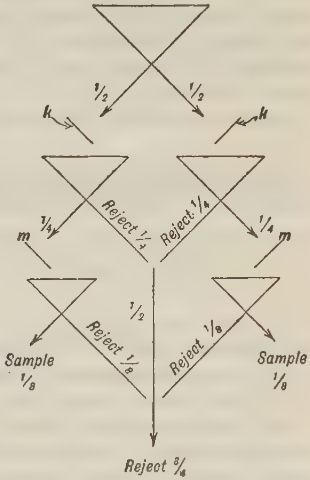

Fig. 6.—Riffle bank.

the other. Discharges from the first riffle impinge on inclined plates (k) and fall to a second set of riffles, smaller than the first. These riffles produce four main streams, two of which unite and pass in to the reject, while each of the others falls to deflecting plates (m) and then to a third set of riffles, smaller than the second, which again halve the streams. One-half from each of the last riffles is rejected, while duplicate samples, each representing one-eighth of the whole, are furnished by the others. The riffles are supported by a rigid frame or may be so hung that one or more sections can be swung across a falling stream of ore.

This machine makes many cuts of the ore stream and, therefore, has ADVANTAGES over methods that make only two or four cuts. It is simple of operation and, as it is generally used on fine ore, wear on the dividing edges is not great. The DISADVANTAGES are that the device is one of the class that cuts part of the stream all the time; construction is not simple; great care is required to insure that each compartment is of same width as others; there is a

possibility that during operation dividing edges will become bent or knocked out of shape so that they do not make a proper division; damp ore and foreign waste clog the riffles, and clogging may not be discovered for some time on account of inaccessibility. Clogging causes one part of the riffle to take no sample or deflects too much into the sample. Tapping with a hammer will obviate clogging, but may deform the riffle edges. If the feed is not carefully delivered to the first riffle, segregation of the coarse and fine material is probable, producing an improper sample. Damp, fine material sticks to the deflecting plates and may cause deflection of coarse pieces with resulting segregation. Riffles are sometimes swung or shaken to avert clogging and segregation.

8. Moving machine samplers

Principle. These take all of the stream part of the time and thus eliminate errors due to changes in character of the stream across its section. They remove equal sections across the stream at frequent regular intervals and since change in character of the material in a stream along its direction of flow is gradual the average of all cuts represents the average grade of the whole mass of material.

Suppose an ore worth $10 per ton passing through a mill. On top of this ore in the feed bin is a lot of ore running, say, $30 per ton. As ore is drawn and the $10 ore becomes nearly exhausted, the grade of ore in the stream gradually changes. If Fig. 7 represents the changes in value along the stream, and the diagonal lines represent sample cuts, it is apparent that the average of assays of the sections cut is the average of assays of all sections from the $10 section to the $30 section. The result is the same if even-numbered sections are taken. Abrupt changes require frequent cuts, the more frequent the cuts the more accurate the sample.

FIG. 7.—Sampling cuts in stream of changing value.

Requirements for accurate machine sampling are:

(1) The sampler should take the whole of the stream part of the time.

(2) Equal percentages should be taken from all parts of the stream. This necessitates that the cutter travel at a uniform rate while passing through the stream, and the scoop move completely across and out of the stream at each cut. If the rate of motion of the cutter is variable, the largest percentage will be taken from those parts of the stream where the cutter moves most slowly, and unless the cutter moves out of the stream on both sides, one side will be unduly weighted in the sample.

(3) The interval between cuts should be constant, otherwise all sections along the length of the stream will not be equally represented.

(4) Cuts should be frequent enough to insure representation in the sample of the most abrupt change in the character of the stream.

(5) The distance between cutting edges should be great enough to allow the largest pieces of material free passage between them; this distance should be at least three times the diameter of the largest piece, better four times or more.

(6) The depth of the scoop should be sufficient to prevent material from bounding or splashing out.

(7) Scoops with closed bottoms should be large enough to hold all of the material taken in one cut without danger of overflowing. The opening to discharge the sample should be large enough to empty the scoop quickly and prevent sedimentation.

(8) Feed should be constant; if the stream is intermittent, the cutter may receive no sample during some of its passages.

(9) Speed should not be great enough to knock away pieces that should go into the sample. In a revolving sampler speed should be so low that centrifugal force will neither throw material out nor prevent discharge.

(10) The stream delivered to the cutting edge should be as narrow as possible in order to lessen the time of passage of the cutter through the stream. The limit of this contraction is determined by the size of the largest particle.

(11) The ore should be thoroughly mixed and all devices that tend to cause segregation eliminated.

(12) The drive should produce uniform motion of the cutter. Relatively high speeds prevent jerky motion. Loose belts should be avoided. It may be advantageous to reduce from a high-speed belt-driven countershaft by gears.

General principles of sampler construction. The following, while not essential for accurate sampling, are desirable characteristics for any sampler. (*a*) The construction should be rugged enough for the service. (*b*) All parts should be easily accessible, both for observation and repairs. (*c*) The feed should be delivered to strike the cutting edge at right angles to the direction of motion of the edge. (*d*) Clearance between the feed spout and the cutting edge should be at least 1.5 times the diameter of the largest particle, to prevent clogging or jamming.

Many different samplers are used; some capable of accurate work, others not. A few machines have become well known and their design is more or less standardized. On the other hand many plants design and build their own samplers, intended to meet local requirements. Moving sampling devices may take the form of a deflecting surface diverting the sample out of the stream; or there may be a deflecting surface which diverts the whole stream, with an opening to allow the sample to pass through; or a scoop may cut through the stream and catch the sample, discharging either through an opening in the scoop or by dumping at some convenient point. The greatest variation in samplers of local design is in the method of driving.

9. Moving samplers for dry ore

Brunton vibrating sampler is shown in Fig. 8. Ore fed through chute (*c*) passes through spout (*b*) in a narrow stream or ribbon to cutting edge (*a*), consisting of a vane oscillating on shaft (*p*). The vane deflects the stream first into chute (*e*), then into chute (*d*). The ore delivered by one of these chutes is taken as a sample. The vibrating cutting edge is actuated by connecting rod (*j*), connected to sliding bar (*i*); motion is imparted to (*i*) through bent rods (*n*) attached thereto and pins (*l*) in wheel (*h*), which is mounted on a shaft with pulley (*g*) and driven by belt from a convenient source of power. Wheel (*h*) has two rows of 20 holes each in the rim to receive pins (*l*). Rows of holes are spaced the same distance apart as the sliding bar is required to travel. Frequency of cuts and the time that the cutting edge deflects the stream into sample is regulated by arrangement of pins. Each hole represents 5 per cent. of the time required for one revolution of the wheel.

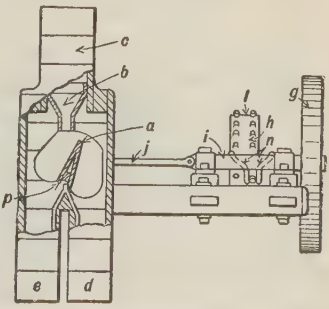

Fig. 8.—Brunton vibrating sampler.

The fundamental error in this machine is that it takes more from one side of the stream than from the other as shown in Fig. 9, *A*; if one side of the stream is the richer, an accurate sample is not secured.

Brunton oscillating sampler (Fig. 10) consists of a hopper (*a*) which receives ore and discharges through vertical chute (*b*) to an oscillating deflector consisting of two reject-deflecting surfaces (*m*) and a sample-deflecting surface (*n*), placed between and separated from the surfaces (*m*) by cutting edges. The machine is so arranged that sample and reject are discharged in opposite directions. The oscillator is made of stiff, strong sheet metal and is attached to shaft (*p*), which imparts an oscillating motion in a vertical plane to the cutter, by means of a counterbalanced crank and connecting rod. A housing of sheet iron surrounds both chute and oscillator. The sampler is usually arranged to take a 20-per cent. cut, but by the use of elliptical gears on the driving mechanism a 5 per cent. cut can be obtained. The cut may also be varied by changing the size of the sample-deflecting spout.

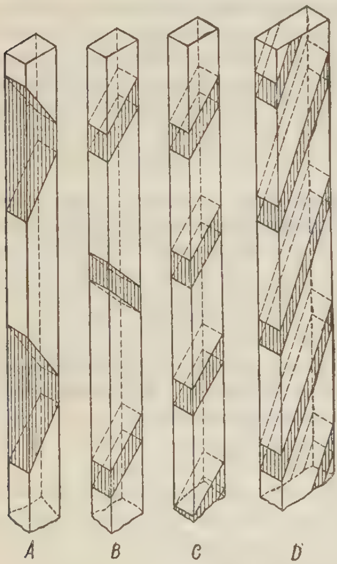

Fig. 9.—Cuts taken by samplers.

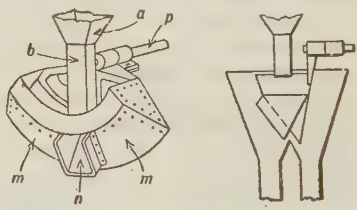

Fig. 10.—Brunton oscillating sampler.

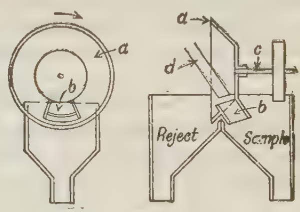

Fig. 11.—Snyder sampler.

At each oscillation the sample spout passes completely through and out of the stream. The cutting edges are short and made of special steel to prevent warping and excessive wear. The side walls of the sample spout should be in planes that pass through the center of the oscillating shaft; otherwise the angular sampling distance will change as the cutting edges wear. The speed may be as great as 72 oscillations per minute. Rapid motion aids materially in discharging, especially if the ore is wet or sticky, and tends to keep the cutting edges free from accumulations of foreign waste.

Advantages. The machine takes a cut of the stream as represented graphically in Fig. 9, *B*. This is correct sampling; the great number of small cuts taken insures an accurate sample. The sampler requires but little head room, is easily accessible for examination and repair, and is quickly cleaned. The fact that sticky ores might clog the spouts is the only serious disadvantage; this danger is common to practically all mechanical samplers.

Snyder sampler (Fig. 11) consists of a pan-shaped plate (*a*) with one or more sample spouts (*b*), supported on and rotated by a horizontal pulley-driven shaft (*c*). The plate and spouts are usually a single strong casting but may be fabricated of good sheet steel. Feed enters through chute (*d*), the

reject is deflected by the conical plate and the sample passes through the spout into the sample hopper. To prevent change in sample weight as the cutting edges wear, the side walls of the sample spout should lie in planes that pass through the axis of rotation. The amount taken for sample is varied by changing the size or number of sample openings; frequency of cuts is varied by changing the speed of rotation or number of openings. The shape of the cut is shown in Fig. 9, *C*.

ADVANTAGES.—The machine is simple in construction, easily cleaned and repaired and can be readily observed during operation. Foreign waste that catches on the cutting edges is readily freed as the disk revolves. Little head room is necessary. A serious DISADVANTAGE is that with wet or sticky ores, fine material adheres to the reject-deflecting surface and as the disk revolves falls through the sample opening; thus salting the sample.

Three sizes are made:

Diameter, inches	Maximum size of feed, inches
60	4
42	2½
27	1

Vezin sampler (Fig. 12) consists of two hollow truncated cones, (*a*) and (*b*), joined base-to-base, with one or more scoops (*c*) attached to the upper cone, all mounted on a vertical shaft. Ore fed through chute (*d*), which may be vertical or inclined, normally passes into hopper (*e*) and is rejected through spout (*f*). As the sampler revolves, chutes (*c*) cut through the stream and divert parts into the conical chamber and through spout (*g*) as sample. The inventor recommends an inclined chute delivering ore so that the horizontal component of velocity is the same as that of the cutting edges. This gives the effect of a piece falling vertically on these edges. Warwick (*loc. cit.*) states that the mode of delivery, whether vertical or inclined, has no effect on the accuracy of the sample.

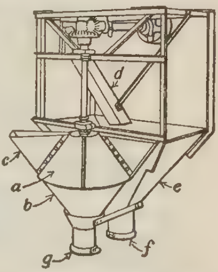

FIG. 12.—Vezin sampler, single.

The cutting edges should be radial to the axis of rotation and the sides of the scoops vertical; otherwise the scoop will take more from one part of the stream than from another. In Fig. 13, *A* the edges are radially placed, the angular velocity is the same at all points, and all parts of the stream, therefore, flow into the sample for the same time. This gives a correct cut. The shape is shown in Fig. 9, *D*. In 13, *B*, the lines of the cutting edges intersect on the scoop side of the center, the arcs subtended increase from inside to outside of the described annulus and a smaller proportion of the stream is cut from the inner edge than from the outer. The opposite case is illustrated in 13, *C*.

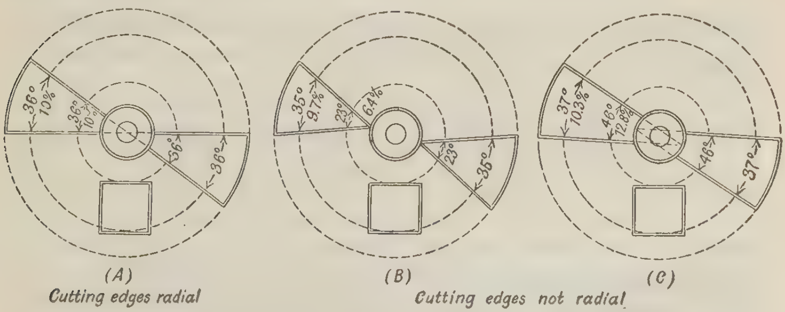

FIG. 13.—Arrangements of cutting edges in Vezin-type samplers.

The proportion of the stream length that is taken for the sample is determined by the ratio of the number of degrees of arc subtended by the sample spouts to 360°. For a 10-per cent. cut a single sample spout should subtend 36° of arc, or with two spouts each should subtend 18°. The speed has no effect on the amount taken for the sample but affects only the FREQUENCY of the cuts; frequency can be varied also by changing the number of scoops. Usually one or two scoops are used, sometimes four. Two samplers are sometimes mounted on opposite sides of the same reject hopper in order to take duplicate samples. SPEED should not exceed 3 ft. per sec. at a point on the scoop at the center of the feed stream, in order to prevent knocking pieces out of the stream, throwing them out of the scoops by centrifugal force, or hindering discharge. Width of scoop should be at least four times the diameter of the largest piece of material at the center of the stream and the opening into the cone should be at least 2.5 times this maximum diameter. Cutting edges should be made of hard, brittle steel to avoid distortion and wear; chips lost will probably be small and not materially affect operation; but bending changes the whole aperture.

Fig. 14 shows a simple and efficient design for cutting edges used in sampling COBALT silver ores. The scoop is made of tempered steel, tapered for a short distance at the top to make a knife edge. Small wedge-shaped pieces of steel are placed between the scoop walls to hold the edges rigidly in place. For ordinary use such careful sharpening of edges is not necessary or common but Cobalt ores are difficult to sample and it is necessary to take every precaution to attain accuracy.

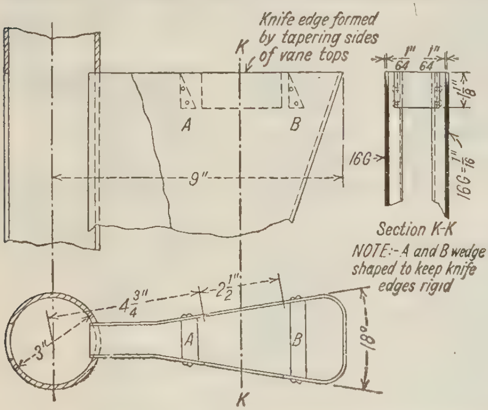

FIG. 14.—Cutting edges on Vezin samplers at Cobalt.

ADVANTAGES of Vezin samplers are the ability to take an accurate sample; simplicity of construction; and easy accessibility for observation and repair. DISADVANTAGES are the head room required, danger of clogging, lack of ruggedness, possible improper construction of scoops, and delivery of feed in a manner to cause segregation and inaccurate sampling. The machine should be constantly watched to detect lodgment of foreign material on the cutting edges and to be sure that the scoops are not clogged. Hammers or mallets should be used only with the greatest care, if at all, to free clogged chutes on account of danger to cutting edges.

Size. Vezin sampler is made in the following sizes:

Number	Max. size feed, inches	Weight, single, lb.	Weight, duplicate, lb.
1	1	500	850
2	2	850	1300
3	4	900	1600

Chas. Snyder sampler (Fig. 15) is similar to the Vezin sampler, except that it has four sample scoops and the feed chute, instead of being square or rectangular, is annular and extends over an arc of 90°. As a result there is a

sample scoop under the feed stream at all times. Feed is scattered by a number of short iron rods extending across the feed chute; these tend to reduce segregation.

Fig. 9, *D* shows the kind of cut made by this machine. The ADVANTAGES and DISADVANTAGES are the same as those of the Vezin.

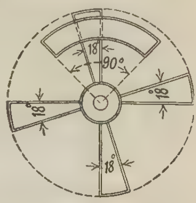

FIG. 15.—Chas. Snyder sampler for 20-per cent. cut.

Simplex sampler is fully shown by Fig. 16. It can be arranged to take cuts from 5 per cent. to 30 per cent. As in other rotating samplers, the sides of the cutter should be in planes passing through the axis of rotation.

The machine is made in the following sizes:

Size, in.	Sample, per cent.	Pulley, in.	Speed, r.p.m.	Weight, lb.
28	10	4½ × 24	24	600
44	10	4½ × 36	15	700
64	10	4½ × 48	10.5	850

ADVANTAGES are simplicity in construction; small head room required; easy inspection and repair. DISADVANTAGE. Wet ores stick in the deflecting scoops, are carried up and fall into the reject, causing, of course, inaccurate results.

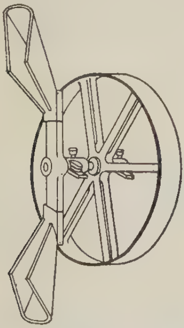

FIG. 16.—Simplex sampler.

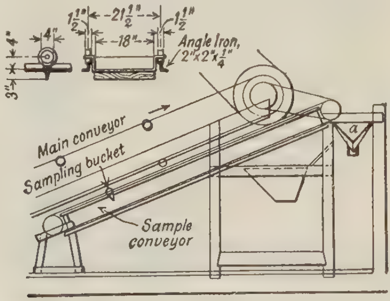

FIG. 17.—Van Mater sampler.

Van Mater sampler (Fig. 17) consists of a sprocket-chain sampling conveyor set under and carrying a sampling bucket through the discharge of the main conveyer. The sampling conveyor is driven by pulley and belt from the head end of the main conveyor. Any number of sampling buckets may be used according to the frequency and size of sample desired. The buckets must be at least as wide as the stream delivered by the main conveyor. The sample cut by the buckets is dumped into a sample hopper (*a*) as the bucket passes over the head sprockets. A wooden wearing block is fastened to the bottom of the buckets to take wear when the bucket passes through the stream of ore on the return trip. The proportion taken for a sample is the percentage of the total length of sprocket chain that is represented by the distance between the cutting edges of a bucket, multiplied by number of buckets. The bucket must be deep enough to prevent material from bounding out. *(88 J 1282.)*

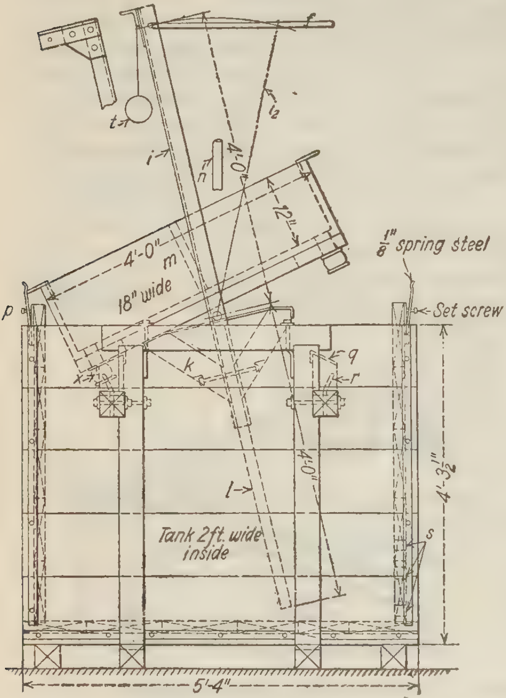
Damp and sticky ores. The machines thus far described are especially adapted for ores that are dry or nearly so. With damp or sticky ore that tends to ball up or stick to machine surfaces, they are unsatisfactory. Such ore is generally dried prior to sampling or some method of hand sampling is used.

Martin sampler was used to sample flotation concentrate at GARFIELD smelter. The machine was mounted on a traveling gantry. A 1¼-yd. clam-shell bucket unloaded concentrate from 75-ton flat-bottom railroad cars and dumped through a grizzly into a 20-ton hopper. The bottom of the hopper, 9 ft. square, consisted of a belt conveyor which carried material through a 6-in. slot 9 ft. wide in one side and discharged on to a "chopper" consisting of eleven 15-in. revolving disks spaced 12 in. on a shaft with No. 12 spring steel wires threaded through holes near the circumference parallel to the shaft. This cut the stream into strips which fell onto a 30-in. revolving hollow cylinder with a 16-in. section of the surface cut out along the entire length, making a 1/10 cut. A 12-in. conveyer inside the cylinder carried the sample to a smaller "chopper," thence to a second cylinder cutting out 1/15th and thence by another axial conveyer to a sample car. Rejects passed to a large conveyer which delivered to the bedding bins. (*114 P 17.*)

10. Sampling wet pulp

Sampling freely-flowing pulps is relatively simple; small cuts may be taken, the products are well mixed, of even grade, and, if flowing, the variations along the stream are gradual.

Cutters vary in shape according to the direction of travel of the stream as cut.



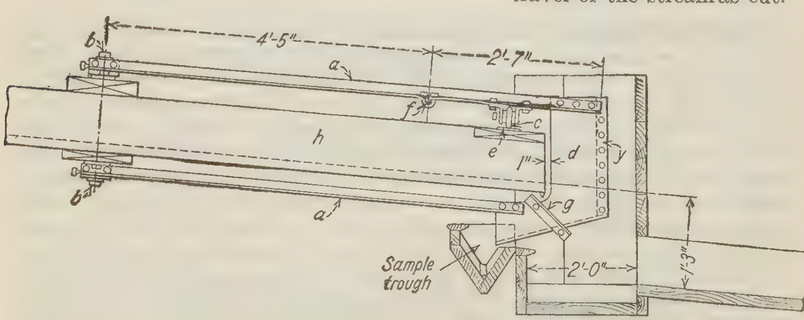


FIG. 18.—Water-tilting box and cutter.

The cutting edges should travel in a plane perpendicular to the stream when cutting. The scoop should be large enough to prevent loss by splashing and splash boards should exclude from the sample any part of the stream that does not enter the cutter directly. The cutting edges should be straight, sharp, easily accessible for observation and repair, and far enough apart to prevent clogging; the aperture is usually made as narrow as permissible to lessen the bulk of each cut and permit a large number of cuts in a small total sample.

Actuating devices are of many varieties. The simplest is a lever automatically operated by a tilting box; cranks, eccentric gears, various simple quick-return mechanisms; pistons, air-, steam-, or liquid-driven; and electrical devices are also used. The essential requirement is uniform, rapid movement to yield a small cut but not to exclude material on account of rapidity. There should be adequate insurance against sticking in mid-stream.

Timing devices are used to insure equal time intervals between cuts. They may be an integral part of the actuating mechanism, as the water feed to a tilting box; or entirely external, as a clockwork mechanism with electrical contacts to control a reversing motor, or tilting boxes to control piston valves. When external timers are used, one such frequently controls all samplers in a section or entire mill.

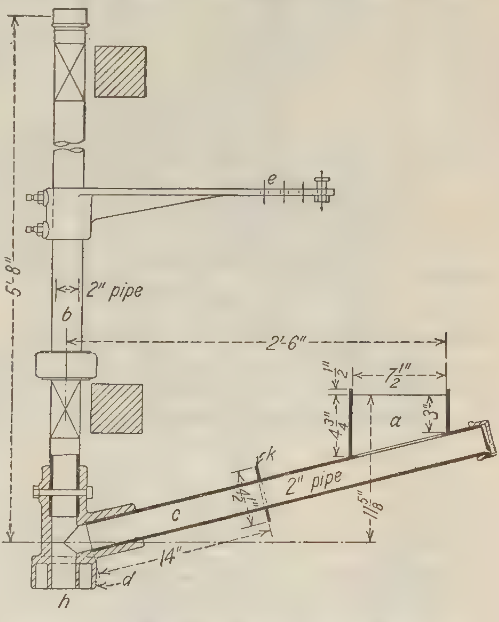

FIG. 19.—Pulley-driven sampler, St. Joseph Lead Co.

Vertical-edged cutter traveling on horizontal circle, actuated and timed by a tilting box is shown in Fig. 18. The scoop (d) is made of a piece of sheet steel cut and bent to proper slope for discharge of the sample and riveted against a ¾-in. wedge-shaped block to close the back; angles (g) prevent drip from sides into the sample. It is carried on a stiff frame (a), made of two pairs of 1½ × 1½-in. angles, back-to-back, carried on pivot bolts (b), roller (c) and plate (e). The carriage is dragged back and forth across the stream by rod (f) attached to upright (i) of a tilting box. The upright is pivoted on a shaft; it carries below the pivot a bumping frame (k) and, at the lower end, paddle (l). Teeter box (m) is also pivoted on the shaft. This box is divided by a central transverse partition and is provided with two check valves. Operation is as follows: With the box empty and in the position shown, water enters the upper compartment through pipe (n). When this compartment is full enough to cause release of the spring catch (p) the box tilts freely until it strikes the upper end of bumping frame (k), which then moves downward and swings the upright (i) across into position (i_2), and thus, through rod (f), drags cutter (d) across the stream. At the end of the swing the tilting box strikes bumper (q) and pin (r) opens check valve (x), allowing the water to run from the tilting box into the tank below. The other end of box (m) now

fills and the cycle is repeated. The level of water in the lower tank is regulated by plugs (*s*) at such a height that the paddle takes up the shock of the striking teeter box and causes uniform motion of the cutter. The sensitivity of the mechanism is increased by the suspended weight (*t*) which raises the center of gravity of the tilting frame; this weight also aids in holding upright (*i*) in off position against the weight of the paddles, and, by reason of its inertia during the swing, prevents stoppage at dead center. Timing is regulated by a valve on water line (*n*) which should be on an open-pressure tank with float valve or constant overflow.

Horizontal-edged cutter traveling on horizontal circle, actuated and timed by pulleys and gearing, is shown in Fig. 19. The cutter is a slotted pipe (*c*) with vertical cutting edges (*a*) in planes passing through the axis of shaft (*b*). This shaft is actuated by a reciprocating mechanism similar to the Scobey timer (see p. 1154). The sample receptacle is at (*h*). Ring (*d*) excludes drip.

Horizontal-edged cutter traveling on vertical circle, piston actuated is shown in Fig. 20. The cutter consists of steel sheets (*a*) mounted on a slot in inclined pipe (*b*) supported by stirrups (*c*) and swung through a stream issuing from the bottom of box (*d*) by movement of the water-actuated piston (*e*) controlled by a Scobey timer (see p. 1154). Reject discharges from the side of box (*f*), sample passes into (*g*) and through pipe (*h*) into sample receptacles (*k*).

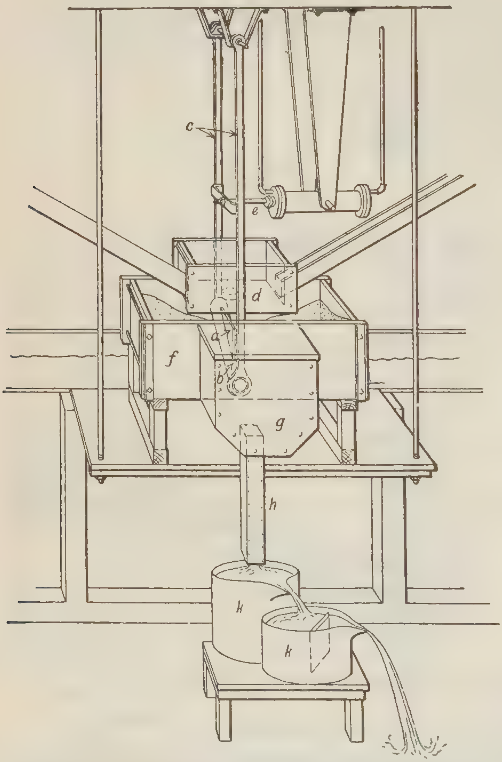

Fig. 20.—Piston-actuated sampler, Alaska Gold Mining Co.

Inclined-edged cutter with straight-line travel, electrically driven and timed is shown in Fig. 21. The cutter (*a*) is a special casting with replaceable cutting edges, suspended by arms (*b*) from a carriage (*c*) running on rollers on track (*d*). Motion is attained through rack (*e*), fastened to the carriage, and reducing gears (*f*) from reversing motor (*g*) controlled by a timing drum and electrical connections as shown in the figure. With the timing drum in position shown and contact blocks, operated by lug (*k*) and rod (*m*), in the right-hand position, the motor connections (*h*), read clockwise, are (*A*), (*C*), (*B*) and the motor runs counter-clockwise. With the timing drum at 180° from this position and the contact blocks in the left-hand position, the motor connections read (*A*), (*B*), (*C*) clockwise and the motor runs clockwise. This timer provides for one cut every 8 min.

Vertical-edged cutter with straight-line travel, actuated and timed by tilting box is shown in Fig. 21*a*. Here three scoops, sampling as many pulp streams, are mounted on one carriage driven by the tilting box.

Borcherdt sampler (*101 J 524*) (Fig. 22) uses the pulp stream for motive power. It consists of two wheels (*h*) and (*i*) mounted on ball bearings on a vertical shaft. Each wheel is divided

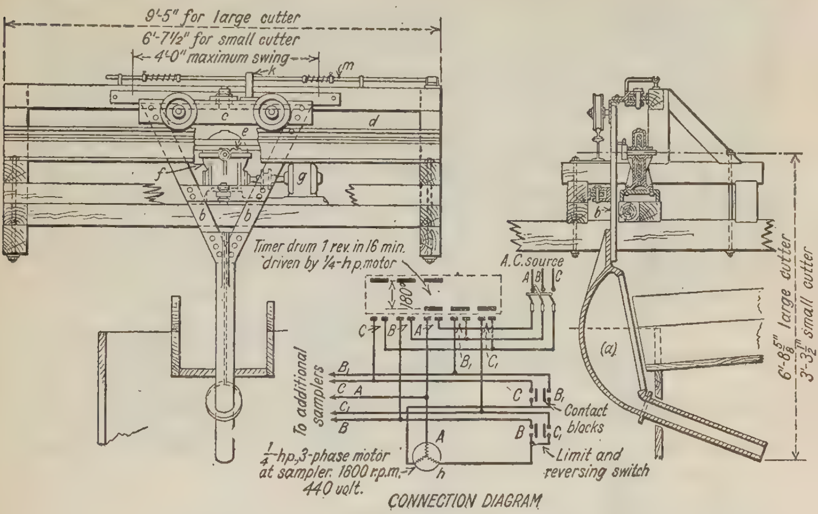

FIG. 21.—Electric sampler, Chino-Copper Co.

into a large number of equal pockets by means of thin pieces of sheet steel, the plane of each sheet passing through the axis of rotation. One pocket of each wheel is fitted with a false bottom (*f*) so arranged that any material entering the pocket is discharged toward the center of the wheel; the remaining pockets are open. The proportion of the stream cut as a sample depends on the number of pockets on the wheel. Pulp is delivered to the upper wheel from a covered box (*a*) through a number of short pipe nipples (*b*) slightly inclined so that pulp passing from them causes the upper wheel to rotate. Pulp caught by the closed pocket of the large wheel is delivered to a distributor (*c*) which spreads it over about one-third the area of the smaller wheel. The latter is rotated by the action of the falling pulp on eight inclined paddles (*d*) fastened to the periphery. Pulp caught in the closed pocket of the small wheel is delivered to the center and discharges through pipe (*e*), passing out of the bottom of box (*g*), which encloses the apparatus. The main pulp stream falls through both wheels and discharges through a launder let into the side of box (*g*). The two wheels rotate in opposite directions at about 7 r.p.m. for the larger

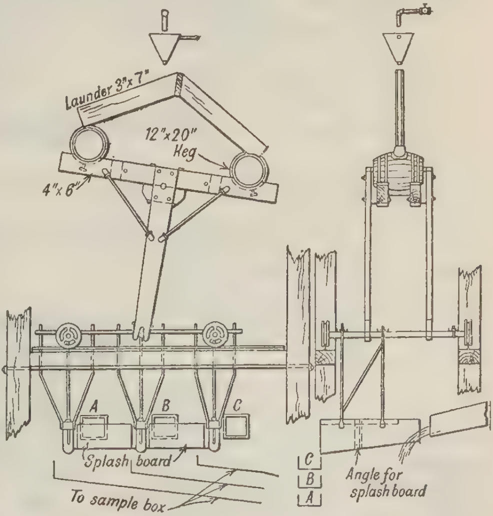

FIG. 21a.—Tilting-box sampler with three scoops.

and 13 for the smaller. The sampler works without splash on tailing from a 45-stamp mill carrying 180 tons of solids and 1440 tons of water per 24 hr.

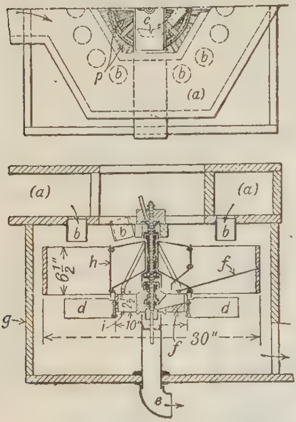

FIG. 22.—Borcherdt sampler.

Flood sampler (Fig. 23) has two vertical solenoids (*a*), energized through a timing clock. When energized, the solenoids draw up soft-iron cores (*b*) carrying a yoke (*c*) which is bored out in the center and has a lug that engages a helical groove in spindle (*d*) causing it to revolve through about 45° and swing the cutter (*f*) through a stream falling from spout (*e*). Shaft (*d*) is slightly tilted so that the cutter swings back by gravity into the position shown when the current is cut off. The master clock keeps the circuit closed a predetermined time, usually one to five seconds and then open for some other, usually much longer, interval. Sampler is made with 4-, 5-, or 6-in. cutter and weighs 35, 45 and 50 lb. respectively.

Tilting box as an external timer is illustrated in Fig. 24 where the actuating device on the cutter is a water-operated piston.

Scobey timing device (Fig. 25) is used to operate samplers directly or to control the power for the actuating mechanism. It is driven by belt from a convenient source of power at about 20 r.p.m. Motion is transmitted through bevel gears (*a*) to a chain of intermittent gears which move a sliding frame (*b*) from side to side. A lug (*c*) on the sliding frame causes arm (*d*), pivoted at (*e*) to swing

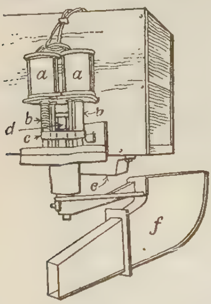

FIG. 23.—Flood sampler attached to bottom of launder.

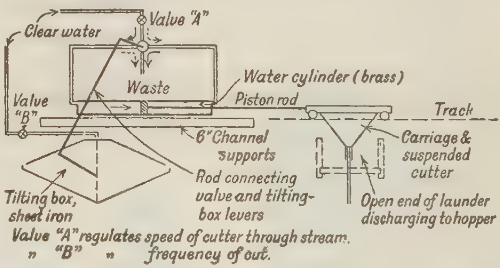

FIG. 24.—Tilting box as external timer.

back and forth. The cutter (*f*) is attached directly to the swinging arm or the arm is connected to a switch or valve controlling the power operating the samplers. The position of the pivot of the swinging arm may be varied by turning hand wheel (*g*), thus changing the length of this arm of the lever and consequently the speed at which the cutter moves. The arc which the arm describes may thus be varied from 10 to 22 in. in length. By using different combinations of intermittent gears, the intervals at which a stroke is made can be varied from 1 min. 20 sec. to 5 min. 20 sec., when the driving pulley is making 20 r.p.m. With a 2-in. cutter attached to the swinging arm and by varying adjustments as above, samples from 1/000th to 1/1000th part can be obtained. When arranged as shown and taking the discharge from a launder, only 10 in. fall is required.

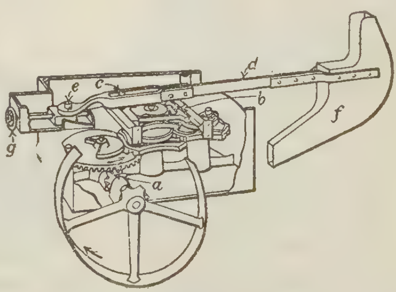

FIG. 25.—Scobey timer.

Galigher mechanism (Fig. 26) for actuating or timing samplers, can be used in the same manner as a tilting box. It may be belt-driven or direct-connected to a 1/6-hp. motor as shown. The motor drives shaft (*B*) through worm and worm gear. Cam (*A*) contacts with roller (*C*) on ratchet lever (*D*), raising the latter, and thus imparting slow motion to the shaft of ratchet wheel (*G*) through friction ratchet (*F*). Bevel pinion (*I*) on this shaft rotates bevel gears (*J*) on stationary shaft (*M*) in opposite directions. Lugs (*K*) on the bevel gears engage lugs (*L*) attached to loosely hanging pendent weights (*N*) and raise them in opposite directions. When either weight reaches an upright position and the center of gravity passes the vertical center-line, it falls. In falling, arm (*O*), attached to the weight, contacts with the cam surface on a trip arm (*P*) and forces it through an arc to the opposite position. The trip arms (*P*) are rigidly connected on opposite ends of shaft (*Q*) and thus cause it to rotate through an arc first in one direction, then in the opposite. Cutter (*S*), attached to shaft (*Q*) by a counterweighted bar, is thus made to move back and forth through the pulp stream discharging from the launder. Weights (*N*) are so placed that one

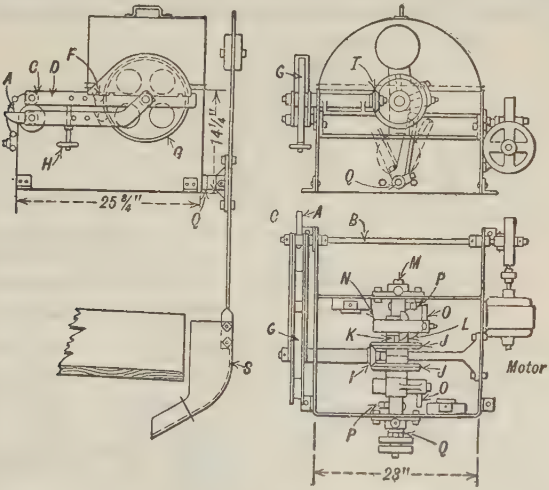

FIG. 26.—Galigher timing and actuating mechanism.

falls while the other is just starting its upward path. Variation of sampling intervals can be made between 10 and 60 minutes by adjusting the length of stroke of ratchet arm (*D*) through adjusting screw (*H*). The counterweight on the sampler bar balances the weight of the cutter and holds it in off position during the interval between falls of the weights.

The machine has advantages over the water tilting box; it is steadier in operation because danger of change of flow or clogging of water supply is eliminated; small space is required and it is easy to connect it up.

Clocks may be purchased which are arranged to open and close an electric circuit through a knife switch at predetermined intervals. They are useful in controlling movements of electric sampling devices such as the Flood.

11. Recording devices

It is essential to accurate sampling to install a recording device on automatic samplers in order to have a check on performance. The simplest recorder is a revolution counter, set to count each cut; the counter is read at beginning and end of the sample period giving the number of cuts and therefrom the average sampling interval. This device does no more, however, than point a lack of cuts in case a sampler is stuck for a part of the sampling period; it tells nothing as to when the hang-up occurred, nor as to whether

it occurred in midstream. Too few cuts indicates unreliability of the sample; too many may point to unreliability of the counter.

Graphical recorders of the Bristol or similar type, arranged to indicate the length of travel of the sample scoop at each cut and the time of the cut, give all information necessary as to performance, in the shape of a chart presenting graphically the relation between time and scoop travel. If the chart indicates that the scoop has stuck in mid-stream, the sample should, of course, be discarded.

12. Hand sample cutters

These are used for wet pulp in practically all plants; in some plants all wet sampling is done by hand; others use them only for taking special and occasional samples. Two forms are shown in Fig. 27. Hand sample cutters

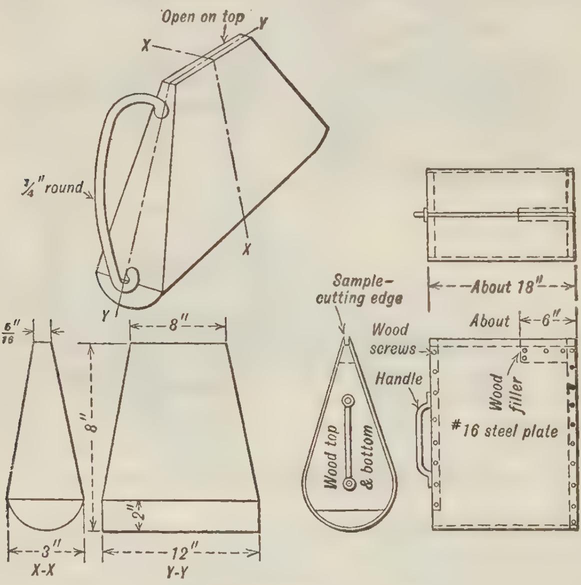

FIG. 27.—Hand sample cutters.

should be held with the edges perpendicular to the direction of motion of the cutter and passed completely through and out of the stream in one direction with a movement as nearly uniform as possible. The best results are obtained by taking cuts at regular intervals of time and by so using the cutter that its operation approaches that of a properly-run mechanical sampler. The cutter should be large enough so that there is no danger of overflow while making one passage through the stream of pulp. The aperture should be at least four times the diameter of the largest grain in the pulp; the cutter should be smooth inside, watertight, and designed to clean itself readily.

13. Preparing wet samples

Splitting wet pulp samples is frequently done before drying, to reduce the bulk. The riffle sampler (Fig. 28) or a device consisting of a revolving

distributor delivering to a compartmented tub may be used. The cutter that takes the sample can be arranged to deliver it over a series of riffles which automatically reduce the bulk.

When the solids are very fine a dip sample may be taken from thoroughly agitated pulp. Air is frequently used for agitation.

Dewatering samples is done by decanting, siphoning or filtering, final drying in any case being by evaporation. Electrolytes such as alum, lime, or sodium bicarbonate may be used to settle solids before decanting or siphoning; 1 to 5 gm. of electrolyte to a bucketful or tubful of slimes is sufficient. (See Sec. 16, Art. 4.) Pressure, vacuum or gravity filters are used. Where the amount of sample for a definite period is large, a series of small settling tanks may be used, arranged so that each succeeding one takes overflow from the preceding, overflow from the last being clear. Final dewatering of material remaining in the tanks is done by evaporation, preceded, if necessary, by filtration. Dewatering before evaporation must not be practiced, if metals are in solution, unless separate solution assays and moisture determinations are made. Great care must also be required of operators in decanting and siphoning to prevent slime losses.

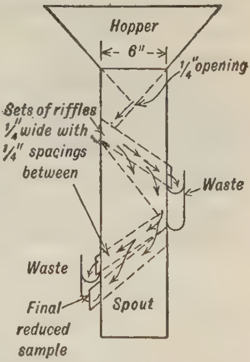

FIG. 28.—Wet riffle.

14. Tonnage determination

Determinations of weight of ore delivered to or passing through different sections of a mill are necessary in order to keep close check on operations. Where ore is being accepted at a mill from a seller, the weight must be determined as accurately as possible; in plants that are milling company ore the weight need be determined only approximately, as a rough check on working. Many schemes are used for tonnage determination, some are accurate and some mere approximations that depend on averages over long periods of time for dependable results.

Track scales are used for carload lots. They ordinarily require the services of an operator who balances the load on the scale beam and notes the weight on a suitable form. This method gives correct results within a small error (0.5 per cent.) but has the DISADVANTAGE of relying on the care and accuracy with which the operator balances the load and notes results. With recording scales the operator merely balances the load, then turns a screw which automatically punches a card and records the weight. Some track scales weigh a train of ore automatically as it passes slowly over the platform. This does away with the personal factor entirely except for occasional standardization. The car must stand free and completely on the scale; snow and ice should be removed before weighing.

Platform scales are used like track scales when wagons or trucks deliver the ore. The tare must be accurately determined. Unless the scales are in perfect adjustment, the load should be centered as nearly as possible at both loaded and empty weighings, or should stand at the same place for both weighings. Naturally, helpers or guests of the driver who weigh in on the full load should accompany the empty wagon over the scales. The wagon

should be at rest when weighed and, in case of animal-drawn vehicles, traces should hang loose.

Automatic dump scales consist of a hopper which receives ore until full, when the weight is recorded and the material run out automatically. This is accurate. Considerable space is required, however, and operation is intermittent, making it necessary to use two units where a continuous stream of material is wanted, so that one will be discharging while the other is filling. Care should be taken to insure that all material runs out before new material is run in.

Conveying weighers are attached to conveyors and automatically record the weight of material being carried. They occupy but little space and need no attendance except for occasional standardizing and adjustment. They are accurate to within 0.5 per cent. when kept in proper adjustment. Several different types may be obtained.

Blake-Denison weigher (Fig. 29) suspends a short section of conveyor from the short arm of steelyard (*a*), which is balanced to the weight of the unloaded conveyor. The load on the conveyor is balanced by a plunger (*b*) suspended in a mercury dashpot (*c*). Shaft (*d*), driven through bevel gears from a pulley revolved by the conveyor, is fitted with cams so that every time the conveyor travels through the suspended distance these cams operate a device (*e*), which grips the steelyard, and a measuring quadrant (*f*) that rotates the ratchet registering wheel (*g*) a distance depending on the position of the steelyard. This amount is recorded on indicator (*h*), calibrated for the units desired. The machine needs no attendance except occasional inspection and calibration with known weights.

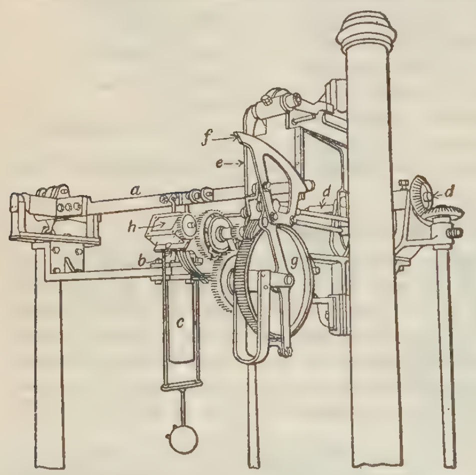

FIG. 29.—Weighing and recording mechanism of Blake-Denison automatic weigher.

Checking operation of the weigher is usually done by feeding known weights of ore to the conveyor at a regular rate for a given period of time. At one plant (*100 J 520*), if the automatic weigher checks within 50 lb. in 8000 lb. in comparison with hand-weighed feed, it is considered accurate enough; if a larger discrepancy is recorded, the weigher is adjusted. To insure proper operation, checking should be done at frequent and regular intervals.

Merrick weightometer (Fig. 30) is so arranged that, instead of weighing the load on the conveyor by a succession of weights of short sections, the weight is taken continuously by means of a specially designed integrator. A portion of the conveyor is suspended by means of rods (*a*) from weighing levers (*l*) that operate beam (*b*). The weight of the load at any instant is automatically counter-balanced by an iron float (*c*) attached to the beam. This float is partially immersed in a bath of mercury and thus as it rises or falls its gain or loss in buoyancy compensates for variations in load. The extreme end of the beam is connected by rod (*d*) to a totalizing mechanical integrator. The integrator (Fig. 31) consists of an aluminum disk (*X*) which has rollers (*Y*) around the periphery, the axes tangential to the edge of the disk and free to revolve. The disk is attached to shaft (*e*) which revolves in bearings on frame (*Z*). The frame is mounted on bearings at both ends which permits it to rotate on an axis that lies in the plane of the disk and passes through the center thereof. A link at one end of the disk frame is attached to rod (*h*) (*d*, Fig. 30) so that any movement of the beam causes the frame to tilt through an angle whose sine is proportional to the vertical

movement of the float which, in turn, is proportional to the load on the suspended portion of the conveyor. Four pulleys (U, U, Q, Q) drive an endless belt (W), which touches rollers (Y) at two points diametrically opposite on the axis of the frame (Z). Contact between the disk rollers and the belt is maintained by pressure rollers behind the belt. The take-up pulley (T) is weighted and insures an even tension of the belt and takes care of any stretch. The two pulleys (U) are geared together and driven by means of gears from a bend pulley under the return conveyor belt, or from a sprocket, if link belt is used. When the belt is running unloaded, the machine is adjusted by means of an adjusting weight on a screw attached to the beam so that the disk remains vertical. In this position motion of (W) causes rotation of rollers (Y) but no rotation of the disk. When a load comes on the conveyor, motion of the beam causes the disk frame to tilt, the axes of rollers (Y) become inclined to belt (W) and the belt pushes the rollers sidewise, causing the disk to rotate at a speed proportional to its inclination, *i.e.*, to the load on the conveyor. Revolution of the disk is recorded on a counter calibrated to read weight in the units for which the machine is designed. Thus the two factors, speed of belt and weight carried per unit of length are accounted for.

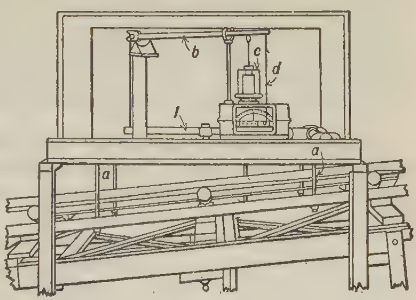

FIG. 30.—Merrick weightometer.

This device can be used for weighing material transported on belt and bucket conveyors, cable railways and overhead transporters. A special attachment can be procured that counterbalances a varying empty weight of conveyor, should the material handled adhere to the belt on the return trip.

Electric weigher operates on the principle that the amount of current flowing through an electric circuit is proportional to the product of the voltage and conductivity of the circuit. Voltage proportional to the speed of the conveyor is produced by driving a constant-field dynamo by gears or a chain and sprocket attached to the driving shaft of the conveyor. Conductivity is varied with change of load by a rheostat operated by a plunger in a mercury dashpot. An ampere-hour meter in circuit is graduated to read in units of weight. A section of the conveyor is suspended in a manner similar to that employed in the Merrick weightometer. A counterweight on the scale beam balances the empty weight of the conveyor while the weight on the beam due to the load carried is counterbalanced by motion of the plunger in the dashpot. To provide for varying weight of the empty belt, a corresponding length of the unloaded part of the conveyor is suspended so that it operates on the opposite side of the scale beam from the loaded portion. The machine is calibrated by moving riders astride two wires of a loop of the rheostat when standard weights are suspended from the scale and the dynamo is run at a known speed. Instruments may be attached to the system to record the rate of handling, time of starting and stopping, and continuity of operation; these instruments may be placed at any desired distance from the weigher. By connection of the scale with a device controlling the feeder, delivery of material at a certain rate or delivery of a certain predetermined amount may be effected.

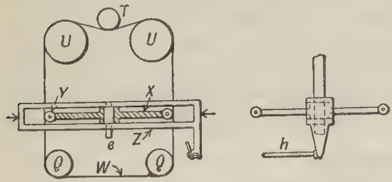

FIG. 31.—Merrick integrator.

Approximate methods of weighing are used when great accuracy is unnecessary or investment for a scale is not warranted. Carloads or trainloads are counted and the weight calculated from the volume of the cars and the weight of a unit volume of broken ore. In some cases carloads or trainloads are weighed occasionally and this weight used as a basis for calculating total tonnage from the number of cars or trainloads counted. Bin measurements of volume are frequently used as a rough check on other methods, or in company mills for inventory at the end of statement periods. Tonnage may be esti-

mated by counting the number of strokes or revolutions of feeding devices, the weight of ore fed at each stroke or revolution being determined experimentally.

At the Portland mill (*63 A 514*) the weight of ore passing was determined as follows: Once each day one Chilean mill was stopped and the feed discharged into a box for 20 strokes of the feeder plunger. This sample was weighed and the average of the five latest weights, applied as factor to the number of strokes of the feeder plunger as indicated by a counter, gave the tonnage per 24 hr. A similar method was used at the Rosebery concentrator. (*114 J 677*.) Ore at 1-in. size was sampled every 15 min. by catching the full discharge of the feeder for a period of 30 sec.; alternate-interval samples were weighed.

Wet-pulp tonnage is ordinarily computed from volume measurements and moisture determinations. The usual problem is that of finely-ground material suspended in water and flowing in pipes or launders. The whole stream is deflected into a suitable container during a period of time measured by a stop watch. Volume is determined by graduations on the container or by measurement. The proportion of solids is determined from a small dip sample taken while the container is filling. If the stream is small, the whole amount diverted may be used to determine the amount of solids in the pulp. Percentage of solids may be determined either (*a*) by weighing, dewatering, drying and weighing the dry solids; or (*b*) by calculation from the specific gravity of wet pulp and a value for the specific gravity of the dry material. The first method is the more accurate but takes longer; the specific gravity of the ore varies from time to time with corresponding effect on computation. Sometimes a cutter of known width is used to catch a time sample and the weight is multiplied by the ratio between width of stream and width of cutter to determine the amount carried by the whole stream. This method is not so accurate as the first because the stream varies in depth and density across its width. Results by this method will be most satisfactory when the material is very finely ground. Tonnage of ore in an agitating tank whose volume is known may be calculated from a dipper sample; the accuracy depends on the degree of pulp uniformity caused by the agitation. The volume of pulp passing through pipes is sometimes measured by solution meters and tonnage calculated from small specific-gravity samples.

Calculations and pulp formulas, see Sec. 22.

15. Moisture sampling

Moisture samples are necessary to determine net dry weight from gross weights obtained by any method. The same care should be used in taking moisture samples as is used in other sampling. Moisture samples should be weighed immediately or placed in tight containers that prevent evaporation until the samples can be weighed. Calculation is simplified by taking moisture samples weighing 100 gm. or 1000 gm. or small multiples of these weights. The samples are weighed wet, dried at a suitable temperature until all hygroscopic moisture is driven off, then weighed again; the difference represents moisture and is usually expressed as percentage of the wet weight.

Moisture samples should be taken at the time the material is weighed, if possible, to avoid errors due to evaporation or subsequent wetting, hence moisture samples are generally taken at different times than assay samples. Some form of grab sampling is frequently used so that the sample can be quickly collected and placed in tight containers. The assumption is that error due to crudeness of method is less than the error introduced by longer exposure of material during more elaborate sampling. Grab samples for

moisture are frequently taken from the end of a conveyor belt after material has passed over a conveying weigher.

It is difficult to obtain moisture samples that check within close limits. When ore is shipped in cars, the outer or top layers contain more or less moisture than the bulk, depending on climatic conditions; if shipped in bags, the material will probably be drier near the outside of the bag than in the middle. Thorough mixing must precede an accurate sample. If the regular sample mill is used for a moisture sample, drying in passage through the sampling mill is considerable and must be compensated in the calculation. This is usually done by an arbitrary percentage added to the percentage determined. Brunton (*40 A 567*) says that, in ordinary practice, this loss would not exceed 10 per cent. of the percentage determined in summer, nor 7 per cent. in winter. In buying and selling a factor is determined by agreement between the parties; in one instance 10 per cent. of the percentage determined was added with a maximum addition of 1 per cent. of water based on the wet weight (*TP 86*, *USBM*). Duplicate determinations on relatively dry material (say under 10 per cent. moisture) should check within 10 per cent. of the percentage present.

Tests by the U. S. Bur. of Mines of 254 pairs of duplicate moisture samples of coal showed an average difference in moisture content of 0.256 per cent. with a maximum difference of of 3.6 per cent. (*Bul. 116*, *USBM*.) The method employed was to use the same 5-lb. sample, obtained as described on p. 1139, for determination of moisture and for analysis; it was kept in sealed air-tight containers until the moisture determination.

16. Sampling mills

The usual procedure is to crush and remove a sample which is alternately re-crushed and re-sampled until reduced to the desired weight.

Lay-out of sampling mills. In many sampling mills, especially the older ones, all ore is elevated to the top of a tower-like building and then falls through successive crushers and sampling devices, the sample and reject being finally delivered at the lowest part of the building. This arrangement necessitates a series of superimposed floors and requires a tall building with sufficient strength to withstand the load and vibration of heavy machinery; the largest pieces of machinery are on the upper floors since the bulk of the sample is reduced as it progresses downward; much of the fall from floor to floor is wasted. The present tendency is to place the machinery as far as possible on one level and to use inclined belt conveyors to elevate to successive machines; this eliminates elevators which require much attendance, are difficult to clean and to observe. A level-site mill is cheaper to build and simpler to operate; one crane can serve all machines; power distribution, attendance, supervision and repairs are all facilitated. Rejects are collected on a conveyor running the length of the building.

Pulsifer (*121 P 866*) points out that by using straight-line single-bay mills the original cost of construction should decrease from 25 to 40 per cent. and that, with the resulting lower operating charges, the cost of sampling should be much lower than at present. The Washoe sampling plant (Fig. 34) illustrates the vertical type of mill; the new sampler at the Tacoma smelter (Fig. 25) the one-level type.

Size at which sampling begins depends on local conditions; in general it is best not to cut a sample from material containing pieces larger than 2-in., but in some cases a sample may be cut when pieces up to 4- or 5-in. or larger are present. In any case, the weight taken at any size should be sufficient to correctly represent the lot, as explained in Art. 1. The size interval between successive sample cuts depends on the amount of reduction in size of pieces

obtained in the crushing machinery used. Taking full advantage of the reduction that a given crusher can make may not always be feasible, as the power consumption may rise so high as to prove more expensive than an extra crushing and sampling operation.

Crushers of jaw or gyratory type (see Sec. 3) are used on coarse sizes down to 1- or 1½-in.; rolls (see Sec. 3) are almost universally used from this size down to ⅛-in..

Sampling machines. See Art. 7, 8 and 9.

Flow of material should be continuous and uniform, otherwise the scoops of a given sampler may take no material during one or more revolutions and this failure may be multiplied in succeeding machines by synchronism, or it may happen that two samplers will so synchronize for several revolutions that the scoop of the second receives all of the sample cut by first. Any case between these extremes may occur, and in any such case the correct proportion of material will not be taken and the sample will be unrepresentative. The means for avoiding such contingencies are storage hoppers, elevators, mixing drums, or feeders with some storage capacity, placed between successive sample cutters.

Feeders are usually placed ahead of the rolls preceding a sampler; they not only spread material and retard its motion sufficiently to give a continous stream, but they feed the rolls in a thin even stream, which aids in preventing uneven wear on roll shells. The feeders are usually of the shaking type. They should be of sufficient length to accomplish the necessary retardation of material and their slope should be low enough so that the larger pieces will not move faster than the main stream; a length of 6 ft. and slope not greater than 2 in. per ft. satisfies these requirements.

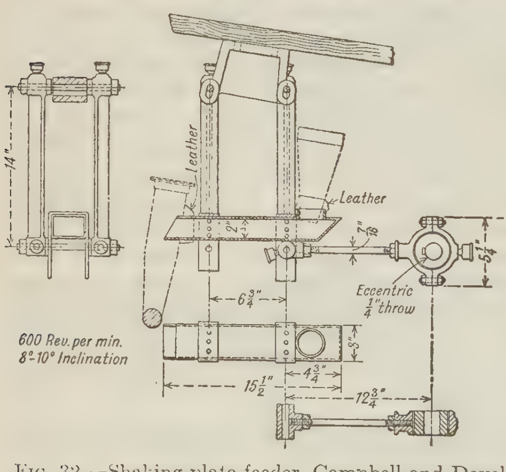

FIG. 32.—Shaking-plate feeder, Campbell and Deyell mill.

A small SHAKING FEEDER used at COBALT (*17 CMI 199*) is shown in Fig. 32. For other types of feeders see Sec. 20.

Drum mixers retard the stream sufficiently to make it continuous, but their ability to mix thoroughly is questionable. Fine material rides up the sides and slides back, coarse material rolls down on top of the fine and segregation rather than mixing is accomplished. Longitudinal ribs on the inside of the shell counteract this tendency; without ribs coarse material discharges mostly at one side and this causes uneven wear on the roll shells.

Drum mixers may be either cylindrical or conical; a ribbed cylindrical mixer is illustrated in Fig. 33. Drum mixers require more head room than shaking-plate feeders and are more expensive to construct. Either device requires but a small amount of power for operation.

Flexibility of plant is desirable when the size or character of ore shipments varies widely. Ordinarily a plant is designed to handle shipments of a certain size; if smaller lots arrive it may be necessary to by-pass the first sampler in order not to cut too small a sample. This can sometimes be done by stopping the sampler so that all material passes through into the sample chute; otherwise, suitable chutes should be provided to accomplish the same end. Allowance for sample variation may be made by varying the speed or cutter widths of the sample machines.

Accessibility. All parts of a sampling mill should be easily accessible for cleaning and observation. Housings on crushing and sampling machines should be detachable and easily-removable doors should be provided in all housings for elevators, chutes, launders, etc. Chutes and launders should be designed with minimum turns. Hoppers and bins should be constructed so that no

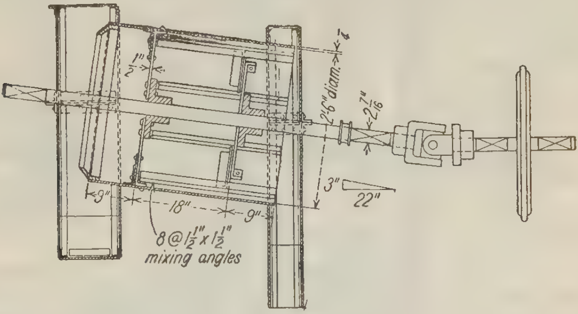

Fig. 33.—Revolving mixer.

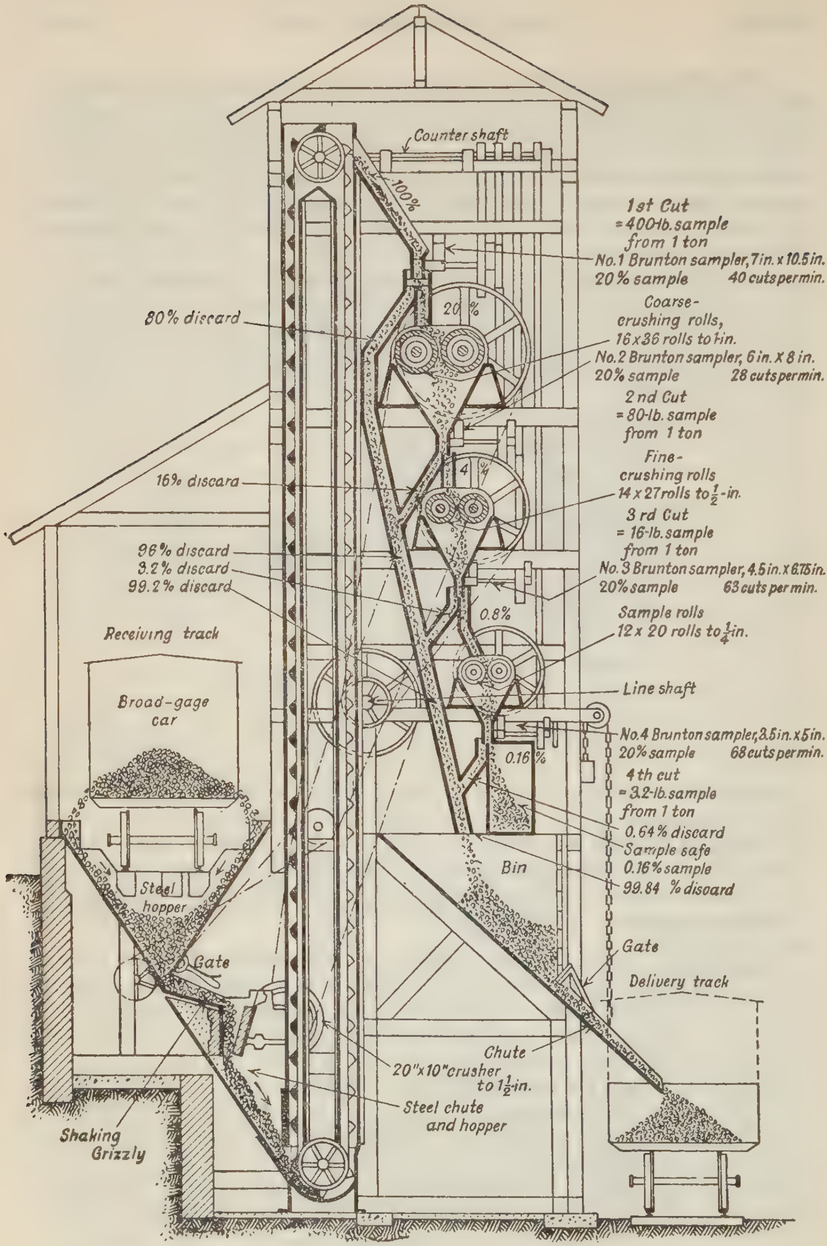
material hangs up when they are emptied. Every precaution should be taken to avoid the possibility of clogging or leakage of material.

Cleaning between successive lots of ore is essential in order to avoid salting. Ordinarily compressed air and brushes are used for cleaning fine material from machines and spouts; floors should be swept and all material collected put with the lot just run through, or so disposed of as to preclude contamination of succeeding lots.

Dust losses. When a sampling mill has many open windows and a strong wind is blowing, the dust loss may be 5 per cent. of the total lot. As fine material is generally of higher grade than coarse, serious losses may thus occur. Further, it is hard to keep good labor in a dusty plant. Where hand sampling is employed, the ore is frequently dampened to keep down dust; this causes fine material to coat the larger pieces and thus aids in mixing. Wetting causes material to stick in automatic samplers and is, therefore, not permissible, hence in sampling mills all sampling machinery and crushers should be enclosed in dust-proof housings and all chutes covered and free from leaks. If frequent observation of moving parts is necessary, small doors that can be readily opened or coverings with removable sections should be provided.

17. Custom sampling mills

These mills sample lots of ore to determine their value for sale. The charge for this service depends usually on the grade of ore and size of lot. In order to keep down the expense as much as is commensurate with accurate



Ore: various. *Capacity:* 500 tons in 8 hr.; 50 tons in about 25 min. On 100,000-lb. lot, *a sample* of 160 lb. is delivered to the sample safe. This is cut down to 25 to 40 lb. in the finishing room before further crushing.

FIG. 34.—Washoe sampling plant.

work, the sample cuts taken at the coarser sizes are made as small in bulk as possible, but a sufficient factor of safety in bulk of sample is allowed to obviate any chance of serious error. A portion of the reject from some point early in

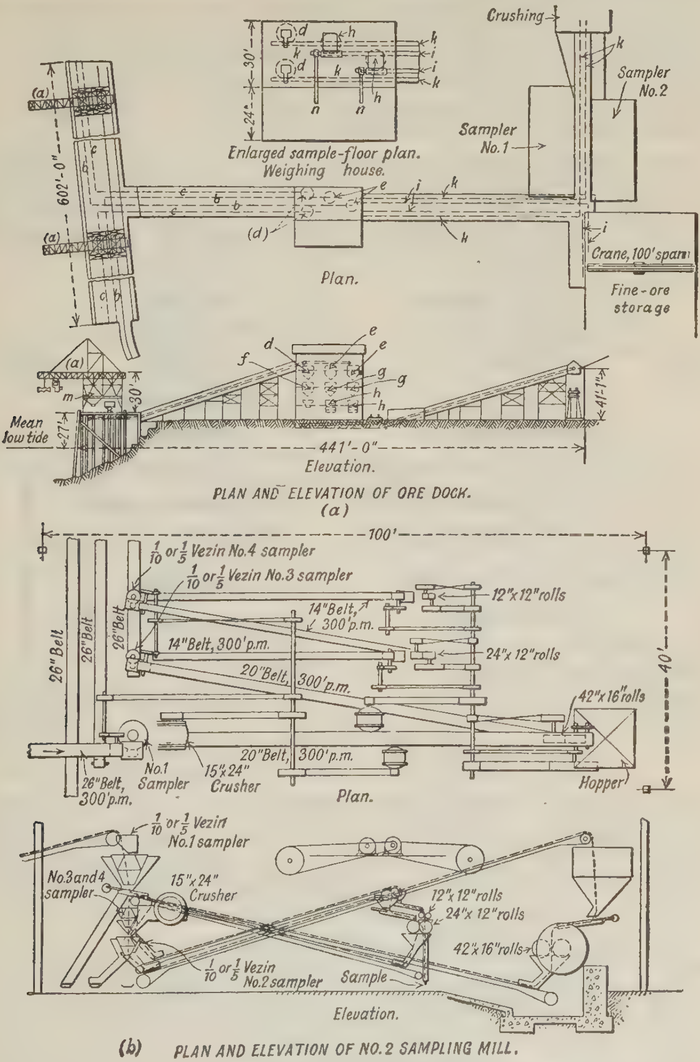


Fig. 35.—Tacoma sampling plant.

the sampling operation is usually kept until settlement is made, to use for re-sampling if necessary.

Washoe sampling plant (Fig. 34) at Butte, Mont., illustrates general practice in western United States.

Sampling plants at mills or smelters that purchase ores have the same characteristics as custom plants except that in cases where the ore is to be finely crushed for treatment in the plant, it may be broken to small size before samples are cut. Unless, however, the purchasing contract makes settlement compulsory on an umpire assay without re-sampling, such fine crushing of the lot must be done in the small crushers in the sampling plant with resulting loss in efficiency. If re-sampling is eliminated by contract, the lot can best be sampled in the mill at a point just prior to any division of the ore stream, all crushing thus far having been done in large mill crushers.

Tacoma smelter (Fig. 35) shows the scheme of unloading from boats and sampling at Point Defiance, Washington. Ore is lifted from boats by 42-cu. ft. Brown-hoist bucket (*a*) and dropped into hoppers (*m*) feeding onto 24-in. belt conveyors (*b*, *c*). Conveyors (*b*) deliver concentrate to 550-cu. ft. hoppers (*e*) and conveyors (*c*) deliver coarse ore to 550-cu. ft. hoppers (*d*) in the weighing house. Directly below hoppers (*d*) and (*e*) are weighing hoppers (*f*) and (*g*) equipped with 60-ton Fairbanks-Morse recording scales. Concentrate

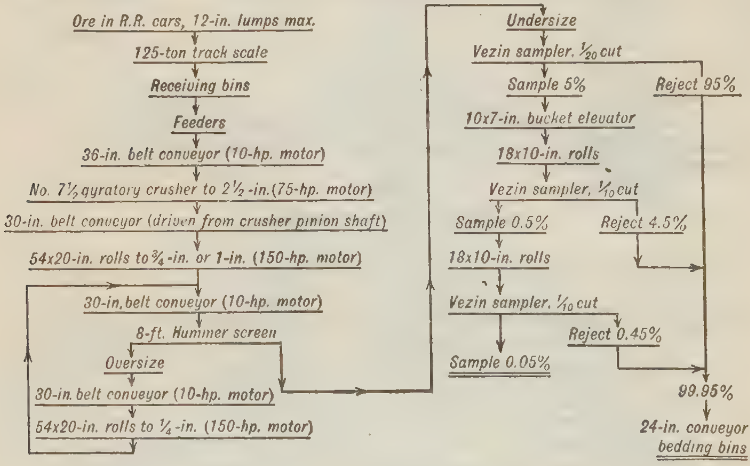

FIG. 36.—Sampling plant, Magma Copper Co. smelter.

passes from the weighing hoppers to Martin samplers (*h*) (see p. 1150) which cut a 1/100 sample in two cuts of 1/10 each. The samples are delivered by belt conveyors (*n*) to the finishing room for preparation of moisture and assay samples. Rejects from the Martin samplers are delivered to storage bins by conveyors (*i*). Ore after weighing is delivered to the sampling-plant bin by belt conveyors (*k*). The method of obtaining coarse-ore samples is shown in Fig. 35, *b* which, by variation in the percentage taken by each sampler, can deliver a final sample of 1/600 to 1/10,000 of the original lot. A large variety of gold-, silver- and copper ores and concentrates is handled (*119 J 557*).

Magma Copper Co. smelter. (Fig. 36.) Ore to be sampled: various copper ores; capacity, 50 to 60 tons per hr. The use of individual motors is noteworthy; a 30-hp. motor drives the two small rolls, elevator and samplers. (*118 J 685*.)

Cobalt sampling mill (*17 CMI 199*) was designed by Campbell and Deyell, Ltd., to sample high-grade silver ores of the Cobalt district. The fact that most of the values were in the form of nuggets or flakes of silver made sampling especially difficult. The flow-sheet is shown in Fig. 37. A specially-designed Krupp-type ball mill crushes all material to pass 8-mesh before any cut is made. A great part of the metallic particles remain in the mill until the whole lot is run through, then the mill is cleaned out and these particles are melted and credited to the lot. All sampling machines are of the Vezin type with special cutting edges. Accuracy is assured by dividing the whole lot into quarters and sampling each quarter separately. Close concordance of samples is accepted as conclusive evidence of accuracy. The QUARTERING MACHINE is a cylinder divided into quadrants, which rotates

on its vertical axis beneath a feed spout whose center is 5.5 in. from the center of revolution. Each quadrant has a hopper bottom with a spout that discharges into a separate annular chute. The machine runs at 30 r.p.m. and thus makes 120 cuts per minute. Each quarter is sampled separately by the same method. The final 100-mesh pulp is mixed by sifting through a 40-mesh screen onto a glass table, and divided as described under (*e*) on page 1177. Metallics on the 100-mesh screen are similarly divided on a glass plate. Metallic iron is removed with a magnet. If the metallics vary in size the different sizes are separated, divided into aliquot parts and combined to make a composite. The moisture sample is

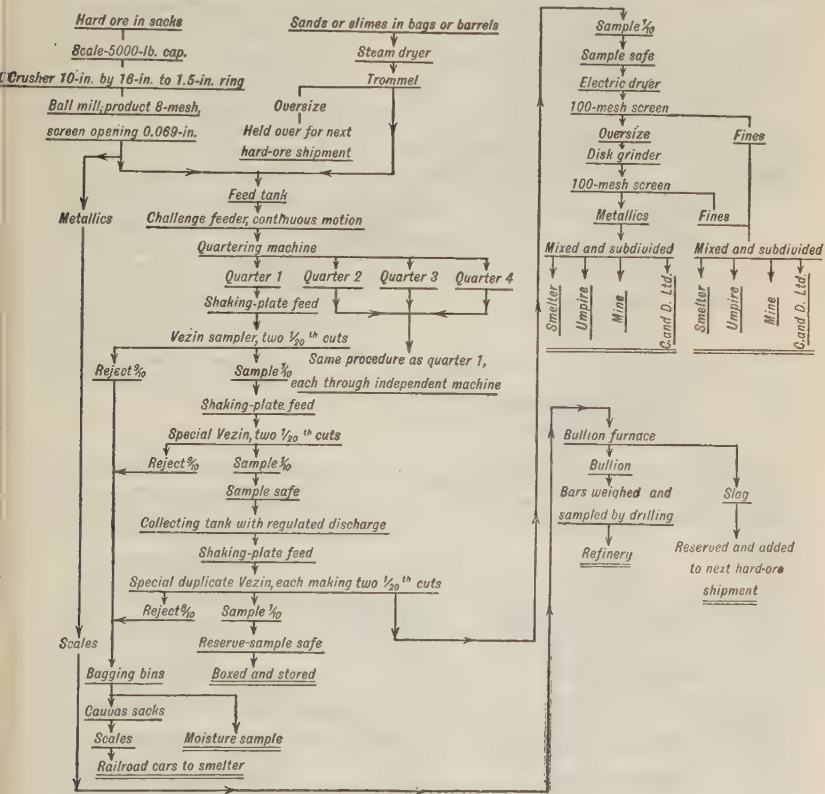

Fig. 37.—Campbell and Deyell sampling plant.

taken with a small scoop from the mouth of every fifth bag while sacking and is placed alternately into two tins. When ore is shipped in barrels a pipe sample is taken when the barrel is half-full and another from the top half, alternating into two tins as before.

18. Head sampling

Most large mills have separate plants to sample the mill feed. The usual practice is to place the head-sampling plant following the coarse crushing plant and deliver reject to the fine-ore bins. Practice is illustrated by the flow-sheets, Figs. 38 to 41, incl.

In porphyry-copper-plant practice, as typified by Chino Copper Co., (Fig. 38) the first cut rejects over 99 per cent. of the lot and the final machine-cut sample is less than one part

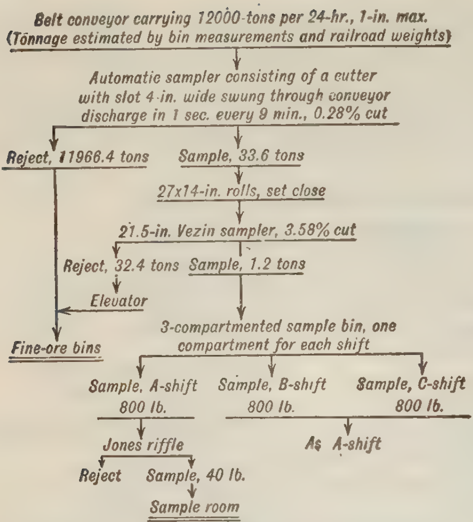

FIG. 38.—Sample plant at Chino Copper Co.

in 200,000. As the metal content of the ore or the value of the metal increases, or both, the proportion of initial reject decreases and the proportion of the final machine-cut sample to the initial lot increases.

In small mills and in mills treating low-grade ore or uniform ore, head sampling is usually accomplished in a simpler manner. In some cases an automatic sampler is used, cutting a small percentage at long intervals, this sample being reduced further by hand.

At ALASKA GASTINEAU (low-grade gold ore) the heads are sampled at 10-mesh size, just before passing to concentrating tables, by automatic cutters ½ in. wide, operated by air cylinders and timed by Scobey timers; the sampling interval is 12 min. The combined sample

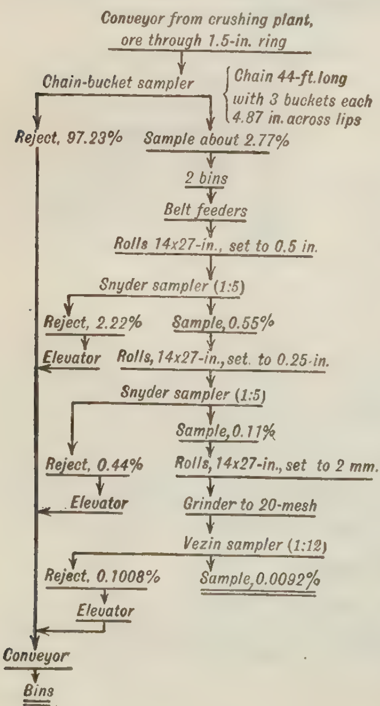

FIG. 39.—Sample plant at Cananea

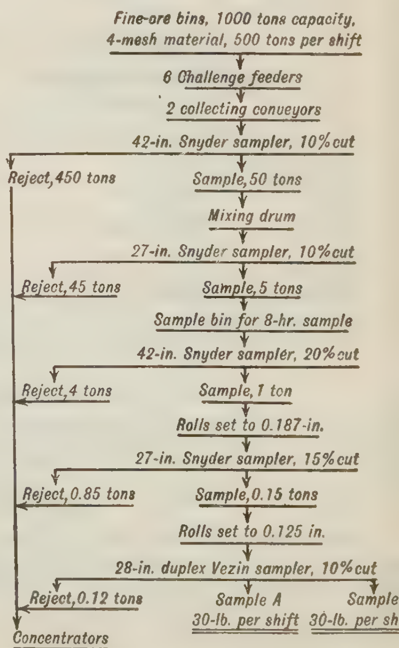

FIG. 40.—Sample plant, Phelps-Dodg

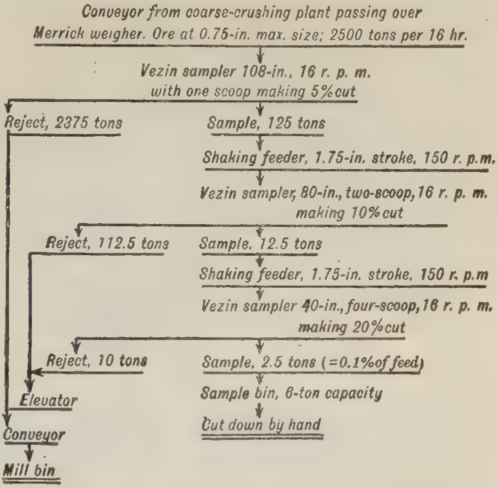
from 6000 tons averages about 3000 lb. (*63 A 502.*) At Belmont Milling Co. (*52 A 100*) (gold (0.32 oz.)-silver (3.2 oz.) ore with some copper and lead present) the ore is weighed by electric conveying weigher; a sample is cut at 1¼-in. size at the discharge of the conveyor every 68 sec. by a scoop mounted on a vertical intermittent-gear wheel. The ¹⁄₅₀₀th sample thus obtained is further reduced to 50 lb. by riffling after crushing to pass ¼-in. ring in a small laboratory gyratory crusher. On a 3500-ton lot this method checked a sampling mill (Western Ore Purchasing Co.) within 8¢ per ton.

At the Sullivan concentrator (*116 J 453*) (zinc-lead sulphide ore with pyrite, calcite and quartz gangue) the ore is weighed on a 150-ton track scale. A 1-per cent. cut is made by a bucket sampler after crushing through ¾-in. square holes. The sample passes over a circular mixing table and a second 1-per cent. cut is made by another bucket sampler at the end of a conveyor belt. The sample ratio is 1 : 10,000.



25-hp. motor runs entire plant. 2 men per shift.

Fig. 41.—Sample plant at Federal Lead Co., Mill No. 4.

At the Silver King Coalition mill (*116 J 369*), (silver-lead carbonate and sulphide ore) 300 tons per day is crushed through a 1½-in. grizzly, and a sample is cut as ore falls from the end of the main conveyor onto a 24-in. apron conveyor, one 6-in. section of which is removed. The 5-per cent. sample that falls through is crushed and again cut to 1 per cent. of the original lot.

Hand sampling of heads is practiced at the following plants:

At Witherbee-Sherman Co., (magnetite ore averaging 25 to 45 per cent. Fe). The head sample is taken from the discharge end of a conveyor carrying −4-in. material. A steel bucket, 12 × 12 × 6 in. deep, swung on an arm from a vertical shaft, is passed quickly through the stream every 30 min. The sample is crushed in a small crusher to 0.5-in. and riffled down. The results obtained check with results calculated from samples of concentrate and tailing taken in similar manner. At St. Joseph Lead Co., the ore is galena in limestone gangue. Hourly samples of the feed to six sections is taken with a hand cutter. The largest piece is 0.35-in. and the cutter aperture 1.5-in. The cuts are combined, mixed, coned and quartered at the end of each 8-hr. shift, then ground to 80-mesh and cut down to assay-sample size. Results check over a period.

At Utah Leasing Co., the ore is reclaimed tailing, −4-mesh and averages 0.7 per cent. copper as chalcopyrite. The head sample consists of a shovelful from each 5-ton car. This is quartered down to 5 lb.

When all of the ore is crushed finely before being divided or subjected to any concentration, the head sample is most conveniently taken from the discharge of the fine-grinding department.

At Sunnyside Mining and Milling Co. a sulphide ore containing Au, 0.06. oz; Ag, 4.5 oz.; Pb, 4.8 per cent.; Cu, 0.40 per cent.; Zn, 5.5 per cent.; Fe, 3.0 per cent. is sampled at the overflow of the Dorr classifier following the tube mills. The sample contains 20 per cent. solids, 1.5 per cent. +65-mesh (0.0082-in.) and 68 per cent. −200-mesh. An automatic cutter with 0.625-in. aperture is used, making a cut every 20 min. The cutter remains in the stream 5 sec. and cuts a sample 0.025 per cent. of the total stream. Reasonably close checks are reported. At United Eastern Mining Co., the ore is quartz and calcite with about 1 oz. Au and 0.57 oz. Ag per ton. A head sample of −8-mesh material is

taken by hand every 30 min. from the Marcy-mill discharge. Crushing is performed in cyanide solution that contains dissolved values. The sample is dried with all solution and a deduction is made for values in solution, as determined by a separate drip sample. The method checks within 3 per cent. of the calculated value from assays of tailing and bullion. At Elko Prince Mining Co. (silicious ore averaging $25 in gold per ton) a head sample is taken every 30 min. by a pan grab from the Marcy-mill discharge. The largest piece is 0.2-in. Results do not check well.

Accurate head samples are not, in general, obtained unless automatic cuts are taken at frequent intervals. Information obtained by crude methods is used as a rough check on operations. Such results, averaged over long period, may check with results obtained by calculation from accurately-taken samples of tailing and concentrate or bullion. The degree to which head-sample results will check a calculated head assay obtained from concentrate or bullion and tailing assays depends not only on the accuracy of the head sample but also on the accuracy of the head-tonnage determination. Probably the best place to sample heads in any mill is just before the first division of the ore stream; the ore is then generally rather finely crushed and well mixed and simple automatic sampling machines can be used.

19. Tailing sampling

Automatic wet-pulp samplers are best. Ordinarily the final tailing from a mill is low-grade, finely crushed and well mixed, and there are no sudden changes in value, hence small cuts and long sample intervals are permissible. Hand-sampling is more likely to be accurate than in sampling heads or concentrate. Practice in several plants is summarized in Tables 7 and 8.

Table 8. Practice in tailing sampling with hand cutters

20. Concentrate sampling

Automatic samplers are used to a great extent. The same forms of cutters as used for sampling tailing are suitable. Table 9 summarizes practice in several plants where automatic sampling of concentrate is used. Hand cutters, as described on p. 1156, are also used extensively. Pipe or gun samples and augers are satisfactory devices for sampling concentrate in bins or cars. Table 10 presents data on hand-sampling of concentrate in various plants.

In general automatic samplers are preferable for sampling fine concentrate or when the material is flowing in a stream with water. This is the case with most flotation concentrate. Some plants report that automatic sampling of flotation concentrate must be used to get

Table 9. Practice in concentrate sampling with automatic cutters

accurate results. However, if the concentrate discharged by a machine is thick and flows sluggishly, when water is added to wash it down launders it surges so much that at one instant concentrate and the next almost clear water is flowing. In such cases automatic samplers are not satisfactory and a hand cutter must be used at the discharge of the machine or some method of sampling concentrate in bins or cars after draining must be employed.

21. Miscellaneous mill sampling

Miscellaneous mill samples are taken to give information concerning the operation of a particular machine or set of machines. When accurate results are desired and the sample must be taken every shift, automatic samplers are best. This is the case when a mill is operated in sections and the feed and products of each section are sampled to check its work. Ordinarily intermediate samples are taken by hand by various operators to serve as guides

to operations of particular machines. Great accuracy is unnecessary and the use of hand cutters and long sample intervals are justified.

22. Preparing samples for assay

Marking samples. In custom-sampling mills, where many different lots are run in succession through the mill, ample provision must be made to avoid possibility of confusion of samples. A satisfactory method is to keep a complete record of the treatment of each lot on a suitable form convenient for filing. This form should accompany each sample until the work is finished and the sacked sample delivered to the assayer. It should then be filed for permanent record. In mill work, when samples are of small bulk and can be held in pails or pans, small numbered tags of copper or brass are convenient for identification. Complete identity of sample is kept in a note-book record on a form numbered the same as the pan or pail.

Samples in sacks may be marked with linen or paper tags. If there is danger of the tags becoming wet, a thin coating of hot paraffin or shellac will prevent the marking on the tag from being obliterated or changed.

DRYING AND CUTTING DOWN

Samples delivered to the bucking room or assay office may vary in weight from a few pounds to 100 or 200 lb. Before these samples can be assayed they must be dried and further reduced in bulk. If coarse, they must be crushed and then reduced in bulk to a few ounces or a pound of fine pulp.

Drying is done in ovens or on stoves or hot plates. Steam, electricity, or burning coal, wood, gas, oil or other material may be used to furnish heat. Exhaust-steam tables are particularly desirable. Steam is usually circulated through coiled pipes arranged in shelves on which the sample pans are placed, or through false-bottom steam tables on which samples are dumped. (See Sec. 22.)

Table 10. Practice in concentrate sampling with hand cutters

Company	Concentrate from	Method	Weight of shift sample	Per cent. of whole
St. Joseph Lead Co., Rivermines, Mo.	Jigs and tables	2-in. auger, 24 holes per car	50 lb. per car	0.055
Tungsten Mines Co.	Tables	1/10 shoveled when sacking; maximum size of particle, 0.1875-in.	120–300 lb. per 24 hr.	10.0

Out of 31 plants reporting, 18 used steam for sample drying and most of these passed the steam through coiled pipes. Electric hot plates were reported by eight plants. Others reported coal, wood or kerosene stoves. One used heat from a Diesel engine exhaust by passing it through a box on which sample pans were placed.

Maximum temperature at which drying is done varies in different plants reporting from 132° F. to 450° F. Temperatures around 200° to 220° F. are most generally used. Ordinarily it is best not to use temperatures above 212° F. on account of danger of loss. This is especially true with easily oxidized sulphide ores which may lose sulphur on heating, or with minerals containing water of crystallization. In some cases temperatures even lower than 212° F. may be necessary, as in the case of certain clays in which water of crystallization is driven off before all hygroscopic moisture has evaporated.

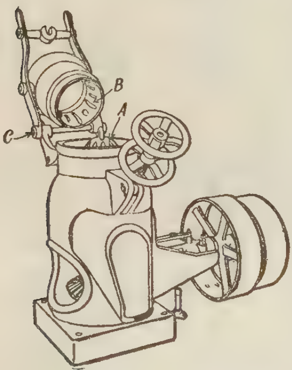

FIG. 42.—Engelbach grinder.

For air-drying samples for moisture determination the U. S. Bureau of Mines uses a temperature of 35° C. (95° F.).

Test for completion of drying may be made by holding a cool, dry watch glass or plate over the sample. Absence of condensed vapor on the glass indicates that the sample is dry. Stirring a hot sample with a spatula gives an indication of the presence of moisture by the vapor which rises. The most accurate test is to weigh until no further loss in weight takes place on further heating.

Crushing samples. Small jaw crushers are best for crushing material from 1- or 2-in. maximum down to about 0.5-in. Either the Blake or Dodge type is satisfactory. Small gyratory crushers may be used. Intermediate grinding is generally done in a COFFEE MILL (Engelbach) (Fig. 42) in which grinding is done between a rotating cone (*A*) mounted on a vertical, gear-driven spindle and stationary circular concaves (*B*) attached to the machine. The grinder is arranged so that the top part, containing the concaves, may be lifted on hinges (*C*) allowing access for cleaning and repairs. The following sizes may be obtained:

Capacity lb. per hr.	From	To	R.p.m.	Power required, hp.	Approx. weight, lb.
200	0.5-in.	10-mesh	225	4	850
100	0.37-5in.	10-mesh	250	3	550

Fine grinding of samples is best performed in DISK GRINDERS of either the Braun (Fig. 43) or McCool type.

Braun pulverizer. The ore is ground between two disks, one revolving (*a*) and other stationary (*b*); fineness of product is determined by adjustment of screw (*c*). The revolving disk is mounted on a horizontal shaft equipped with tight and loose pulleys (*d*). Material is fed through hopper (*e*) and enters the space between the disks at the center whence it is fed by gravity and centrifugal force to the periphery and there ground. Ground material passes between the disks and is discharged into a removable tray (*f*) beneath. Removable cover (*g*) and the hinged stationary disk permit easy access to the grinding parts for cleaning. Feed may be ¼-in. size. The principal dimensions are: length, 23 in.; width, 14 in.; weight, 235 lb., 850 r.p.m.; 1 hp. One set of grinding disks should handle from 2500 to 7500 ordinary ore samples. They are readily replaced.

McCool pulverizer is a similar machine except that slow relative motion of the disk centers is superimposed on rotation, which is supposed to accent the rubbing motion

between the disks. The machine is made in two sizes, the larger rated at 1 lb., the smaller at 0.5 lb. to 100-mesh in 30 sec. Dimensions follow:

Size	Length, in.	Width, in.	Height, in.	Pulleys, in.	Pulley speed,	Power, hp.	Shipping weight, lb.
Large........	40	18	17	12 × 4½	275	2	570
Small........	30	11	14½	11 × 4½	250	1	330

Bucking board consists of a flat cast-iron plate with finished surface on which ore is pulverized by means of a cast-iron muller on a wooden handle. The operation is usually manual, but mechanical drive may be used, if desired. Bucking boards are not as efficient or quick as disk grinders but furnish suitable means for grinding in places where power and more elaborate equipment are not available or for grinding very small quantities of material that might be lost in a mechanical grinder.

Grinding surfaces should be of material that is not so hard that it becomes polished, with consequent reduction in efficiency, nor so soft that the value of the sample is affected by admixture of fragments from the surfaces. If the surfaces are very soft, pieces of valuable mineral may be taken up, thus not only reducing the metal content of the sample being ground, but possibly salting succeeding samples. Grinding surfaces developing small holes or cavities should be avoided and discarded. Filling such holes with soft metal should not be practiced. Iron introduced into a sample by grinding can be removed with a magnet, if objectionable.

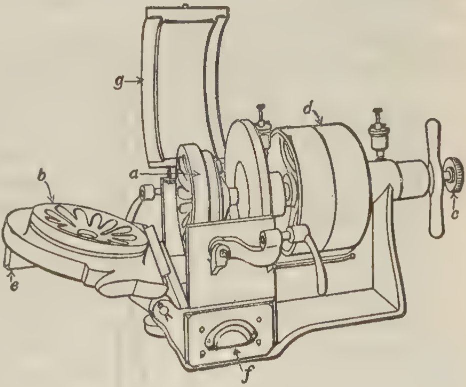

FIG. 43.—Braun disk pulverizer.

Fineness of sample required for assay varies with the character of ore. Since the actual material assayed must be cut out of the assay sample, the maximum size of grain must bear the same relation to the weight of the sample cut as at any other step in the sampling operation. Further, where a wet method of assay is employed, grinding must expose all of the valuable mineral to the action of the solvent. Usually a large factor of safety is allowed in the final sample and no sample for assay is coarser than will pass 80-mesh; many plants pass the final sample through 100-, 120-, 150-, or 200-mesh before delivering to the assayer.

Usual procedure in final grinding is to pass the sample through the grinder and separate undersize through a screen of the desired aperture. Oversize is returned to the grinder and the operation repeated until all passes the screen. Iron washers or stiff brushes are frequently used to aid in pushing material through the screen. Time is thus saved but washers cause wear on screen wires and in case of ores containing fine elongated pieces of valuable metal or mineral a piece may be forced through the screen that will have a serious effect on the value of the sample. With ores containing metallics it is often found impossible to pass the last flat metallic pieces through the screen, even on repeated grinding. In such cases the final oversize of metallic pieces is collected, weighed and assayed separately, and its value is allotted in proportion

to its weight and the weight of the sample. The screens used should be perfect.

Jones riffle (Fig. 44) is the most satisfactory device with which to make final reductions in bulk of sample prior to delivery to the assayer. It consists of an even number of equally sized chutes, adjacent chutes discharging at opposite sides. Ore is fed to the riffle from a scoop. Jones riffles may be procured in the following sizes:

Dimensions, in.	4 × 4	6 × 6	10 × 10	10 × 18
Width of troughs, in.	½	½	¾	¾
Number of troughs	6	8	10	18

Flat riffle (Fig. 45) is used for the same purpose as the Jones riffle, but is less convenient. It has alternate slots closed at the bottom so that half of the material fed is retained in alternate troughs while the other half falls through. In using this riffle care should be taken that the closed troughs do not fill up and overflow into the open troughs.

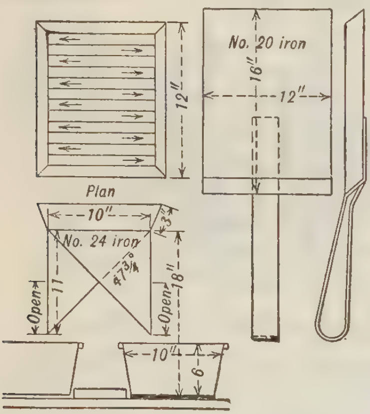

FIG. 44.—Jones riffle and scoop.

Use of riffles. Riffles should be of strong construction and carefully handled. Rough treatment causes distortion of the dividing edges between chutes with consequent inaccuracies in samples. Chutes should be wide enough to prevent bridging of coarse particles; at least three times the diameter of the largest particle in the feed and better more. Feed scoops should be of the same width as the total combined width of the riffle chutes; if greater, end chutes receive an undue proportion; if less, chutes receiving the edge of feed stream are under-loaded. The same number of riffles should discharge each side. Some manufacturers furnish riffles with an uneven number of chutes, so that both end chutes discharge the same side. This will cause material discharged on the favored side to contain an undue proportion of coarse material as well as to weigh more than the other portion. Such riffles should be rejected. Material should be spread evenly across the full width of the feed scoop and delivered to the riffles well toward the center. A good way to feed is to place the loaded scoop with ore at rest thereon so that the edge rests on top of the riffle-chute dividers along a line perpendicular to these and near the edge farthest from the operator; then draw the scoop smartly from under the charge, allowing it to fall evenly on the riffle. It is desirable to keep the edge of the scoop straight and to avoid a scoop that, through long usage, has a turned or uneven edge.

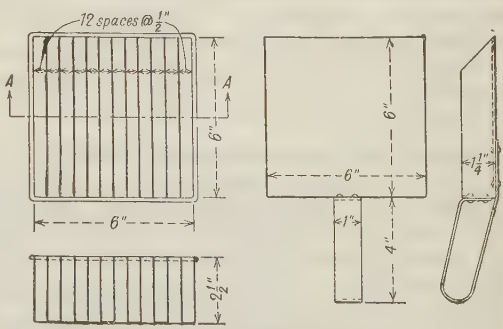

FIG. 45.—Flat riffle and scoop.

Mechanical devices are sometimes used to make the final reduction in bulk of sample. They have the advantage of eliminating the personal equation but it is questionable if their substitution for a Jones riffle gives any greater accuracy.

Umpire sampler (Fig. 46) has two buckets revolved in opposite directions by means of bevel gears. Each bucket is divided into four compartments by plates at right angles, two opposite compartments being open at the bottom while the other two are closed. Material is fed from a scoop (*a*) that is shaken by a cam (*b*) striking a strap (*c*) attached to the scoop and to the coiled spring (*d*). The sample passing through the second rotating bucket is caught in a bucket (*e*) and represents one-quarter of the material fed to the machine.

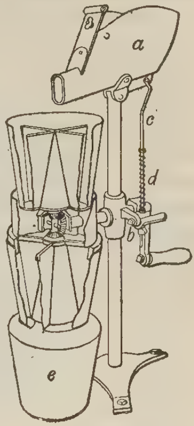

Fig. 46.—Umpire sampler.

Mixing is essential before dividing a sample or weighing out for assay. Simple methods are usually employed: (*a*) coning; (*b*) turning over and over with a spatula; (*c*) rolling on a piece of glazed paper, rubber or oil-cloth. Rolling is accomplished by drawing the corners of the paper or cloth horizontally toward diagonally opposite corners, causing the sample to roll over and over on itself. If the corner is lifted instead of drawn horizontally, the sample merely slides along the surface of the cloth and no mixing occurs. (*d*) Anaconda mixer, consisting of a cubical box rotating on a horizontal axis forming a diagonal of the box, makes an efficient mechanical mixer for small samples. (*e*) Jones riffle may be used for mixing finely-ground material, the two portions obtained being united and passed through again and again.

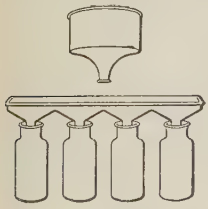

Fig. 47.—Bottle-filling device.

Final division of ground samples into small parcels for assay may be effected by riffles or machines as described above, or by one of the following methods: (*a*) Coning and quartering. (*b*) Spreading and taking small portions with a spatula from points scattered at random over the surface of material, taking care that the spatula tip goes down to the bottom of the pulp layer each time. (*c*) Pouring into bottles from a rolling cloth or scoop after mixing, using the bottle-filling device shown in Fig. 47. (*d*) Mechanical dividers of various types, usually diminutives of apparatus already described. (*e*) A method including mixing and dividing, successfully used on cobalt silver ores (*17 CMI 199*) is as follows:

The finely-ground sample (−100-mesh) is sifted several times through a 40-mesh screen onto a glass table, the screen being held about two inches above the material on the table. The pile is kept spread with a spatula. The glass table is marked off radially from a center into 16 equal sectors, and the material sifted is centered. After the final sifting the material is divided along radial lines. Material from alternate sectors is placed in separate packets, thus giving eight samples for such disposition as is desired. The balance of the material is rejected.

23. Cost of sampling

Information is limited and of such character that averages have little value. Costs at custom plants using machine-sampling methods vary from about 20 to 65¢ per ton (*Peele*), according to the character of the ore, location of plant, cost of labor, tonnage sampled and whether the ores are purchased or

not. The above figures include assaying and overhead but not the cost of buying and selling. In smelters cutting the first sample by hand methods, costs vary greatly according to whether the first handling is charged to sampling or other operations; they may be as high as $1.00 to $1.50 per ton. In mills having a mechanical head-sampling plant, the amount of labor required varies from 0.125 to 3 or more man-shifts per 24 hr. This does not include preparation of the sample for assay. For estimating the cost of general mill samples taken by hand, from 15 to 50 samples per man-shift, depending on local conditions, may be taken as a basis. From 12 to 45 samples can be prepared for assay per man shift, depending on the size of samples to be prepared character of material, degree of fine grinding necessary, equipment and general organization of the working force.

At HOLLINGER the mill-sampling cost per ton milled in 1923 was $0.0052 while assaying cost $0.0236 per ton milled. At UNITED EASTERN (*63 A 566*) the cost of general mill sampling in dollars per ton milled was as follows:

Year	Operating Labor	Supplies	Power	Total
1917	0.0011	.0034	.0005	.0050
1918	.0004	.0018	.0009	.0031
Average	.0007	.0026	.0007	.0040

The mill treats gold ore by cyaniding and has about 250 tons per day capacity.

SECTION 22

TESTING

Testing has two purposes, *viz.*: (1) determination of the best method for treating a given ore, and (2) determination of the best method of operating a given process. The purposes and methods of procedure overlap to a considerable extent, but in general, testing for a process demands the application of several different processes to the same ore while testing processes involves investigation of the effect of changes in the operating characteristics of a given process in treating the same or different ores. In either case the work requires painstaking attention to detail; close, careful and accurate observation and record of performance, and incessant speculation as to causes. Correct interpretation of results requires wide experience both in testing and mill operation and a healthy balance between pessimism and optimism. The best laboratory results can frequently be bettered in mill operation; on the other hand it is frequently impractical to expend in the mill the care lavished on laboratory operation and it is rarely that mill operation is economically subject to as close control in the matter of quantities treated and purity and uniformity of substances used as is the laboratory. This is particularly true in hydrometallurgical processes and flotation.

Time is ordinarily an element in all testing work. The experimenter is continually ground between the upper millstone of demand for quick results and the nether necessity for exhaustive investigation before announcing conclusions. Clear recognition of the situation should be sufficient guide.

The principal tools for testing are the assay, the testing sieve and the microscope. Others are the specific-gravity flask, heavy solutions, and small-scale replicas of or substitutes for mill machines. Among the latter are hammer and anvil for estimating crushing resistance; hand jig, pan, batea and plaque for gravity concentration; portable magnets, bottles for agitation-froth flotation tests, and the like.

1. Testing for a process

Outline of procedure

1. Obtain a proper sample.
2. Determine the qualitative mineralogical composition.
3. Determine the content of valuable mineral. (Assay.)
4. Determine the distribution of valuable mineral. (Sizing-assay test.)
5. Determine the aggregation of valuable mineral. (Microscopic examination and sizing-sorting-assay test.)
6. Study existing flow-sheets for the treatment of similar ores.
7. Devise a tentative flow-sheet for laboratory procedure.
8. Procure, by following this flow-sheet, material representing the feed to each machine in the tentative flow-sheet, and treat these materials in batches on the indicated machines, in order to determine the best possible conditions of treatment and the corresponding results.
9. Construct a metallurgical balance sheet of the results of the batch testing. (Four-column table.)
10. Make a continuous run to confirm the results shown in (9).

At this point the lines of procedure diverge according to the size of mill contemplated and the elaborateness of the laboratory equipment. It is rarely that a testing laboratory has sufficient equipment, properly balanced as to size, to make a continuous run on a scale that will yield a reliable indication of mill performance, except to an experienced interpreter, and the more experienced the interpreter the more doubt he is likely to feel of his interpretation. Consequently, if the size of the mill installation will justify the expense, the continuous run should be made in a pilot mill, built at the mine, fed with freshly-mined ore that is as nearly as possible representative of what the final mill will get, and run for a sufficient time to answer definitely, with as little interpretation necessary as possible, what the performance of each machine will be and what the performance of the whole mill. Practically all of the big mills in this country, when they have not been the result of progressive growth from small beginnings—which, of course, is the equivalent of a pilot mill—have been preceded by pilot mills of more or less elaborateness, in which, usually, a variety of different machines have been thoroughly tested for each step of the process. The cost of the pilot mill is usually only a small fraction of that of the big plant and the expense is readily justified as insurance and quickly saved if, as a result, the big mill falls more rapidly into regular operating stride.

When the contemplated mill is too small to justify the expense of a pilot mill, the continuous run or runs must be made in the laboratory. In the laboratory run it is usually impossible to duplicate mill conditions as to middling circulation and water reclamation. Except from the mechanical standpoint, however, *i.e.*, sedimentation and incrustation in the water channels and effects, reclaimed water makes no difference in the performance of gravity concentration. Its probable effect in flotation or in hydrometallurgical processes can be investigated by a series of small-scale tests supplementing the continuous run. On the other hand, middling must be circulated in the continuous run and eliminated from the final products. If the middling circuit differs, as it almost inevitably will, from that to be expected in the operating mill, its effect on performance must be closely studied and suitable allowance made in the final design. This is by far the most difficult part of testing and interpretation. No rules can be set down for guidance. Success

in handling the problem is in proportion to the ability of the experimenter to observe closely and to his experience in mill operation and in similar testing work.

Sample. The first essential is a correct sample, of such weight as to furnish all the material necessary for the initial small-scale laboratory tests. This weight will usually lie between 50 and 1000 lb. The smaller amount is ordinarily sufficient when enough is already known concerning the ore to indicate fine grinding and a simple method of treatment such as cyaniding or flotation. The larger amount is necessary when nothing is known or when what is known indicates a complicated flow-sheet.

Mineralogical composition. The first step in the testing work is to determine the approximate mineralogical composition of the ore, at least in so far as the principal minerals are concerned. With simple base-metal ores this can usually be done from hand specimens. (See Rogers, Dana, Davy and Farnham, Murdoch, Johannsen.) Precious-metal ores ordinarily require an assay to determine the presence of gold and silver. Complex base-metal ores demand microscopic examination (see p. 1192, also books on petrology).

Assaying is not within the scope of this book. The following books are reliable and complete: A. H. Low, *Technical methods of ore analysis*, John Wiley and Sons, Inc., 1919. E. A. Smith, *The sampling and assay of the precious metals*, J. B. Lippincott Co., Philadelphia, 1913. E. E. Bugbee, *A text book of fire assaying*, Wiley, 1922. C. H. Fulton, *A manual fire assaying*, McGraw-Hill Book Co., N. Y., 1911.

2. Sizing tests

Sizing analysis consists in quantitative separation of a mass of material of various sizes into a number of grades, each characterized by a relatively small size interval between largest and smallest particles. The means of grading are (*a*) screening and (*b*) settling in a fluid, usually water. Screen grading, used on granular material, is called SCREEN ANALYSIS; grading by settling in fluids, used for the finest sizes, is called ELUTRIATION. Frequently the various grades are assayed, in which case the operation is called a SIZING-ASSAY TEST.

Testing sieves (Fig. 1), used for screen analysis, are circular pans, 6 to 12 in. diameter and 1 to 2 in. deep with screen bottom. The frame is ordinarily made of brass with upper edge beaded on a stout wire and lower edge extended below the screen, crimped inward, and rolled to an easy fit with the upper edge of other screens in the set, in order that the screens may be nested.

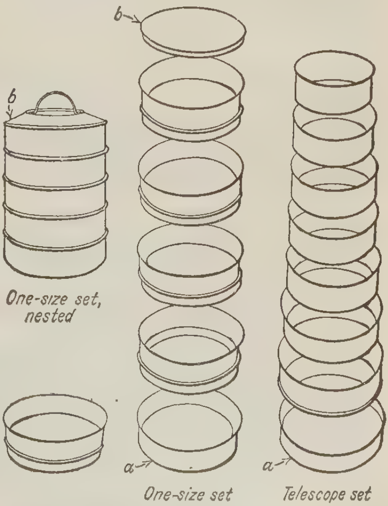

FIG. 1.—Testing sieves.

A pan (*a*) to collect undersize and cover (*b*) to confine oversize may also be obtained; their use lessens dust loss. TELESCOPE NESTS, usually made with

each finer screen of sufficiently smaller diameter than the preceding to permit telescopic packing, are made for field use. The pan of a telescope set is made of sufficient diameter to receive the nested set.

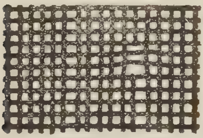

FIG. 2.—Microphotograph of 200-mesh screen cloth, magnified 12.5 diameters (warp wires vertical).

Standard testing sieves. The U. S. Bureau of Standards has done considerable work in the study of fine testing sieves and their performance, in connection with the determination of fineness of cement. The work early showed the irregularities in fine cloth (Fig. 2) and the first specification of a standard was designed to overcome the irregularity by setting up tolerances in diameter of wires and their spacing. (*USBS, Circ. 39.*) Further investigation (*USBS, TP 29 and 42*) led to a statement of larger tolerance as to mechanical construction, placing the principal weight on performance. The present specification follows:

"*Bureau of Standards Specifications for No. 200 Cement Sieves.*

"Wire cloth for standard sieves for cement shall be woven (not twilled) from brass, bronze, or other suitable wire and mounted on frames without distortion. The sieve frames shall be circular, about 20 cm. (7.87 inches) in diameter, 6 cm. (2.36 inches) high, and provided with a pan about 5 cm. (1.97 inches) deep and a cover.

"*No. 200 Cement sieve, 0.0029-inch opening.*

"The No. 200 sieve should have 200 wires per inch and the number of wires in any whole inch shall not be outside the limits 192 to 208. No opening between adjacent parallel wires shall be more than 0.0050 inch in width.

"The diameter of the wire should be 0.0021 inch, the average diameter shall not be outside the limits 0.0019 to 0.0023 inch.

"The sieving value of the sieve, as determined by sieving tests made in conformity with the standard specifications for these tests on a standardized cement which has a fineness of 75 to 80 per cent. passing the No. 200 sieve, or on other similarly graded material, shall not show a variation of more than 1.5 per cent. from the standards maintained at the Bureau of Standards.

"The Bureau also reserves the right to reject sieves for obvious imperfections in the sieve cloth or its mounting, as, for example, punctured, loose, or wavy cloth, imperfections in soldering, etc."

The 100-mesh and 20-mesh sieves are standardized on a mechanical basis only. For a nominal fee, the Bureau of Standards will test any sieve and certify its approach to the standard.

The Bureau investigation developed that single fineness determinations, made by experienced operators, rarely vary from the mean of several determinations by more than 0.5 on material testing between 75.00 to 85.00 fine and that the constant variations of invidual operators ("personal equation") were of the order of 0.1 to 0.2; that tests made when the humidity is high are unreliable; that the effect of humidity is different with different materials, least with cement, ground quartz sand and ground marble, of 11 materials tested, and greatest with trap rock and alumina.

Sieve scales. If a piece of substantially homogeneous rock is broken by any of the usual methods of crushing and the product is divided into a number of grades according to size, it will be found that the weights of the grades change gradually from size to size, that they pass through a maximum in one of the coarser sizes, and, sometimes, through a secondary maximum near the fine end, while the weight of the undersize of the finest screen is usually greater than that of the last preceding grades. This behavior is apparently a natural characteristic of crushed homogeneous material. The location of the maximum point in the curve varies according to the extent of the size reduction, the method of crushing, and perhaps also to other factors. If the rock

is non-homogeneous, the secondary maximum will usually be more pronounced and its position distinctly related to the rock structure, while the principal maximum will be located differently than with a homogeneous rock similarly treated. Graphical representation of these facts is given in Fig. 3. As the number of grades is decreased the smoothness of the curves decreases and a small amount of experimental work makes it apparent that irregular intervals between successive grade sizes increases the irregularity of the results. While this is an *ex post facto* explanation, it is the principal physical justification for a testing-sieve scale with regular size intervals. Testing-sieve scales have been proposed by Rittinger (*Aufbereitungskunde, 1867*), Richards (*OD*), DeKalb (*80 J 151*), Institution of Mining and Metallurgy (I.M.M.) (*19 IMM 486*), Hoover (*19 IMM 486*), W. S. Tyler Co. (*13 ASTM 1053*), and U. S. Bureau of Standards, the chronological order of the proposals being the same as the order of listing. Of these proposed scales only the I. M. M. and the Tyler series have taken form in actual testing sieves.

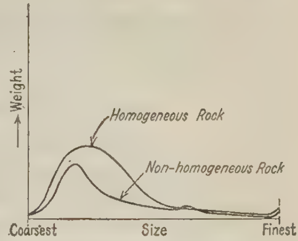

Fig. 3.—Direct plots of sizing tests of homogeneous- and non-homogeneous rock powders.

Rittinger series. The unit aperture is 1.0-mm. Apertures of other screens form a geometrical series both ways from the unit with a ratio of $\sqrt{2}(=1.414)$. Areas of individual apertures in successive screens vary, therefore, in the ratio of 2.

Richards series (also known as DOUBLE RITTINGER) starts from 1-mm. aperture and progresses both ways with the constant ratio $\sqrt[4]{2}(=1.189)$.

DeKalb series is pseudo-arithmetic. Starting with 0.003-in. as the smallest aperture, the succeeding apertures in the proposed series are found by adding $0.001n$ in. to the aperture of the preceding screen, n being the number of the screen in the series.

I. M. M. series (Institution of Mining and Metallurgy) has no regular basis, but contains screens whose mesh designation is in common use in the mills, *e.g.*, 20-, 30-, 40-mesh, etc. (see Table 1). In the hope to insure perfect locking of the wires on crimping, the wires in any given screen are chosen equal in diameter to the apertures. This specification makes the coarse screens too heavy for weaving and the fine too light for durability, while the percentage of opening in the intermediate screens (25 per cent.) is smaller than necessary and there is consequent reduction in rate of sifting. The aperture of any screen in the series, in inches, is the fraction $1/(2 \times \text{mesh-designation})$, (*e.g.*), the aperture of the 20-mesh screen is $\frac{1}{40}$ in.

Hoover series is a constant-ratio series (geometrical progression) with the ratio $\sqrt[3]{2}(=1.2599)$, starting with 1-in. as the unit aperture. It happens that the fifteenth screen, 0.0394-in., is 1-mm. aperture, so that this may be looked upon as the unit aperture for metric designation.

Tyler series is a geometrical progression with the multiplier $\sqrt{2}(=1.414)$, starting from the standard 200-mesh testing sieve (0.0029-in.). This is substantially the Rittinger series, except that instead of choosing 1-mm. aperture as the starting point, the series is based on a screen (200-mesh) already long established in testing-sieve practice and standardized by the U. S. Bureau of Standards. The 20-mesh (0.833-mm.) and 100-mesh (0.147-mm.) screens have also been standardized by the Bureau. The W. S. Tyler Co. made the series effective by manufacturing the screens in durable and attractive form and advertising them widely. As a result they have been adopted by a large number of mills, and for the first time, published screen tests of results at one mill can be interpreted in terms of screens familiar to readers at other mills in practically every part of the world. The Tyler Co. also manufactures sieves to the $\sqrt[4]{2}$ ratio, in order to give closer sizing, if desired. These start at the standard 200-mesh and hence fill in the gaps between the screens in the regular series.

U. S. B. S. series (United States Bureau of Standards) is the old Rittinger series, revivified by the Bureau several years after the introduction and adoption of the Tyler series. It includes the $\sqrt[4]{2}$ screens (double-Rittinger) below 1-mm. and thus brings in the standard 200-mesh sieve, but this sieve would not form a regular member of the series.

a Alternate sieves in parenthesis, taken with the regular sieves, form a series with constant ratio = $\sqrt[4]{2}$. Sieves with 3-, 2-, and 1.5-in. openings which, for all practical purposes extend the $\sqrt{2}$ series upward, are obtainable from the Tyler Co. *b* Approximate. *c* Series not manufactured.

In view of the satisfactory quality and wide adoption of the Tyler series, the proposal of the Bureau is deplorable and it is to be hoped that it will not meet with acceptance by mill laboratories with resulting confusion in screen-test literature. Table 1 gives the mesh and apertures of the Tyler and I. M. M. testing sieves and, in parallel columns the apertures proposed in the other series.

Screens for coal testing. Holbrook and Fraser (*Bull. 234, USBM*) call attention to the fact that none of these scales is applicable for ordinary commercial coal testing for several reasons, *viz.*: (1) The proposed series all include such fine screens that woven-wire screen surface must be used, while most commercial coal preparation is done on round-hole screens and the testing sieves should correspond. (2) The series are based on the metric system while coal is sold in sizes commonly rated in common (English) units. (3) The majority of screens in the proposed scales are below 1-mm. while the usual coal investigations are interested in coarser sizes. (4) The usual testing sieves have 8-in. frames; coal testing, involving as it does much coarse material, requires larger samples than ore testing and consequently larger sieves. They propose a series with 1-in. as the base and a sieve ratio of two, viz.: 8-in. 4, 2, 1, ½, ¼, ⅛, 1/16, 1/32 and 1/64-in., the sieves to have round holes punched in steel or brass plate, mounted in frames 18 in. square. They suggest 6-in., 3-in. and 1½-in. sieves, if closer grading is desired in the coarser sizes. For pulverized coal the problem is different and the usual square-mesh wire-cloth sieves are suitable.

Methods of screen analysis. Crude analyses, suitable for all ordinary work, are made by placing a weighed dry sample of the material to be tested on the top or coarse screen of a nest, shaking the nest until most of the undersize has passed the coarse screens (one to two min.), then removing the screens one at a time, beginning at the top, shaking each separately over a pan until the amount passing through in a minute is less than 1 per cent. of that remaining on the screen. Undersize is added to the top screen of the remaining nest. On coarse screens (0.75-in. or larger apertures) pieces near the screen size may justifiably be tested and put through, if possible, by hand. Oversizes and final undersize should be weighed and kept separate until all have been weighed and the weight checked against the original weight. Weighings should be accurate to within 1 per cent. and the total weight of the grades should check the original weight of the sample within 1 per cent. Screens should be shaken in such a way that the material is caused to travel slowly in a thin sheet over the whole surface of the sieve and at the same time the sieve should be jarred in a way that will cause the cloth to vibrate gently in a direction perpendicular to its plane. In specifying a standard method for sieve testing of cement, the U. S. Bureau of Standards states that the sieve "shall be held in one hand in a slightly inclined position . . . , at the same time gently striking the side about 150 times per min. against the palm of the other hand on the up stroke. The sieve shall be turned every 25 strokes about one-sixth of a revolution in the same direction." The reason for the final specification appears in some work by Griesenauer (*70 EN 1296*) showing a variation of 1.4 per cent. in the mean of tests across warp and shoot wires. When the fine material is caked, it may be broken up by rubbing on the sieve with a bristle brush or a rubber cork. Cut-metal washers are sometimes placed on the finer sieves during shaking, but this practice wears and distorts the fine cloth and, with soft material, produces an improperly large amount in the finest size.

When coarse material is tested the sample must be large because of the impossibility of cutting down accurately. On the other hand, except for the most accurate work, a carefully riffled sample of −0.12-in. material weighing 250 to 300 gm. is large enough. Hence considerable time can be saved by sifting the large sample roughly on the 3.33-mm. screen, cutting down the undersize to 250 to 300 gm. and screening this on the finer screens while the oversize is re-screened beginning with the coarsest screen. The undersize from the 3.33-mm. screen on the re-screening may usually be safely considered

oversize on the next finer screen and so treated in calculating the re-distribution.

Wet samples are best handled by jigging on the finest screen at the surface of water in a pail and washing the material on the screen with a fine jet until substantially all of the slime has passed. Oversize is then dried and re-screened on a nest including the fine screen, and the undersize of the fine screen on the dry sifting is added to the dried undersize of the wet screening. This procedure is quicker and more accurate than preliminary drying and dry sifting, on account of the difficulty in breaking up slime cake formed in drying. Sampling wet pulp for the screen sample is, however, a difficult matter, and this consideration may justify drying, riffling and subsequent wetting to break slime cake.

Mechanical testing-sieve shakers. It requires from one to three hours to sift a 200-gm. sample containing 30 to 50 gm. of -200-mesh material by manual shaking. Mechanical shaking will reduce the time to from 30 to 45 min. and during the time the sieves are being shaken the operator is free for other laboratory duties.

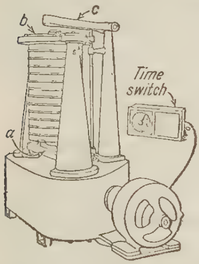

Fig. 4.—Ro-tap testing-sieve shaker.

The Ro-tap testing-sieve shaker (Fig. 4) made by W. S. Tyler Co., for 8-in. testing sieves, consists of a movable cage with base (*a*) and top plate (*b*) between which a nest of 13 half-height sieves or 7 full-height with pan and cover can be mounted and subjected to a rotary sifting motion while at the same time the lever (*c*) strikes the top plate once per revolution and produces vibration of the screen cloth. A time switch on the motor is useful. Duplicate samples sifted for equal periods of time on the same or different machines check well within the limits of sampling error. If the total amount of dust in the sample is important, the sieves after removal from the shaker, should be brushed around the inside of the rims with a soft brush and shaken individually for a short time as in hand sifting, as a small amount of dust collects around the edges of the coarser screens during the mechanical shaking and does not pass through.

Standard sizing test. No standard procedure for sizing tests is accepted or generally used, but Hersam and Gross (*Reports to Milling Comm. A. I. M. & M. E., Jan., 1924 and Jan., 1925*) have proposed the following method, after long study. The time required for performance is excessive except in cases where an apparent refinement is demanded that is greater than is actually possible by any method known at the present day. However, while adoption of the proposed method *in toto* is certainly neither justified nor desirable, many of the individual suggestions are valuable. A summary follows:

Table 2. Tolerances in testing sieves as recommended by U. S. Bureau of Standards

Screen opening, mm.	Tolerances in percentage		
	Wire diameter	Average opening	Maximum opening
2.83 +	10	1.5	10
1.00 +	10	3.0	10
0.35 +	10	4.5	25
0.125+	20	6.0	40
0.044+	20	7.5	60

Screen cloth should have square holes and be made of double-crimped wire of sufficient weight to resist deformation, but not so heavy as to permit enough wear to change the aperture materially. Sieve frames should be 8-in. diameter, strong and well-made, and free from crevices that can hold material. The actual average dimensions of apertures should be known and recorded and variation in aperture should not exceed U. S. Bur. of Standard tolerances. (See Table 2.) The sieve-scale ratio should not exceed $\sqrt{2}$. The sample should be dried at 110° C., riffled down to within 10 per cent. of the weight corresponding to maximum size of particle, according to Table 3. Sift wet on finest sieve,

using distilled water, until all slime is removed. This may be done either by placing the charge on the sieve and jigging it through the surface of a body of water in a container, or by decantation through the sieve. In either case the quantity of water used should be kept as small as possible. DRY oversize at 110° C., cool and weigh. SIFT OVERSIZE dry, beginning with the finest sieve, SHAKING as recommended by the Bureau of Standards (p. 1185). Sifting should be done with pan and cover, the sieve held over glazed paper to indicate and save SPILLS. When the undersize for one minute is less than 0.1 per cent. of the original weight of sample, remove the oversize, brush dust from both sides of the sieve, remove particles loosely held in the screen, then return all oversize and shake again until less than 0.05 per cent. of the weight of the original charge passes in one minute. Repeat the brushing operation, return the oversize and sift for one minute. If the undersize is less than 0.05 per cent. of the original charge weight, the END POINT has been reached, otherwise repeat the foregoing procedure until this condition is reached. Return the last-minute undersize to the oversize. Weigh final undersize and add it to the wet undersize. CLEAN SIEVE by tapping, brushing and rubbing with fingers, add material thus obtained to the oversize and weigh. Repeat sifting of oversize on successively coarser screens, weighing the final oversize in each sieve and obtain the WEIGHT OF UNDERSIZE by difference. This method credits the LOSS on each screen except the finest to the undersize of that screen, which, in lieu of other information, is logical. WEIGHT OF FINEST UNDERSIZE is obtained by drying at 110° C. and weighing. This material may be further sized, if desired, by ELUTRIATION. The sample for elutriation should be riffled down to about 20 gm. and separated by free settling in water into several grades. The proposed grades are shown in Table 4. SIZES OF ELUTRIATED PRODUCTS may be estimated from Fig. 5 or determined on wet samples by microscopic measurement (Art. 4). Return microscope samples, dry all products at 110° C., cool and weigh. When riffled samples have been used for elutriation, the weights of products must be re-calculated on the basis of the original fine undersize.

Table 3. Sample weights for sizing analysis, proposed by Hersam and Gross

Range of size of coarsest particles in sample, mm.	Sample weight, gm.
16.00–11.32	40,000
11.32– 8.00	12,500
8.00– 5.66	5,000
5.66– 4.00	2,000
4.00– 2.00	1,000
2.00– 1.00	500
1.00– 0.50	250
0.50– 0.25	100
0.25– 0.00	50

Table 4. Settling rates for elutriation, proposed by Hersam and Gross

Product	Material that settles one meter in	Material that does not settle one meter in
Slime...............	....	3 hr.
Finest sand........	3 hr.	2 hr. 40 min.
Next coarser sand...	2 hr. 40 min.	2 hr. 20 min.
Next coarser sand...	2 hr. 20 min.	1 hr. 35 min.
Next coarser sand...	1 hr. 35 min.	50 min.
Next coarser sand...	50 min.	24 min.(*a*)
Next coarser sand...	24 min.	12 min.(*b*)

a When aperture of finest screen is about 0.05 mm.
b When aperture of finest screen is about 0.07 mm.

Apart from the excessive amount of time required for this procedure the principal faults are the large sample weights recommended and the sifting of the dry material on progressively coarser screens. Duplicate screen tests of 10-kg. shovel samples of −16-mm. material will check well within the limits of the differences in sifting by two different operators and the same is true of samples of −0.12-in. material weighing between 250 and 300 gm. Placing coarse oversize on fine screens is equivalent to the use of metal washers, which is universally and rightly condemned.

Elutriation, as applied to ore dressing, is the process of grading finely-divided solid matter according to size by washing with water. There are two general methods, *viz.*: (1) by allowing the solids to settle freely in still water for varying periods of time, and (2) by subjecting the solids to rising water currents of different velocities.

Decantation is the simplest method of elutriation.

Take a tall beaker of 300 to 500 cc. capacity, place therein the sample to be sized, which

should weigh between 10 and 20 gm., fill with water to a predetermined depth, say 10 to 20 cm., stir thoroughly, then allow the beaker to stand for such a time that this time in seconds divided by the depth of water in millimeters will equal a predetermined settling rate corresponding to the largest-sized particle desired in the grade. The required time may be read from Fig. 5, or determined by application of Stokes' equation (Sec. 6, Art. 1). Now pour off the supernatant liquid with the non-settled solid in suspension, re-fill to the mark and again allow to settle for the same time. Repeat this until the appearance of the supernatant liquid indicates that all of the finest slime has been removed. Combine the decanted portions, take a sample, while wet, for microscopic determination of size (Art. 4), then dry at 110° C., cool and weigh. Re-fill the beaker to the mark with fresh water, and repeat the above operations, allowing a shorter time for settling corresponding to the next coarser grade desired, and repeating with this settling time until the supernatant liquid, at the end of the period, shows no solid in suspension. Repeat as above until the desired number of grades is obtained. If there is obvious chemical action during the operation, using tap water, *e.g.*, formation of gelatinous precipitates, distilled water should be used. If this does not remedy the trouble, weak solutions of acid or alkali may be used, but in such cases the presence of the added chemicals or their salts in the dried solid must be recognized. If microscopic sizing of the different grades is dispensed with, it must be recognized that there is considerable overlapping of sizes, due to the fact that not all of the solids start settling from the surface of the liquid in the beaker and that some fine particles that start settling from a point below the surface will reach bottom while coarser particles starting above them are still in suspension. Repetition, as directed, lessens this inaccuracy but does not eliminate it.

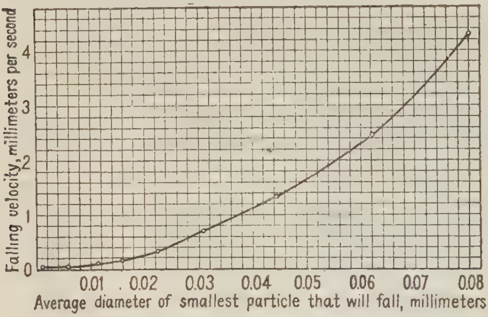

FIG. 5.—Free-falling velocities of quartz (*after Richards*).

Still-water settling tube is an improvement on decantation.

The apparatus (Fig. 6) consists of a glass tube of about 1.5-in. uniform diameter and 8 ft. long, converging in a 60° cone at the bottom to a stopcock with 1.5- to 2-mm. hole and expanded at the top into a funnel of about 200 cc. capacity, with 60° apex angle. Calibrate the tube from stopcock to base of funnel sufficiently closely that the length at any point in the tube corresponding to a given volume withdrawn at the stopcock will be known. From this calibration make a table of volumes for the required number of successive drafts such that the distance that the slowest settling particles are dropped, *i.e.*, that the surface originally at the base of the funnel drops, at each draft, is the same. Thus in Fig. 6 if the tube is calibrated for 10 draws, the successive volumes drawn should be such that the distance *ab*, *bc*, . . . *jk*, representing the successive drops of the surface originally at *a*, are equal. The charge of material to be sized, weighing from 20 to 50 gm. should be mixed with water to form a volume somewhat less than 200 cc. Place a closely-fitting disk of metal or fine screen cloth at the base of the funnel with a handle extending above the rim. Charge the feed carefully and wash in the last with a fine jet. Then, first observing and noting the time, remove the disk carefully to prevent the solid from plunging and allow settlement for a pre-determined time, or for a time dependent upon the appearance or amount of material at the stopcock. The tube should be jarred slightly at intervals to prevent material from clinging to the sides of the apparatus. Draw off now the volume corresponding to the first equal drop in surface of settling column and set aside. Make successive draws at inter-

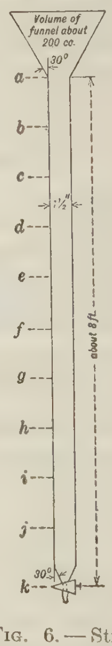

FIG. 6.—Still-water settling tube.

vals determined by the requirements of the analysis, *e.g.*, at equal intervals, or at intervals determined by Fig. 5 or by Stokes' equation to yield predetermined sizes, or at intervals which the settling behavior indicates will yield equal weights of solid. When the total volume of withdrawals is equal to the original volume of water in the settling column, there will remain a volume equal to that of the feed pulp and containing the finest slime. Remove this at one draw and class it as of slower settling rate than that of the slowest-settling particle in the preceding grade. Sizes of the particles in the different grades may be determined by microscopic measurement or may be estimated from the known settling rates. Decant clear water from the different grades, dry at 110° C., cool and weigh.

If l is the total length of settling column, measured from neck of funnel to top of stopcock, N = the total number of draws, and n = the number of any given draw, then the average distance D_n that the particles taken in the *nth* draw have settled is given by the equation $D_. = l(2N - 2n + 1)/2N$. If t_n = the total time elapsed from the beginning of settlement until the end of the *nth* interval, the average settling velocity V_n of the solids collected during the *nth* interval is given by the equation $V_n = l(2N - 2n + 1)/2Nt_n$. If equal time intervals t are taken, this equation become $V_n = l(2N - 2n + 1)/2Nnt$. The slowest-settling particle in the last grade settles through the distance $D_{SS} = l - l/N$ in the time t_n. Its settling velocity is, therefore, $V_{SS} = l(N - 1)/Nt_n$ and the most rapidly-settling particle in the final draft has a slower velocity.

Elutriation by rising currents is performed by subjecting the material to be graded to rising currents of different velocities and collecting separately the material lifted by each current.

The apparatus shown in Fig. 7 (*32 M & M 125*) is one of the simplest of these devices. As described, it was used merely to separate slime from a sample that was to be subsequently screen sized. The procedure was to set the dial cock (f) so that the current at the overflow level was sufficient to carry over all slime, then to close the rubber tube (g) with a pinch cock, charge the weighed sample into (a) and then release the pinch cock. When overflow was clear, the material in (e) and that remaining in the tube were collected and sized. The same apparatus may, however, be used to separate a number of different grades. There are two alternative methods of procedure, viz.: (1) To set the current at the lower part of constriction (c) to just prevent slime from settling, feed the sample into (a) and collect the overflow in a pail or tub. Then raise the current slightly, feed back the settled material collected in (e) and again collect the overflow, and repeat this procedure until the desired number of grades has been made. (2) Set the current originally so that the velocity at the lower part of section (c) will permit only the coarsest material to settle. Collect overflow and settled product. Separate the slime from the sand in the overflow by decantation. Slack off the current slightly, feed back the sandy portion of the first overflow and again collect the settled material. Repeat with gradually slower currents until as many grades as desired have been made. Final products will consist of the various settlings and the decanted portion of the first overflow. This apparatus is adapted to relatively coarse grading only.

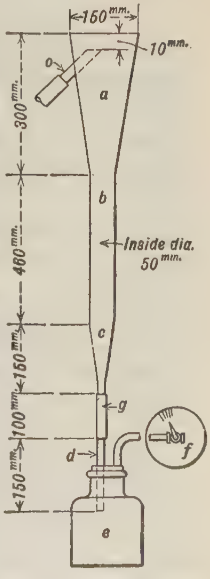

FIG. 7.—Rising-current sizing tube.

Schoene apparatus (Fig. 8) is distinguished by the fact that overflow is made through a piezometer, which permits ready setting of current velocities, once the piezometer is calibrated to the tube with which it is to be used. In the figure, (a) and (b) are sorting tubes of smaller and greater diameter respectively for coarse and fine sizing. The procedure consists in first determining the average cross-section of the cylindrical portions of the tubes by weighing the water drawn through the stopcocks corresponding to the measured length between two marks delimiting the cylindrical section. Knowing the average cross-section from this determination, average rising-current velocities can be determined by weighing overflows collected for known times. This is done and at the same time the corresponding piezometer readings are taken and a curve showing average rising velocities in terms of piezometer readings plotted. To make a sizing analysis, fill the feed-water tank and maintain sufficient inlet so that the tank will overflow throughout the test. Close the stopcock

at the lower end of the sorting tube and admit sufficient water from the tank so that the level in the sorting tube stands a couple of inches above the stopcock. Make up the weighed feed sample into a dilute pulp sufficiently small in volume to less than fill the tube and introduce this through the funnel. Close the funnel stopcock. Open the water cock slowly until the piezometer reading indicates the desired minimum current and continue this current until the discharge carries substantially no solids. Set aside the overflow, then increase the current and collect another grade and continue until all but the coarsest material is overflowed. Collect this last through the stopcock at the bottom of the sorting tube. Determine the size of material in different grades by microscopic methods or estimate from Fig. 5 or from Stokes' equation. Stadler (*22 IMM 686*) points out that, if the specific gravity of the material being sized is known, solid weights may be determined by weighing the material in a specific-gravity flask, or its equivalent (see Art. 23), thereby saving much time in drying.

According to Schoene a calibration curve is unnecessary and the velocity V corresponding to any piezometer reading h may be obtained from the equation $V = V_1\sqrt{\frac{h-c}{h_1-c}}$ when V_1 and h_1 are corresponding values from one observation and c is a factor, determined once for all, from the relation $c = (Q^2h_1 - Q_1{}^2h)/(Q^2 - Q_1{}^2)$ in which Q and Q_1 are quantities in cc. per sec. corresponding to piezometer readings h and h_1 respectively in cm.

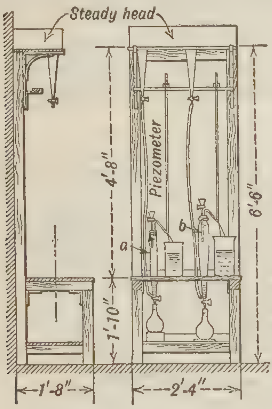

Fig. 8.—Schoene elutriation apparatus (modified).

Multi-tube elutriation. If a series of Schoene tubes of the type shown in Fig. 8, of different diameters, is set up without piezometers, the overflow tube of the smallest entering the apex of the next larger, and so on, and a charge of solid is placed in the first and a current started of sufficient velocity to lift all but the coarsest material out of the first tube, then if the last tube is of sufficient diameter to overflow only the finest slime, there will be collected in the successive tubes successively finer grades and the entire separation can be done at one operation. This is the best type of apparatus for routine tests, but lacks flexibility.

Interpretation of elutriation tests. The settling rate of solids in water is dependent upon the specific gravity and shape of the particles, upon the degree of packing in the sorting column and upon the uniformity of the sorting current (see Sec. 6, Art. 1). It is inevitable that, if the sample sorted contains grains of different specific gravities, the grades will contain grains of highly divergent sizes, and that, even if all of the material is of the same specific gravity, the coarser grades will contain finer grains carried down mechanically or by eddy currents, and the finer grades will contain flat scaly particles that settle much more slowly than their average "diameter" would indicate. Hence the only sure way to determine the average size of grains in a given grade is by microscopic measurement. If desired, this measurement may be made separately on the heavy and light particles and on the flat and rounded particles, and the analysis recast on the basis of these measurements.

Air elutriation. Pearson and Sligh (*TP 48 USBS*) review eight forms of air analyzers and describe in detail the construction and operation of a form developed by the Bureau.

This consists (Fig. 9) of a vertical cylindrical polished-brass sorting tube (a), 2.7 in. inside diameter by 60 in. long with a bulb (b) at the bottom for holding the sample, three nozzles (c), 0.04-, 0.09- and 0.13-in. diameter, for varying the velocity of the entering air and hence the intensity of agitation in the bulb and the velocity of the rising air current in the sorting tube, and a collector (d), about 10 in. diameter by 20 in. high, with canton-flannel covering, for receiving the various solid fractions while passing the air. Air is supplied at constant pressure (ordinarily about 1 lb. per sq. in.) from the reservoir, which is supplied by a motor-driven blower and controlled by a blow-off valve and an oil regulator. The latter

is a vertical pipe about 4 in. diameter by 5 ft. long, closed at the bottom and nearly filled with kerosene. A long glass tube, open at the lower end and connected at the top with the reservoir, extends to within a short distance of the bottom of the oil-filled cylinder and the back pressure is adjusted by changing the depth of submersion by raising or lowering the tube. In operation the blower is run at a speed sufficient to maintain slightly more than 1 lb. per sq. in. pressure with a small amount of blow-off and the regulator is then set by trial. The sample taken is −200-mesh material, weighs 30 to 50 gm., and is divided into four fractions. The flow of air in the sorting stack is reasonably constant in velocity and uniform across the section; air delivery is not retarded by the sample, if the nozzle tip is kept 1 cm. or more above the surface, nor by the back pressure of the collector sack. The sample must be kept stirred up in the bulb, if operation is to be satisfactory. The dependent factors are air pressure in reservoir, diameters of nozzle, bulb and stack, shape of bulb and quantity of sample. Lodgment of material in the separating stack, which would hinder separation, is guarded against by polishing all interior surfaces, beveling the upper rim of the stack to a knife edge, tapping the stack continually during operation with an electric tapper, and so designing the collector that material once therein cannot again enter the sorting tube.

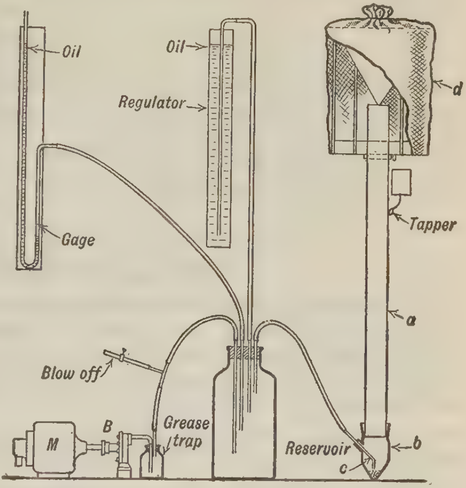

Fig. 9.—Air analyzer, Bureau of Standards.

Operation is as follows: (1) With the nozzle that is to be used for the finest separation connected to the reservoir, but not in place in the bulb, start the blower and adjust the speed, blow-off and oil regulator for a constant pressure of very slightly more than 1 lb. per sq. in. with the regulator blowing off a slight amount of excess air. Disconnect the nozzle, insert it in the bulb and weigh the two to the nearest 0.01 gm. Add the sample to the bulb (33.33 gm. if the 0.04-in. nozzle is to be used for the finest separation, otherwise 50 gm.), attach to the stack, start the tapper and connect the air tube. Continue elutriation until the loss per unit of time is at the rate of some pre-determined amount (Pearson and Sligh have adopted 0.02 gm. per min.). The end point is determined by stopping blowing some 15 or 20 min. before the estimated time of completion, allowing 30 sec. to 1 min. for material to settle from the stack, then weighing the bulb and contents. Continue blowing 10 min. and again weigh. Repeat until the 10-min. loss is less than 0.2 gm. Interpolate for the weight at the minute when the loss was at the rate of 0.02 gm. per min. Repeat with 0.09-in. and 0.13-in. nozzles.

Actual sizes of the various grades for a given apparatus and material must be determined by microscopic measurement, but once determined the sizes are reasonably constant for other samples of the same material in the same apparatus. With cement, experiment shows that the average diameter reckoned as $D = \sqrt[3]{blt}$, where b, l and t are the arithmetical means of a number of determinations of breadth, length, and thickness, respectively, of grains, checks very closely with the mean of b for both the air-elutriated grades and the material on 100- and 200-mesh sieves. Results of one determination are shown in Table 5.

Shape of bulb is not important except in so far as it determines the amount of material that can be treated with the minimum air stream. Diameter of nozzles need be neither accurately specified nor determined. Diameter of stack should be the least that is consistent with the finest separation, *i.e.*, the least that will give sufficiently low air velocity in the stack when the material in the bulb is properly permeated. At this, the agitation in the bulb when sufficient air is rising in the stack for the coarsest separation will be great. Length of stack has been tested over the range from 5 to 8 ft. and results with the short stack shown to be reasonably concordant with those of the long stack. Abrasion is negligible under conditions of minimum stack diameter. Atmospheric conditions have inconsiderable effects,

Small variations in pressure (less than 10 per cent. range) may be neglected. Size of sample may range between 25 and 50 gm. without noticeable effect on results.

Table 5. Comparison of average diameter with mean breadth of air-elutriated and screened particles. (*After Pearson and Sligh*)

Grade	Mean breadth, b, inch	Average diameter, $\sqrt[3]{lbt}$, inch
Rising with 0.04-in. nozzle.........	0.00062	0.00066
Rising with 0.09-in. nozzle.........	0.00130	0.00129
Rising with 0.13-in. nozzle.........	0.00181	0.00178
Not rising with 0.13-in. nozzle but passing 200-mesh sieve..........	0.00368	0.00371
Passing 100-mesh, retained on 200-mesh.........................	0.00703	0.00690

3. Testing with the microscope

The microscope is used in ore testing (1) to aid in mineral and rock identification and classification; (2) to aid in the study of mineral occurrence and the ore characteristics upon which the treatment scheme depends; (3) in quantitative mineralogical analysis; (4) in sizing analysis. Until the present time adoption of this tool in testing laboratories has been very slow and much time and money have been and still are wasted in work that could have been more quickly done with the microscope or which microscopic examination would have shown to be useless.

Microscopic mineralogy and petrography are familiar tools to the geologist and the literature is excellent and large. The principal apparatus required is a petrographic microscope. Samples for examination are prepared either in the form of thin sections or pulverized fragments. Detailed description of methods of study and interpretation of thin sections are given by *Johannsen*; L. M. Luquer, *Minerals in rock sections, Van Nostrand, 1913;* Winchell, N. H. and A. N., *Elements of optical mineralogy, Van Nostrand, 1909;* the study of pulverized fragments is best described by *Rogers*.

Mineragraphy is the study of opaque minerals, including native metals, most sulphides, certain base metals, oxides and the like, by means of the metallographic microscope. The methods include study of polished sections by reflected light, etching and various microchemical tests, hardness tests, etc. The methods are much more effective in identification of opaque minerals than either of the ordinary petrographic methods above mentioned.

C., *The reflecting microscope in mining geology and metallurgy, 108 P 922.* Further books and papers are named in the last two articles.

Of even greater importance to the ore tester than identification and the information concerning ore genesis afforded by mineragraphical work is the information that the polished section gives as to particle size and method of occurrence of the valuable mineral. The first fact can be established with coarse-grained ores by means of a sizing-sorting-assay test (Art. 7) and with such ores the second is not of much importance, but with finely disseminated

and complex ores the polished section quickly gives essential information that can be obtained in no other way. Determination of grain size will tell the size to which the ore must be crushed to free the valuable mineral and upon this fact and the kind of mineral and gangue, the principal elements of a tentative flow-sheet can be immediately founded. The appearance of the edges of the sulphide-mineral grains and of cracks traversing them will tell whether any alteration that would be likely to affect flotation has occurred. Inclusions of worthless or deleterious substances that would lower the grade of concentrate, such as silicates between the laminæ of graphite grains, blende in galena and the like, are immediately apparent in a polished section. The degree of admixture of sulphides in complex ores can be studied readily and in many cases one or two properly chosen sections are sufficient to tell the hopelessness of any attempt at separation by mechanical methods. Thus much time and money can frequently be saved and no test of any ore should proceed beyond the preliminary assay stage without such microscopic examination.

Quantitative mineralogical analysis is useful primarily in study of the products of a concentrating operation. The first step is identification of the important minerals and mineral groups. The analytical work is done with low magnification since identification of the valuable mineral, the accompanying heavy mineral or minerals, and the gangue minerals as a group is easy. Failing this, however, analysis must be preceded by identification, and for this work *Rogers'* crushed-fragment method with the petrographic microscope is best.

Apparatus: Low-power microscope, preferably binocular type, so mounted as to permit ready relative movement of stage and objectives. The stage should be ruled in squares about 10 mm. on a side and the microscope should have an eye-piece net micrometer with one of the squares subdivided. Zeiss and Bausch and Lomb both make binocular microscopes for ore-dressing work having magnification up to 20 diameters, fitted with racking mechanism in two directions at right-angles, and provided with net-ruled glass stage and eye-piece micrometer. For greater magnification a metallurgical binocular with 25- and 55-mm. objectives and 6 × and 10 × oculars is a suitable instrument. This instrument, which is obtainable from any microscope house, is not usually fitted with racking stage, and the sample, mounted on a suitably ruled slide, must be moved manually to change the field. This can, however, be done readily with a little practice.

Procedure consists in close and accurate sizing of the sample and a mineral count of a sufficient number of fields of each grade to establish a reliable number percentage. Sizing should be done by first washing out the slime through the finest screen, then drying and screening the oversize and, if necessary, grading the undersize by elutriation. Washing through the finest screen may be done with a soap or saponin solution, which prevents skin flotation and the formation of floccules that will not pass the screen and also lessens the surface tension of the liquid films that form across the screen apertures and thus aids the passage of undersize.

Coarser grades can be transferred to and distributed on the slide by means of a small spatula. The layer should be only one grain deep and if the grains are spaced at least one diameter, which may usually be accomplished by tapping the slide, counting will be made much easier. Finer grades are best transferred to the slide by shaking them on through a suitable fine screen. If, as is rarely the case, the analysis must be carried down into very fine water-separated grades, the methods of mounting employed in microscopic sizing analysis should be used.

Sampling of the grades to obtain a representative lot for counting is one of the most difficult and unsatisfactory parts of the whole procedure. The most accurate cutting down can be effected on the unsized sample, but if this is made too small, inaccuracies and losses in sizing become proportionately great. It is probably best to set 25 gm. as the lower limit of screen-sample size and to approach this for samples containing 0.5-mm. maximum grains and finer and run up to 50 to 75 gm. for samples up to 1.5-mm. size. For material coarser than this the method becomes distinctly inaccurate.

Irrespective of the size of sample taken for screen analysis, the bulk of most of the grades will be too great to permit mounting of the entire grade on one or even on several slides, and it is necessary to sample the individual grades. Probably the best method of doing this is as follows: Pour the sample through a small-necked funnel on to a glass plate, so as to form

a cone-shaped heap; flatten out the heap with a small spatula to make a circular cake, taking care that so far as possible all particles that move are displaced radially outward; divide the heap into quarters by first making a diametral cut with the edge of the spatula and pushing one-half with the spatula face a distance of about one inch in a direction at right angles to the first cut, then split each half into two equal parts by cuts along the radii at right-angles to the initial cut; finally reject opposite quarters, combine the remainder and repeat, if necessary, until a sample is obtained that will give the required layer one grain deep on the slide.

Counting should proceed systematically. In the largest sizes, with a few particles only in each square, it is best to count all of the grains in the ruled field; in the intermediate sizes only the grains in selected squares need be counted, the squares selected being regularly spaced to cover the ruled field and the number counted being proportioned to the size of grain, so that each size shall be analyzed with substantially the same degree of accuracy. Application of this criterion requires experience and judgment on the part of the analyst. The factors involved are: degree of uniformity of distribution of the different kinds of grains in the field, degree of uniformity in size of particles, amount of composite material (middling grains), relation of the weight of one particle to the weight of material in one square and in the whole field, relation of the weight of material in the field to the weight of the grade, and relation of the weight of the grade to the weight of original unsized sample. In the finest size the squares counted are the smallest in the micrometer net and one or several of the squares in this net should be counted from each selected square on the stage net, according to the above criteria. Some analysts recommend counting all or selected squares along one or both diagonals of the net, thus substantially cutting sections through the center of the field; others choose squares equally spaced in both directions covering the entire area. In no case should random selection or selection involving judgment on the part of the operator be permitted.

In counting the grains in any square it is best to carry through and record the count on each kind of grain separately. If one kind of grain breaks in such a fashion that its volume is consistently different from that of the grains of the other minerals in the grade, this fact should be noted and the relative volume established or approximated. In counting grains that are composites of the varieties sought to be separately reported, the relative volumes of the constituents must be estimated and if, as is usually the case, the relative proportions vary in different grains, the count should be classified on the basis of this proportion. Four classes are enough in any case, viz.: less than 25 per cent., 25 to 50 per cent., 50 to 75 per cent., and more than 75 per cent. Grains containing traces of, say, sulphide should be classed as tailing and those containing traces of gangue as concentrate. For most purposes three or even two classes are sufficient.

It should be borne in mind in microscopic estimation that the aspect presented to the eye is a surface aspect while relative volume is the figure sought, and the visual impression must, therefore, be suitably weighted in recording the percentage estimate. Thus Coghill and Bonardi (*see below*), analyzing a molybdenite flotation concentrate containing pyrite and silica, weighted FeS_2 and the MoS_2 locked in middling at two, compared to one for silica, basing the rating on the relative specific gravities, but the free MoS_2 was rated at one on account of its flaky character and the fact that the free flakes lay flat. Their microscopic analysis, thus weighted, showed 41.4 per cent. MoS_2 against 38.2 per cent. by chemical assay.

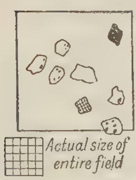

FIG. 10.—Sketch of molybdenite flotation concentrate (*after Coghill and Bonardi*).

Fig. 10 shows one of the fields counted, sketched by means of a camera lucida. This sketch, showing that most of the silica in this particular concentrate was in the form of middling, pointed the obvious conclusion that the proper method to raise the grade of concentrate was to grind finer.

Time for a test will range from 3 to 8 hr. according to the size of sample and the number of minerals counted.

4. Microscopic sizing analysis

Sizing by screens below 200-mesh (0.074-mm.) is highly inaccurate, both on account of the inaccuracy in screen manufacture and because of the great difficulty in getting material through the screen. Elutriation and air classification alone are similarly undependable because of difference in settling rates induced by differences in shape and specific gravity of particles. Microscopic sizing has been highly developed in recent years to supplement or supplant the settling methods. With proper equipment and good technique microscopic sizing can be carried down to less than one micron (1 MICRON = 0.001 mm.) and the average size of excessively fine products stated with a precision of one- or two-tenths micron.

Green (*Jour. Frank. Inst., Nov., 1921*) predicts that precision will shortly be increased to hundredths or even thousandths of a micron. Such fine sizing is not necessary in concentration but is of importance in many commercial grinding operations.

Apparatus. The principal piece of equipment required is a monocular microscope with 16-, 8-, 4- and 1.9- or 2-mm. objectives. A petrographic microscope has the advantage that by the use of crossed nicols floccules in the field may be identified. Necessary accessories are indicated in the following descriptions of methods.

Direct measurement. Weigel (*TP 296, USBM*) describes two methods. In one, the −200-mesh material was elutriated into five fractions and each one was measured separately; in the other, a representative sample of the whole −200-mesh material was measured. Microscopic work was the same in both cases.

Preparation of slides. Slides should be about 50 × 75 mm. Dilute the sample in a test-tube with distilled water until it appears cloudy or very slightly milky on shaking. A drop or two of ammonia aids dispersion with clays. Pour off until the tube is about one-third full, agitate by blowing through a pipette then quickly transfer a few drops to the slide, covering an area about 20 mm. diameter. Dry in an air bath at 105° C. Particles should be spaced with little or no overlapping and no flocculation. New slides should be prepared until this condition obtains. The slide may be used uncovered for work with 4-mm. and longer objectives and these should, therefore, be objectives corrected for use without a cover glass. For the finest material (1 micron or less) an oil-immersion lens must be used and the slide must be mounted with a cover glass. Glycerine (index ref. = 1.47) is satisfactory for most non-metallic minerals. Methylene iodide (ref. index = 1.74) is used for clays and tales, if necessary, but it produces diffraction rings. To mount, place a drop of the mounting liquid on the center of the dried sample, drop the cover (35 × 50 mm.) into place and work it down with slight pressure and a rotary motion. Remove excess liquid with a filter or blotting paper, then run a ring of melted paraffin around the edge, using a fine camel's-hair brush. An excess of mounting liquid may result in washing fine material from under the edges of the cover and ruining the slide.

Measuring. Use a micrometer disk in the ocular, ruled with 6 to 8 squares on a side of the inscribed square of the field and with one of the larger squares subdivided. The size of most particles can be estimated from the large open squares, but the subdivided square can be used, if necessary, to measure the smallest particles. Particles in outer squares are distorted at high magnifications, hence use only the inner squares. Determine the undistorted area for each objective by calibration with a stage micrometer. Set the sample slide so that the field is in one corner. Have the microscope fitted with lowest-power objective. Search the field for the largest particle, estimate the mean of the two principal dimensions exposed to the nearest 5 microns, then, beginning at one corner of the inner (undistorted) square work over all squares in order, counting and recording the number of particles within this range. Repeat this process with successive fields until the whole slide is worked over, making as many counts as seem necessary to obtain a fair average of the grains per field. Repeat with the higher-powered objectives, narrowing the range of sizes each time, and counting fewer squares per field but the same number of fields as with the first objective. The range of the 16-mm. objective with 10 × ocular (100 diam.) is, conveniently, down to 30 microns, the 8-mm. objective (200 diam.) from 30 to 10 microns, the 4-mm. (430 diam.) from 10 to 1 micron. and the 1.9-mm. oil-immersion lens (950 diam.) for finer than 1 micron. Check on the relation of counts with different objectives was obtained by Weigel by re-counting the smaller size with one objective with the next higher power and reducing the results to equivalent areas. Eighty fields were counted with the 16-mm.

objective, 40 with the 8-mm. and 20 each with the 4-mm. and 1.9-mm. The more uniform in size the material counted the smaller the number of fields necessary.

Procedure in count of total sample is the same, except that more fields and more squares per field must be counted on each slide, yet the total microscopic work is less than when elutriation is practiced. The time for a total-sample measurement, including calculation was 5 to 6 hours. An elutriation test requires about 3 days and the count and calculation one day more. Less skill and experience are needed for the elutriation test.

Indirect measurement is described by Green (*loc. cit.*) and is adapted to very fine materials of greater uniformity than the non-metallic natural fillers measured by Weigel. The method involves making a slide, photographing one or more fields, projecting the negative on a screen and measuring and counting the grains thereon.

Mounting. Place about one mg. of the material on the center of a slide and cover with a drop of re-distilled turpentine. Rub out with a straight, smooth glass rod, stroking lengthwise of the slide. Continue rubbing until the mixture is thick enough to prevent particles from floating and flocculating but thin enough not to streak, then stop with a slight lift on the last stroke to leave a wedge-shaped deposit on the slide and yield fields of different intensities from which to choose the one for photographing. Evaporate the turpentine completely on a hot plate at a temperature that completes the drying in 40 to 50 sec. Mount with glycerine as described by Weigel (p. 1195).

Photograph with transmitted light that is absolutely axial. Fine-grained contrast plates and hydroquinone developer are easiest to handle but panchromatic plates and pyro developer give better detail. The important point in the photography is sharp definition of particle edges. The negative should show 200 to 250 particles.

Measurement. Project on a screen so that the total magnification is 20,000 to 25,000 diam., measure with a millimeter rule to the nearest whole millimeter and record. Fig. 11 shows a form of record calculation.

5. Average size of particles

Mineral particles produced by crushing and grinding show an almost infinite variety of shape and size. No simple and accurate numerical expression of the dimensions of a single particle nor of the average dimensions of a group is possible; the best that can be done in any case is an approximation which is ordinarily expressed as a single number, as though the particles were spheres or cubes. This number is called the DIAMETER or SIZE of an individual particle or the AVERAGE DIAMETER or AVERAGE SIZE of a group of particles.

Diameter of a particle. The fundamental assumption of particle measurement is that it has three principal axes at right angles and that its dimensions are completely stated when the distances between the intercepts of the surface on the respective axes are given. Starting with this assumption, which is, on its face, only a crude approximation except in the case of materials with cubical cleavage, averaging of the three principal dimensions into a single figure is attempted by one of several different methods, as follows:

$$d = b, \qquad (1) \qquad\qquad d = \frac{l+b}{2}, \qquad (2)$$

$$d = \frac{l+b+t}{3}, \qquad (3) \qquad\qquad d = \sqrt{lb}, \qquad (4)$$

$$d = \sqrt[3]{lbt}, \qquad (5) \qquad\qquad d = \frac{\sqrt{2lb + 2bt + 2lt}}{6}, \qquad (6)$$

$$d = \frac{3lbt}{lb + lt + bt}, \qquad (7)$$

where d = "diameter" and l, b and t are respectively the distances between the intercepts of the surface on the long, intermediate and short axes, or, in common parlance, length, breadth and thickness of the particle. The significance of the first five approximations is immediately apparent; the sixth gives the edge of a cube whose total surface is equal to the total surface of a rectangular parallelopiped, the dimensions of which are equal to the principal dimensions of the particle. The seventh is the harmonic mean of the dimensions. Green (*loc. cit.*) develops the fact that this harmonic mean is a factor in the expression for the SPECIFIC SURFACE of a mass of particles, *i.e.*, the total surface per unit weight of the material. Thus, for a mass of spherical or cubical particles of the same size, $S = 6/\rho\mu$, where S = specific surface, ρ = specific gravity and μ = the diameter. But $S = Ns$, where N = the number of particles per unit weight and s = the surface of each particle, whence, if the particles are taken as rectangular parallelopipeds, $S = (1/\rho lbt)(2(lb + lt + bt)) = 2(lb + lt + bt)/\rho lbt$, and, by substitution in the first equation, $\mu = 3lbt/(lb + lt + bt)$.

Which one of equations (1) to (6) is to be used in any given determination of particle size depends upon the method of measurement and the predilection of the experimenter. When screens are used the first assumption is adopted perforce. When elutriation is employed without subsequent microscopic measurement of the fractions the fifth assumption is necessarily involved. When individual particles are actually measured, any one of the seven assumptions may be employed, but the second and fourth are the ones most commonly used. The sixth is no more accurate than the fifth and involves much more computation, while the seventh requires so much measurement and calcula-

tion, if a large number of particles is to be measured, as to be substantially impracticable.

Average diameter is calculated by some method of averaging the mean or equivalent diameters of a number of particles. Perrott and Kinney (*The meaning and microscopic measurement of average particle size*; 6 *Jour. Am. Ceramic Soc.* 417) give the following summary of suggested methods:

1. Arithmetical mean $D = \frac{d_1 + d_2}{2}$.
2. Geometrical mean $D = \sqrt{d_1 d_2}$.
3. Laschinger's mean $D = \frac{d_1 - d_2}{\log_e d_1 - \log_e d_2}$.
4. Mellor's mean $D = \sqrt[3]{\frac{(d_1 + d_2)(d_1^2 + d_2^2)}{4}}$.
5. Mean of form $D = \frac{4}{5}\left(\frac{d_1^5 - d_2^5}{d_1^4 - d_2^4}\right)$.
6. Von Reytt's mean $D = 0.435(d_1 + d_2)$
7. Number mean $D = \frac{\Sigma nd}{\Sigma n}$.
8. Length mean $D = \frac{\Sigma nd^2}{\Sigma nd}$.
9. Surface mean $D = \frac{\Sigma nd^3}{\Sigma nd^2}$.
10. Volume mean $D = \frac{\Sigma nd^4}{\Sigma nd^3}$.

To these should be added

11. $D = \sqrt{\frac{\Sigma nd^2}{\Sigma n}}$.
12. $D = \sqrt[3]{\frac{\Sigma nd^3}{\Sigma n}}$,

where D is the mean diameter, d_1 and d_2 are the maximum and minimum mean particle diameters, respectively; d represents the successive mean particle diameters in a sizing operation, and n the numerical frequency of the corresponding d.

Formulas 1 to 5 inclusive are based on the assumption of an even gradation in size from maximum to minimum and necessarily also on an equal number of particles in each size group, or else they disregard the effect of frequency of occurrence of particles of the different sizes. Formula 6 is clearly an approximation to formula 1. Formulas 7 to 10 consider and weight the intermediate sizes on the bases, respectively, of (*a*) number of particles in the successive grades; (*b*) total length of mean diameters in these grades, *i.e.*, number of particles in a grade × mean particle diameter; (*c*) total surface, *e.g.*, number of particles in the grades × mean particle diameter squared; (*d*) and total volume, *i.e.*, number of particles × mean particle volume.

Equation 7 has the physical significance that if the particles under investigation were laid side-by-side in a line and the length of the line were divided by the number of particles the quotient would be the number D. If the area covered by these particles were divided by the length of the line, the quotient would be the value D given in equation 8. On this base, the average height of a parallelopipedon equal in volume to the total volume of Σn particles is the D of equation 9. Formula 10 is the equivalent of $D = \Sigma wd/\Sigma w$ where w = percentage weights of the different grades and the other letters have the significance already assigned. This is the formula commonly used when sizing is done by screens, sedimentation or elutriation, and when the amounts of the various grades are determined by weight. Formula 11 gives the edge of a cube whose surface multiplied by the total number of particles in a given mass of particles is equal to the total surface of the mass, if the particles are taken as cubes. Formula 12 gives the edge of a cube whose volume multiplied by the total number of particles is equal to the total volume of the particles sized, considered as cubes.

Comparison of methods. Perrott and Kinney (*loc. cit.*) give the microscopic sizing analysis shown in Table 6. Comparison of the average diameters calculated by the different formulas points clearly the uncertainty of meaning of this term and the necessity for stating the method of calculation when giving a numerical result. The result by formulas 1 to 6 incl. is not affected in any way by the amounts in any of the grades. These formulas will, therefore, each give the same result for any mass of grains of mixed sizes, irrespective of the size composition of the mass, if, only, the largest and smallest particles are in every case of the same sizes. This fact condemns these for-

Table 6. Comparison of methods of calculating average diameter

Microscopic analysis

Diameter, microns (d) ...	60	50	40	30	20	10	5	2

Average Diameter

Formula	Microns
1. $D = (d_1 + d_2)/2 = (60 + 2)/2$	= 31
2. $D = \sqrt{d_1d_2} = \sqrt{60 \times 2}$	= 11
3. $D = (d_1 - d_2)/(\log_e d_1 - \log_e d_2) = (60 - 2)/(2.303[1.7782 - 0.3010])$	= 17.0
4. $D = \sqrt[3]{(d_1 + d_2)(d_1^2 + d_2^2)/4} = \sqrt[3]{(60 + 2)(3600 + 4)/4}$	= 38.2
5. $D = 4(d_1^5 - d_2^5)/5(d_1^4 - d_2^4) = 4(60^5 - 2^5)/5(60^4 - 2^4)$	= 48
6. $D = 0.435(d_1 + d_2) = 0.435(60 + 2)$	= 27
7. $D = \Sigma nd/\Sigma n = (0.05 \times 60 + \ldots 81.8 \times 2)/100$	= 3.0
8. $D = \Sigma nd^2/\Sigma nd = (0.9 \times 60 + \ldots 53.2 \times 2)/100$	= 7.0
9. $D = \Sigma nd^3/\Sigma nd^2 = (7.8 \times 60 + \ldots 15.6 \times 2)/100$	= 21.0
10. $D = \Sigma nd^4/\Sigma nd^3 = (22.4 \times 60 + \ldots 1.5 \times 2)/100$	= 36.4
11. $D = \sqrt{\Sigma nd^2/\Sigma n} = \sqrt{(87 \times 60^2 + \ldots 155{,}000 \times 2^2)/(87 + \ldots 155{,}000)}$	= 4.6
12. $D = \sqrt[3]{\Sigma nd^3/\Sigma n} = \sqrt{(87 \times 60^3 + \ldots 155{,}000 \times 2^3)/(87 + \ldots 155{,}000)}$	= 7.6

mulas for anything but the crudest kind of work. Formulas 9 and 10 place too much weight on the coarser sizes and both they and No. 8 give results that have no real meaning in terms of the diameter of ideal particles which could be substituted for the actual particles. On the other hand, No. 9 is useful when specific surface is important. Results by formulas 7, 11 and 12 have the meanings already developed. Which of the three should be used in any given case is a matter of individual preference, since it is impossible to choose scientifically. No. 7 gives the easiest calculations and the physical significance is most readily visualized. It weights the finest particles most heavily and, therefore, gives an average that leans toward the fine end. No. 12 weights the coarsest particles most heavily and consequently the result leans toward the coarse end. No. 11 is intermediate between the other two and would, on that score alone, seem to be preferable. It is distinctly to be preferred when surface is the valuable property of the material.

Uniformity. The complete information regarding the texture of a mass of broken material is not expressed by the average size. Thus in Fig. 12 curves

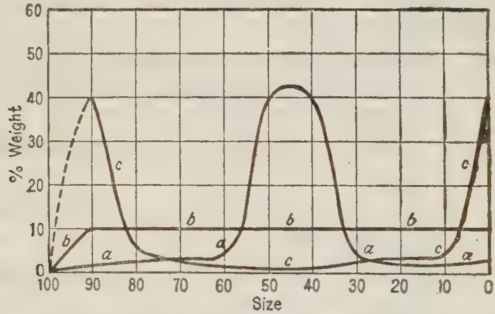

FIG. 12.—Plots of three products showing the same average size $D = \Sigma wd/\Sigma w$.

(*a*), (*b*) and (*c*) represent three possible sizing tests which indicate the same average size of material, but (*c*), on account of the coarse material present, will appear coarser than either of the other two while (*a*) on account of the lack of fines, may appear coarser than *b*. Green (*loc. cit.*) gives the following equation from statistical mathematics for expressing the degree of uniformity as a coefficient, $U = \Delta x\sqrt{\frac{n}{2\Sigma v^2}}$ where Δx is the difference between two successive values on the X-axis (size-axis), made equal to unity for convenience in calculation; n is the total number of particles measured, and v is the difference in units of length between the measured diameter of a given particle or group of particles of substantially the same size and the average diameter of the whole number of particles n.

Thus in Table 7, columns 1 and 2 represent the results of a particle count on a slide at a magnification of 20,000 diameters. Average particle size as measured at 20,000 magnification is

$$D_{(\times 20,000)} = \frac{\Sigma nd}{\Sigma n} = \frac{2881}{276} = 10.44 \text{ mm.}$$

and $D = 0.522$ micron. Column 4 gives deviations, in millimeters, at 20,000 magnification, between the diameters of the particles in the corresponding size groups and the mean diameter (*i.e.*, 10.44 less the number in Column 1). Column 5 gives the squares of the

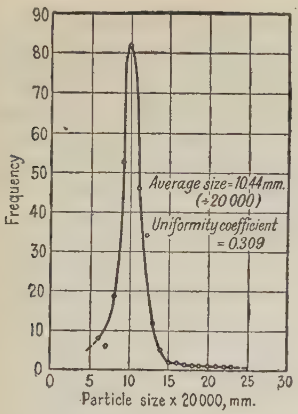

FIG. 13.—Frequency plot of data in Table 7.

numbers in Column 4 and Column 6 the product of columns 2 and 5. The total of Column 6 is Σv^2 of the formula. The total of column 2 is n.

Hence $$U = 1\sqrt{\frac{276}{2(1449)}} = 0.309.$$

The uniformity coefficient ranges between 0, representing complete lack of uniformity, or no two particles of the same size, and ∞, which indicates all particles of the same size. The significance of the number 0.309, given above, is indicated by Fig. 13, which is a frequency plot of the data given in Table 7.

6. Plotting sizing tests

Sizing tests are most easily compared and their significance, frequently, most readily understood from graphical representation. A number of different methods of plotting are shown in Fig. 14.

Direct plot is shown by curve 1. It has the advantage of familiarity but the disadvantage that the fine sizes are so crowded as to lose substantially all of their significance.

Cumulative direct plot is shown by curve 2. This curve reads directly at any point the

total oversize and undersize of a screen of given aperture, but has the same disadvantage of crowding in the fine sizes as the first curve.

Direct-logarithmic plot is illustrated by curve 3. Weights are plotted directly as ordinates, while the abscissas are the logarithms of the screen apertures. With screens whose apertures increase according to a constant ratio the logarithms of the apertures increase by a constant, hence the points corresponding to successive apertures are equally spaced along

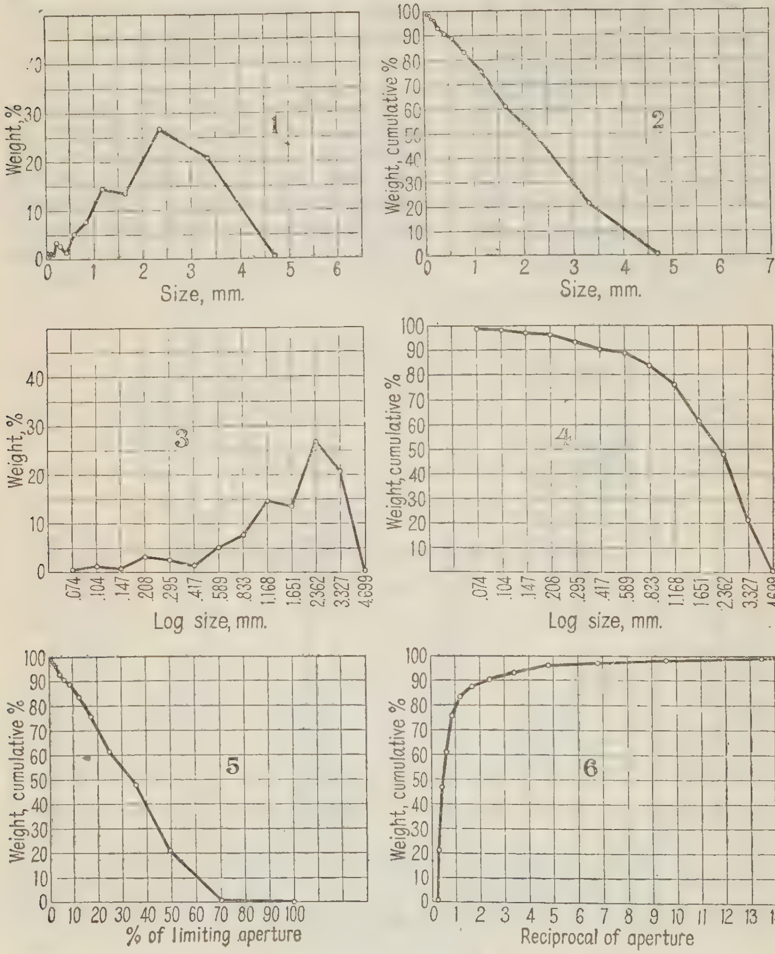

FIG. 14.—Methods of plotting sizing tests.

the horizontal axis of the plot. The curve necessarily terminates with the oversize of the finest screen because of lack of knowledge of the size of the finer material and the fact that the logarithm of zero is infinity. Comparing curves 1 and 3, it is to be seen that the latter spreads out the fine part of the curve and compresses the coarse and that it is much easier to read.

Cumulative-logarithmic plot is shown in curve 4. This has the advantages of both logarithmic and cumulative plots and is probably the most convenient for all ordinary presentations.

Percentage-aperture plot, curve 5, is particularly useful in comparing screen tests of products in different size ranges, as, for instance, the discharges of a jaw crusher and a ball mill. It reduces both ordinates and abscissas to the same scale and all curves have common end points.

Reciprocal plot, curve 6, reverses the crowding of the direct plot, and is useful to spread out the points when the amounts of fine material are small and of large material great, as in the case plotted. In the reverse condition, the curve becomes very crowded in the coarse end. This curve (and any of the other cumulative curves) may be turned over by making the ordinates percentages through rather than percentages on the particular screens. Gates adopts the reciprocal plot in estimating crushing efficiency. (See Sec. 4, Art. 27.)

Frequency curves are plots in which, ordinarily, the number of particles of a given size, or some function thereof, is plotted against the size itself or a function. The simplest form is that of number against size (Fig. 13). Martin, Blyth and Tongue (*Researches on the theory of fine grinding, Part I, British Portland Cement Research Association, Pamphlet No. 4, 1924*), plot increase in number of particles per unit increase in diameter ($\delta N/\delta X$) against diameter (x). In this curve any ordinate represents the rate of increase in number of particles at the corresponding value of particle diameter and the area between the curve, the X-axis and any two adjacent ordinates is numerically equal to the number of particles between the corresponding diameters.

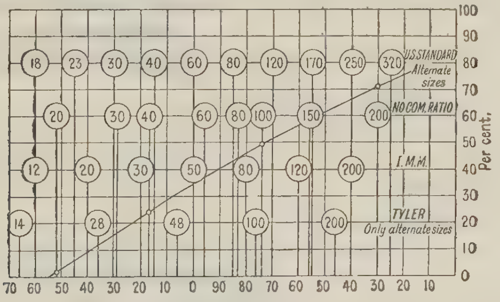

FIG. 15.—Multiple-scale plot.

Multiple-scale plot (Fig. 15) was suggested by Randall (57 *A* 481) to enable ready interpretation of screen tests by users of different testing sieves. Otherwise it is the usual cumulative-logarithmic plot.

Callow method for graphical representation of screen analyses and sizing-assay tests is shown in Figs. 16 and 17. (*92 J 884.*) Fig. 16 shows in block (1) a screen analysis of the product of a Dodge crusher; in block (2) the product of two sets of rolls taking the material plotted in (1); and (3) shows the product of a Chilean mill fed with the roll discharge. The dotted rectangles in block (2) represent the coarse material that was contained in the roll feed which has been broken, and the dot-hatched rectangles in block (2) represent additions to the line-hatched rectangles of block (1). Similarly the open rectangles in block (3) represent coarse sizes in block (2) that have disappeared, and the cross-hatching represent fines produced from this material. This is an excellent picture, simple to construct. Fig. 17 pictures the products and performance of an hydraulic classifier showing both distribution of sizes and of valuable content. This likewise presents clearly data hard to comprehend from an array of figures. Presentation of results of sizing-assay tests is shown in Tables 8 and 9 and Fig. 17.

a Assumed.

Recovery, from weights $= \frac{5.0616}{5.2718} = 96.0$

Ratio of concentration $= \frac{100}{7.488} = 13.3$

Recovery, from formula $= \frac{67.6(5.27-0.227)}{5.27(67.6-0.227)} = 96.0$

Ratio of concentration $= \frac{67.6-0.227}{5.27-0.227} = 13.4$

7. Sizing-sorting-assay test

A sizing-sorting-assay test affords an excellent basis for estimate of the recovery that it is possible to make on an ore and of the flow-sheet needed for treatment.

Procedure consists in making a sizing test of a sample ground to approximately the size at which clean mineral or clean tailing can be made, separating each of the grades by appropriate means into concentrate, middling and tailing, and weighing and assaying the several products. Hand picking can be used for separation down to the oversize on a 1-mm. screen and panning on the finer sizes, or, if the bulk of the finer sizes is large enough, they may be combined into a sample for a flotation test. Table 9 shows the results of a test thus run and the method of calculation.

Interpretation. Neglecting the middling, or, what amounts to the equivalent, assuming that if it were re-ground and put back into circuit, the grades of concentrate and tailing would not be affected, the recovery indicated in this test is 96 per cent. It is improbable, however, that middling assaying 14.42 per cent. Pb would yield as low a tailing as that yielded by the original ore, assaying 5.27 per cent. Pb, especially since in concentrating the original ore a relatively high-grade middling was made. If the assumption is made that the concentrate obtained by re-treating middling separately would average 65 per cent. Pb and the tailing 0.40 per cent., the recovery on middling would be 97.8 per cent. Such an assumption was justified in this test on the grounds that microscopic examination of the middling showed that substantially all mineral would be free at 100-mesh, that the concentrate obtained by floating 14-per cent. feed would be of somewhat higher grade than that from 5-per cent. feed, and that the assays of flotation tailings from the two feeds would be roughly in proportion to the feed assays. Such middling re-treatment would add 3.710 tons of concentrate containing 2.4095 tons of lead and 13.386 tons of tailing containing 0.0535 ton of lead. If any doubt exists as to the behavior of the middling on re-treatment, it should be actually ground and treated.

The test presented would indicate a flow-sheet in which the material should be crushed through 10-mm., screened on 2-mm., the oversize sent to jigs making finished concentrate and tailing, and middling for re-crushing; undersize to a classifier for de-sliming at 100-mesh; classifier sand to tables making finished concentrate and tailing, and a middling for re-crushing; classifier overflow to flotation, making finished concentrate and tailing. On account of the high grade of the middling, it would appear best to grind the combined middling directly to flotation size and treat it separately, but, if this proved unsatisfactory on test, the re-ground material could be returned into the de-sliming classifier. The table indicates the tonnages that would go to the different machines on first pass. The amount that the middling would add would depend on how finely it was ground and whether it was treated separately or thrown back into circuit.

8. Testing of machines

Crushing. The behavior of ore in both coarse and intermediate crushing and in grinding should be investigated, for the reason that the behavior of a rock when the work consists in breaking apart mineral aggregates, as in coarse and intermediate crushing, may be entirely different from its behavior when individual mineral grains are being broken down, as in grinding. The safest method of testing for capacity, barring actual trial on full mill scale, is to make parallel tests on a rock of known crushing characteristics and the unknown rock. These tests should be made in machines of the types used in mill treatment of the known rock and to be used in treatment of the unknown. Laboratory crushing tests that are to be used as a basis of mill installation are about 5 per cent. manipulation and 95 per cent. interpretation based on experience, in any case, and an experienced investigator with a few lumps of the unknown and some known rocks and a hammer and anvil can tell more than an inexperienced man with a most complete laboratory crushing equipment.

Classifier tests give information, not yielded by screen tests, as to the distribution of material to be expected in a gravity-concentration plant; and, in conjunction with screen tests, form a basis for prediction of the results to be expected from gravity-concentration treatment. Testing classifiers are also used to prepare material for concentration tests on shaking tables and the like. Elutriation tests (Art. 2) are classifier tests applied to sizing fine material, but these same tests, subjected to different interpretation, give useful information regarding gravity-concentration.

Beaker classification involves the same manipulation, in so far as separation into different grades is concerned, as the decantation method of sizing by elutriation. When applied to coarse material (0.5 mm. to say 2.5-mm.) the time required for settlement is so short that there is much overlapping of the grades and results are very different from those attainable in a rising-current classifier.

Sorting tubes are made in glass for both free-settling and hindered-settling classification.

A free-settling tube (designed by H. S. Munroe and manufactured by Eimer and Amend and by Emil Greiner, N. Y.) is shown in Fig. 18. The essential parts are sorting column (*C*) with feed inlets (*F*), vortex fitting (*D*), overflow tube (*B*), and feed and spigot flasks (*A*) and (*E*) respectively. Joints between flasks and apparatus are made with rubber tubing. The ends entering the flasks are expanded by means of brass thimbles of suitable diameter slipped inside the tubing. Joints between (*B–C*) and (*C–D*) are made tight by rubber tubing slipped over the lower ends of (*B*) and (*C*) respectively. The annular space between the lower end of (*B*) and constricted portion of (*C*) should be about ⅛ in. wide. The lower end of (*C*) should project about ½ in. below the bottom of the water inlet in (*D*). When set up, the tubes (*B*) and (*C*) should be clamped rigidly in vertical position in a ringstand which carries also two large rings near the top in which flasks (*A*) may hang. Flask (*E*) should rest on the base of the stand. There should be no kinks in the rubber tubes connecting the flasks. Tubes are made in several sizes, ranging from about 1- to 3-in. diameter of sorting column (*C*). The actual average internal diameter of (*C*) is obtained by measuring the water drawn from between spaced marks and applying equation $q = av$. (see Sec. 27, Art. 28). The quantity of water necessary to overflow in a given time in order to produce any required average rising velocity in (*C*) may then be calculated from the same equation and the desired current set by bringing the overflow to this figure.

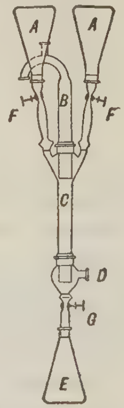

Fig. 18.—Munroe tube classifier.

Procedure. A weighed sample of ore is divided about equally between the two flasks (*A*). Enough water is added to moisten the ore thoroughly, with shaking; the bottles are then filled with water, and put into position for feeding, the cocks (*F*) being closed. The rubber tubes must be full of water both above and below (*F*), because an air bubble prevents proper discharge of ore. Having adjusted the flow of water up the column to the desired velocity, cocks (*F*) are slightly opened to allow ore to drop slowly. Light material will be carried over, while the heavier will fall through the rising current and into flask (*E*). When all ore is out of the upper flasks, a few minutes are allowed for the sorting column to clear partially, the current is then shut off and a little more time allowed for matter still in suspension to settle. Cock (*G*) is then closed, flask (*E*) removed, and its contents transferred to feed flasks (*A*). This last operation may be simplified by having at hand an extra flask (*E*) filled with water; when about half the ore has fallen into the first flask, it may be replaced by the second flask, after closing (*G*) temporarily. Two flasks (*E*) may then be put into the position first occupied by flasks (*A*). Current is now adjusted for the next faster velocity desired, and the operations repeated. While working with velocities up to, say, 20 mm. per second, it is well to catch the entire overflow, water and solids, in pails which may be set aside for a sufficient length of time to permit solids to settle perfectly; with the higher velocities, overflow may be led to pans in which solids will settle while water overflows. Solid matter carried over at each velocity is caught separately, dried, and weighed.

Hindered-settling tube (Fig. 19) consists of a glass tube (*A*) about 1-in. diameter and 30 in. long, drawn down at the lower end to smaller diameter, and provided with a side

tube (B) for water inlet. The ratio of the diameter of section (C) to that of section (A) for all-around work on feeds ranging from, say, 2-mm. maximum to 0.5-mm. maximum should be 1 : 2, but a ratio of 1 : 1.5 is better for the coarse separations and one of 1 : 3 or 4 for fine sizes, and a series of tubes is best for close work. The length of section (C) should be 3 to 4 in. Inlet (B) and the spigot should be about ¼-in. internal diameter. A galvanized-iron or sheet-copper funnel with side tube about ¾-in. diameter should be provided for feeding and collecting overflow, and a number of small-necked flasks for collecting spigot products. The joint between tube and flask is a rubber tube controlled by a stopcock.

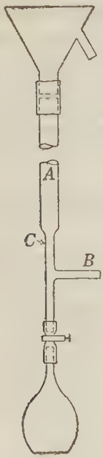

FIG. 19.—Hindered-settling tube.

Final settlement of any particle is determined by its ability to pass the constricted section (C), free-settling against a given current. Hence this is the important diameter and currents are set for section (C) by the methods described under "Free-settling tube" above.

Operation starts by filling the entire system with water, then setting the minimum current (about 5 mm. per sec.) and feeding material slowly into the funnel. The feed should be wet to prevent skin flotation and the best results will be obtained if the slimes are slowly decanted into the funnel several times before any of the sands are poured in, taking care that the rate of feeding slimy water is insufficient to make the rising current at the overflow level equal to or greater than that in section (C). Collect the slime in a pail and set aside. The water in the flask should be slime free; if not, re-feed the spigot product. Collect the spigot product. Set the current at the maximum rate, re-feed the first spigot product, run until only an occasional grain falls through section (C), then close the stopcock, collect the spigot product and replace the flask, full of water; slack off the current gradually until the next lower current is reached, open the stopcock, feed back any sand that overflowed in the preceding operation, and run as before until settling substantially ceases. Repeat with decreasing current velocities until the 5-mm. velocity is again reached. It is better to run at this current a second time, adding the overflow and material remaining in the teeter-chamber (A) to the first overflow. Dry and weigh the products.

Laboratory classifiers. Miniatures of mill-type classifiers (Sec. 6), are used. The most satisfactory miniatures are those of the tank type, either hindered-settling or free-settling. Fig. 20 shows a useful size, which has a capacity of about 1 kg. per min. Laboratory classifiers are much more con-

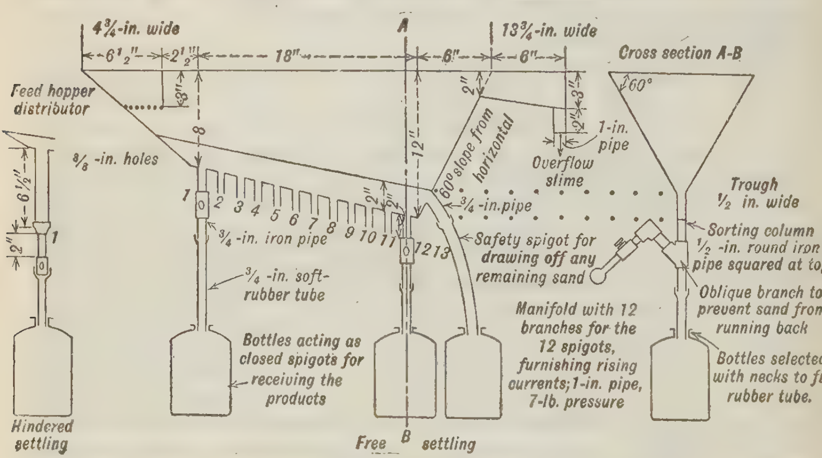

FIG. 20.—Laboratory classifier (*after Richards, 91 J 415*).

veniently operated with closed spigot, when possible, as it is then unnecessary to supply and dispose of large quantities of spigot water.

Interpretation of classifier tests. The weights of the products tell the tonnages of different grades for which concentrating machines must be provided. Assays of the combined products do not yield much information concerning probable mill performances, on account of the middling present; actual concentration tests should be made. Sizing the products on a series of screens will approximate the work of shaking tables, the finest sizes representing concentrate, the coarsest the tailing, and the intermediate middling. If the sized products are laid out on a ruled board in such a way that the abscissa of any grade is the number of the classifier spigot from which it came and its ordinate the screen size, an excellent picture of the work of the classifier is obtained. The best classification is represented by maximum spread on this board between the heaps of pure heavy mineral and pure gangue. The smaller the middling heaps, the heavier the loads that can be put on the following shaking tables and, of course, the size of the middling heaps indicates the tonnage that must be re-ground.

Settling ratio is the ratio of the average diameter of light-mineral grains to that of the heavy-mineral grains in a classified product. It may be calculated from the layout described in the preceding paragraph by sorting out the middling grains in the various heaps, assaying the residues for heavy mineral, and then calculating average sizes of the two kinds of grains in each spigot product. The larger the settling ratio the easier the work of the concentrator treating the product and the better the work of the classifier. *Richards* has determined the average free-settling ratio of quartz and galena as about 4 and the hindered-settling ratio slightly less than 7. These figures were obtained by careful laboratory work with artificial mixtures of the two minerals and making a large number of successive spigot products with small current differences. Excellent mill work will show not more than 2.5 and 4 respectively for these same minerals, on account of the smaller number of spigots, the interference by middling grains and overloading of the classifier.

Mechanical-classifier tests can be made properly only in machines of the type concerning which information is sought, and, since so many other factors than simple settlement in water are involved, *e.g.*, agitation of the rakes, time of draining sand, slope of draining surface, depth of pool, and the like, it is almost essential that the testing machine be a replica of the full-size machine in longitudinal section, at least. An experienced man can tell something by beaker tests on the settling rate of the sands in pulps of the same density as those that are to be classified, but at the best his conclusions from such work are little more than guesses.

Thickening. For methods of testing, see Sec. 16, Art. 10.

Testing for vacuum filtration. The usual apparatus is a small filtering surface reproducing essentially the type of surface to be investigated.

The Oliver Filter Co. uses a surface 0.5 sq. ft. in area made as follows: Make a piece of 1-in. board, square or round, exactly 0.5 sq. ft. in area. On one side tack parallel cleats, ¼ in. wide by ½ in. deep, spaced ¾ in. face to face with ends staggered so that there is a passage from every point on the riffled surface to the center point. Bore a hole for a ½-in. nipple at the center and set a short nipple in place from the back side, not projecting through the front surface. Paint the edges and bottom of the board thoroughly with No. 2 P.-and-B. paint or its equivalent. Cut a piece of stiff screen cloth the size of the board. Make a band of ¼-in. × 3½-in. or 4-in. strap iron with inside dimensions about 1/32 in. larger than the board. Cut a piece of canvas large enough to cover the cleated side and turn down over the edges of the board. Place the screen on the cleats with the canvas over it, then force down the strap-iron band so that the canvas makes a tight fit

at the edges. Connect the nipple to a receiver, which is best a wide-mouthed bottle with 2-hole cork, and connect the receiver with a vacuum pump.

A test leaf may also be made on a ½-in. pipe frame having the inner element of the bottom and side pipes perforated on 1-in. centers with ⅟₁₆-in. holes. The corners should be made with tees. Set ¼ × ½-in. wooden spacers in place by notching the ends and wedging them between top and bottom pipes. Sew on a canvas cover, making sure that the seam is tight. A good corner joint may be made by placing capped nipples in the outer ends of the tees and wrapping the canvas tightly with twine around the nipples, then painting the joints.

Procedure consists in immersing the leaf, canvas side down, in agitated pulp for different times until the time required to produce cake of maximum thickness is determined. Next dry the cake for a definite time, holding it with canvas side up. The time allowed for drying should be about the same as the time of submergence. Blow off the cake with water or air. Determine the percentage of moisture and dry weight of solids. These data give the capacity per half sq. ft. (with the wooden leaf) per revolution of a continuous filter. The time per revolution will depend on the periods required for forming cake and drying and the usual percentages of submergence. If the test showed 4 min. for forming cake and 4 min. for drying, and 40 per cent. submergence were used, the rate of revolution would be once in 10 min. If the leaf made 1 lb. of dry cake in 4 min., this is equivalent to 2 lb. per sq. ft. per revolution or 288 lb. per sq. ft. per 24 hr. If 10,000 lb. of solid is to be filtered per 24 hr. it will require 10,000 ÷ 288 = 34.7 sq. ft. The corresponding size of commercial filter can be chosen from this figure.

The Oliver Filter Co. makes a laboratory-size filter, with drum substantially 3 ft. diam. by 6 in. long. A single-leaf American filter, suitable for laboratory purposes can also be purchased. Miniature Moore and Butters plants are not difficult to construct. None of these, however, gives any more information than is obtainable from the test leaf.

9. Concentration tests

Hand-picking often affords valuable information, even when not considered a practicable method of treating a given ore under existing conditions. It may be applied to ore as fine as pea sizes; and, in the investigation of screened products, may be carried down to 1.0- or even 0.5-mm. with the aid of a hand glass or a low-power binocular microscope. For satisfactory hand-picking, ore should be sized between rather close limits, and should be clean; washing brings out the distinctive color or luster of some minerals.

Practicability of hand-picking on a commercial scale may be tested by attempting to make the following products, or so many of them as practicable: (*a*) Rich minerals, fit for market or for metallurgical treatment. These will include not only such minerals as galena, blende, chalcopyrite, etc., nearly or quite pure, but also rich mineral which possibly can be treated better by some metallurgical process than by mechanical means, for example copper carbonates, silver chloride, finely disseminated silver ore, etc. (*b*) Rich ore, with coarse disseminated mineral, for coarse crushing and jigging. (*c*) Fine-disseminated ore, usually poor, in which the useful mineral occurs in such small particles that exceedingly fine crushing will be necessary to liberate it. (*d*) Barren waste, or material that does not seem to be mineralized. Several classes may sometimes be made of this, according to gangue minerals or rocks in the ore, or when a difference of color, texture, or other characteristic indicates a possible difference in richness. Assays of these different classes of barren or seemingly barren material will show which may be thrown away, and which should be included with the ore for milling. Finally, inspection of the different products may show that some classes are present in small quantity only, and that perhaps several sorts may be combined without disadvantage.

Economy of hand-picking may be investigated by means of the formulas in Art. 22.

Hand jigging, for testing ore ranging in size from 10- to 2-mm., requires a tub of water and a few small screens of differing mesh. Before jigging, the ore should be sized fairly closely.

Put about 2 in. depth of sized ore into a sieve having a mesh fine enough to retain it, and jig for several minutes under the surface of the water, with a long, slow stroke for the coarser sizes, and a shorter and quicker stroke for finer sizes. A quick down stroke combined with a slower up stroke is best. Care should be taken to keep the sieve level and to avoid any horizontal or overturning movement of the mass of ore. When the tailing appears to be clean, scrape off the upper layer and replace it with an equal amount of ore, and resume jigging. Middling and concentrate should be allowed to accumulate unless the layers become too thick. The main object of this preliminary jigging is to produce tailing as poor as possible. When the whole sample has been treated, the accumulated concentrate is cleaned up by careful jigging, aided by handpicking if necessary. Skimmings from the cleaning operation should be added to the middling and the whole re-jigged and reduced to the smallest possible bulk by combining part with the concentrate and part with the tailing. Assays and microscopic examination of the products will indicate the maximum size at which jigging can profitably be begun.

A rather more elaborate hand jig, described by *Richards*, consists of a square frame about 12 × 12 × 6 in., made of heavy galvanized sheet (10 to 14 gage) turned over ⅛ × ¼-in. strap top and bottom for stiffness. Slats of the same strap to support the screen should be placed 2 or 3 in. above the bottom of the frame and the screen wired thereto. It is desirable to solder the joint between screen and sides, but this makes it difficult to change screens, if desired. Otherwise some leak at the edges must be tolerated. In operation the screen is hung from a helical spring at the desired height above the tub in which jigging is to be done and is then plunged and lifted in the usual manner.

Elmore (*18 CA 1132*) recommends a large hand jig for coal testing. For description and performance of such a jig on bituminous coal see Sec. 9, Art. 9.

Machine jigging. Experimental jigs for testing purposes, operated by hand or power, are made by manufacturers of commercial jigs; they are useful equipment for testing laboratories, but their results are no more illuminating than those obtained by hand jigging. All small-scale continuous jigs are subject to the disadvantage that the ratio of dead space along the sides to total sieve area is relatively large and that an undue amount of heavy grains travels along these dead sides into subsequent compartments or even into the tailing.

Pan. Gold pan. Miner's pan. These are different names for the same device. (See Sec. 8, Art. 8.) The pan has three principal uses, *viz.*: (1) to assay gold-bearing gravels in prospecting, and less frequently, to make a rough assay of crushed vein material for gold; (2) to work gold-bearing gravel on a small scale; (3) to make gravity-concentration tests on heavy-metal ores. The procedure differs according to the material being panned.

Method of gold panning is to take a pan load, submerge it, then work the material over carefully with the hands, rejecting large boulders that are free of adhering fines and clayey material, until all of the coarse material is removed and all clayey or cemented material is disintegrated. Next with the pan submerged or with the material in the pan submerged, holding the bottom substantially horizontal, subject the pan to a rotary motion of sufficient intensity to produce suspension of the solids. The heavy particles, having the faster settling rate in water, settle toward the bottom in the loose suspension and leave the surface metal-free. Now, with the pan above the water surface, tilt it slightly away from the operator and at the same time rock it from side to side. The resulting action of the water will tend to wash solid matter to the lower edge of the pan, and the amount of tilt and speed of rocking should be such that only the surface layers of particles are washed down into a "toe" at the lower rim. The toe is next washed off by alternately dipping and raising it through the water surface. These three operations are repeated in order until the amount of material remaining in the pan is small and con-

sists of heavy minerals and some fine light sand. Further separation can sometimes be made by moving the pan in such a way that a small amount of water therein will course around the trough formed by the intersection of side and bottom. Such treatment strings out the material with the lightest sand ahead and the heavy material bringing up the rear, and it is often possible, by careful manipulation to thus work out a further quantity of light sand. This treatment will usually, also, bring any gold to light at the tail of the fan of material. Final separation of gold from the heavy minerals is made by amalgamation or by drying, separating magnetite with a magnet and the balance of the waste by blowing.

Testing an ore differs from the above procedure in that (1) the ore must first be ground to a size that will free a goodly part of the valuable mineral, (2) the weight of the sample taken can be and should be determined, (3) stratification requires more careful and prolonged swirling and (4) the thickness of the surface layer removed in each cycle must be thinner. The operation should be conducted over a tub in which the first tailing is collected for re-panning. Concentrate will always contain considerable gangue and the tailing some valuable mineral. In the hands of an experienced operator the recovery will be about the same as is possible in mill work, but mill concentrate, especially the coarser sizes, will assay higher.

An experienced panner, working steadily, can treat about 100 pans of uncemented gold gravel per 10-hr. day and proportionately less according to the degree of cementation. The same man cannot run down more than one-third as many samples of galena-quartz ore and even less of ores in which the difference in specific gravities of heavy and light minerals is smaller.

Vanning is somewhat similar to panning but not applicable to as coarse material (0.5-mm max.) and limited to much smaller quantities, *e.g.*, about 50 gm. Vanning plaque is made of enameled iron in the shape of a spherical segment, about 12-in. diameter and ¾ in. deep at the center. The Cornish vanning shovel is essentially a plaque mounted on a handle about 24 in. long. A batea or a large watch glass may be used as a substitute for a plaque.

Procedure. The sample, if dry, is first wet down carefully, taking pains to prevent skin flotation. The wet pulp is then swirled vigorously to get the slime in suspension, next more slowly to let all granular material settle, after which slime is decanted. This operation is repeated until all slime is removed. Thereafter the elements of a vanning operation are three-fold, *viz.*: (1) stratification as in panning, (2) throwing the lower stratum (heavy concentrate) to one edge of the plaque while the upper stratum remains nearer the center, and (3) washing the upper stratum to and over the side of the plaque away from the head of concentrate. Stratification is effected by simple swirling of the pulp by a horizontal rotary motion of the plaque. In order to throw up the head of concentrate the plaque, held on opposite edges in the two hands, is moved as in swirling with one hand while the other describes, at each revolution, a small vertical circle, say 1 in. in diameter, in a clockwise direction, moving downward more rapidly than upward. The swirling motion keeps the upper stratum in suspension while the lower stratum hugs the surface, hence as the plaque moves away from the operator the heavy material moves with it, but it moves from under the gangue in suspension. The rapid down stroke drops the plaque from under the heavy mineral and when the latter again reaches the plaque surface it rests at a point further away from the operator than before. The head of concentrate is, in this wise, made to travel up onto the edge of the plaque away from the operator while the lighter sands remain nearer the center. Horizontal separation is continued by imparting a gentle swirl that moves the water only, and giving the plaque a smart shake at the time that the swirling water is traveling away from the head of concentrate. In this way the sand is washed down slope toward the operator by film-sizing action (Sec. 8, Art. 14). Some operators manipulate the second phase of the separation so as to draw the head toward them and then wash tailing off the far side. Others throw up the head by simple swirling with one hand and jarring the side of the plaque at each revolution against the heel of the other hand. In the latter case the mechanics of the horizontal separation is different, but the result is the same. This method is easier to learn than the other, but is very tiring, if much vanning is to be done. With a vanning shovel the head is thrown up by a slight side fillip on the backward stroke of the swirl.

Principal uses of the vanning plaque are in examination of finely-ground mill products, and in assaying, particularly in CORNWALL to assay tin ore. Vanning has the advantage over a chemical assay that it gives some idea of the amount of middling grains and of the size of the free-mineral grains. It is now being superseded in Cornwall tin assaying by chemical methods, but for

many years it was the principal, if not the only method of assaying used in that district. It had, of course, the apparent advantage that it indicated only recoverable tin, *i.e.*, free cassiterite of a size that could be won by gravity concentration, and this was all that most millmen were interested in, but careful experiment showed that skilful operators reported discrepant results on the same sample and that none, of course, checked the chemical assay.

Shaking tables. Mine and Smelter Supply Co. manufactures a Wilfley table with 12 × 30-in. deck; Deister Machine Co. makes the Plat-O-table in quarter size, 3 × 7-ft. deck, and Deister Concentrator Co., the Deister-Overstrom table also quarter size, with 3½ × 7½-ft. deck. Interchangeable decks for coarse and fine feeds are obtainable with all three tables. The little Wilfley table is the most convenient for small-scale tests, of course, as it can be made to give an excellent result on a sample as small as 1 lb., but larger tables are better when a considerable amount of material is to be run. The difference in performance between the different makes of table on most ores is so small that results on any one can safely be used as indicative of results to be expected on any of the others. The work of the small tables is substantially the same as that of full-size machines. Tables should be set up with variable-speed drive and with provision for making more than the usual number of splits of the discharge. Provision should also be made for collecting all of the various products separately. Much information can be gained by microscopic study of products in addition to the assays. Relative capacities of small and full-scale tables is best established by a series of tests on the two machines with the same feed, but a fair approximation can be made by multiplying the capacity of the small table by the ratio of deck areas. The capacity of the large table will usually exceed somewhat the figure thus obtained.

Vanners and buddles. Performances can be approximated by use of a shallow trough, 3 or 4 ft. long and 8 to 12 in. wide, with a bottom of planed board, ground glass, linoleum, or the like, resting on adjustable supports.

A more elaborate form (designed by H. S. Munroe and made by Eimer & Amend, N. Y., Fig. 21) consists of a strong metal frame about 5 ft. long in which flat plates of pine, maple,

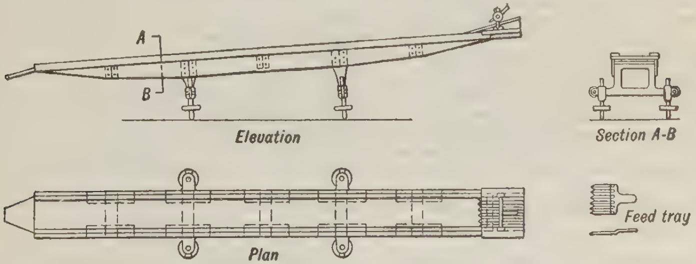

Fig. 21.—Laboratory film-sizing table.

slate, glass or other material may be secured. These plates are held by springs, and the joint between frame and plate is made tight by inserting a strand of cotton wicking. Inclination of the table is adjusted by leveling screws, and amount of water by a dial cock. These adjustments are controlled by testing a small sample of the material to be treated, and giving to the table such inclination and amount of water as will effect the desired separation. A portion of wet ore is gradually pushed under water jets at the head of table, care being taken not to feed too fast. After 2 or 3 min. the feed is interrupted and material on the table is washed 2 or 3 min. until most of the tailing has run off. The tailing pan is then removed, and middling and concentrate are successively washed off with a jet of water, into separate pans. The operation is then repeated with

another portion of ore, first replacing the tailing pan. By making at first a large proportion of middling, clean concentrate and low-grade tailing may be secured. Next wash the middling by itself, varying the amount of water and inclination of table to suit. Collect concentrate, middling, if any, and tailing; dry, weigh, and assay.

The performance of the laboratory table gives no direct information as to the capacity of mill-size machines, except in so far as it shows separation to be difficult or the reverse. See also *27 A 76*.

10. Heavy solutions

This method of separation is much more useful in the laboratory than in the mill for the reason that the cost of supplies is a minor item. A complete series of solutions ranging in specific gravity from well under 1.0 to about 3.5 may be made or bought and intermediate densities of any desired value may be obtained by diluting or mixing the proper solutions in the proper proportions. *Johannsen* describes in detail the preparation and use of these liquids. The following abridged descriptions cover the more common.

Sonstadt (Thoulet) solution is an aqueous solution of potassium mercuric iodide. It is made by dissolving 270 gm. of mercuric iodide (HgI_2) and 230 gm. potassium iodide in 80 cc. of cold distilled water, then evaporating on a water bath until crystallization just begins. On cooling, the specific gravity is 3.196. The solution may be diluted to any desired density with water and re-concentrated on a water bath. In warm, humid weather the density drops materially. Dense solution filters readily. Metals and organic matter decompose it; it is highly poisonous and corrodes the skin. If iodine separates, the solution may be restored by re-concentrating with the addition of a small amount of metallic mercury.

Klein solution is an aqueous solution of cadmium borotungstate

$$(2\ Cd(OH)_2 \cdot B_2O_3 \cdot 9\ WO_3 \cdot 16\ H_2O).$$

The concentrated solution, sp. gr. 3.36, is obtained by evaporation of a more dilute solution on a water bath, and any lesser specific gravities are obtained by dilution. This solution is not very poisonous, it filters readily and is not decomposed by filter paper nor organic dust and does not affect the skin. It may be used for years. It is decomposed by iron, lead and zinc and reacts with carbonates. When the latter are suspected the pulp should be washed with dilute acetic acid.

Rohrbach solution, sp. gr. > 3.55, is an aqueous solution of barium-mercuric iodide made by heating 100 parts barium iodide and 130 parts mercuric iodide and 20 parts distilled water on an oil bath at 150 to 200° C. The solution is non-filterable, highly poisonous, very hygroscopic, and difficult to dilute. This is best done by slowly adding a dilute solution of the same substance. It is not decomposed by carbonates, but the material to be separated must be absolutely dry. Separated solids should be washed with a very dilute solution of potassium iodide. Separations should be made in closed vessels.

Methylene iodide (CH_2I_2) is a very mobile, easily handled separating fluid whose specific gravity varies from 3.3485 at 5° C. (freezing point) to 3.2890 at 33° C. It is diluted with benzol, carbon bisulphide or chloroform, but, while it is unchanged in the atmosphere, if concentrated, the specific gravity rises rather rapidly by evaporation of the dilutant. It filters readily and is unaffected by the paper. It does not attack the skin and is not decomposed by metals or carbonates but is by sulphur. It is readily washed away from solids by benzol.

Retger's solutions are a variety of mixtures of higher specific gravities than those already described. They are uncertain and difficult to make and handle.

Procedure is simple. It consists in placing the powdered mixture in a suitable solution and diluting until the desired constituent or constituents sink, then separating the floating from the sunken portion, separating the solution from each portion, and washing the solid free of solution. Johannsen describes a large number of separating vessels, chiefly applicable to close separations of a number of constituents. Tomlinson (*52 A 852*) describes a method of mineralogical analysis of sand that is adaptable to most ore-dressing work.

Preparation. The material to be investigated should first be carefully sized and the weights of the grades recorded. Apart from the information thus obtained, sized products are more accurately separated in heavy solutions than unsized.

Solution. Sonstadt solution is the easiest to make and handle. The concentrated solution will drop all sulphide minerals and rich middling while holding up most gangue minerals and lean middling. If separation of the gangue minerals is desirable, a density of 2.9 will drop practically all of the dark silicates, 2.7 will drop calcite and dolomite and float quartz, and 2.59 will drop quartz and float feldspar, although this separation will not be as close as the others.

Separation is most readily made in a Harada tube, which is a special separatory funnel (see *Johannsen*), but it may be made satisfactorily in beakers. Use a beaker whose capacity is about six times the volume of the lot of sand to be separated, dry it thoroughly, add the solution (two volumes of solution of proper density to one of sand), stir in the sand slowly, allow it to stratify, skim the bulk of the float with a glass or platinum spoon, then pour off some of the liquid with the balance of the floating material. Some floating sand will usually stick to the beaker in pouring off. If so, push it away on the sides of the beaker with a glass rod until sufficient clear space is available to pour out the settled solid with the balance of the liquid without contamination. Wash the separates repeatedly with water to remove and save solution. If several grades are to be made, it may be well to separate first at an intermediate density and re-work these rough grades at higher and lower densities respectively, making sure that they are thoroughly dry before re-treatment.

Coal analysis is the most important application of heavy-solution testing. Any of the solutions and the method described may be used, but the volume of sample is usually so large and the coal so light that special methods and cheaper solutions are usually employed.

Sink-and-float test for coal

The heavy-solution method is particularly suitable for coal analysis for the reason that with any given coal the ash content has a direct and substantially constant relation to the specific gravity of the coal, so that once an allowable ash content for such a coal has been set and the specific gravity of the highest-ash particle therein has been determined, a solution of that specific gravity will float good coal and everything that sinks will be of higher ash content than the permissible limit. Table 10 shows a sink-and-float test on a low-grade bituminous coal. The specific gravities of the usual impurities associated with coal compared with those of coal are shown in Table 11. It is apparent that a heavy solution of specific gravity between 1.50 and 1.65 would put all of the distinct impurities and some of the bone coal into the "sink" fraction. With different coals the ash content and the specific gravity have distinctly different relations, as is shown in Table 12. Hence, as above intimated, it is necessary to establish the ash-specific-gravity relation and the critical specific gravity for each coal.

Table 10. Results of a sink-and-float test on a bituminous coal. (*After McMillan and Bird*)

Specific gravity	Weight, per cent.	Ash, per cent.	Cumulative per cent.

10	1.43	26.25	....	....

a There is no necessary relation between the clean coal and the refuse in any given horizontal line; they may not be from the same coal.

Solutions. The usual heavy solution is a water solution of zinc chloride. This gives a maximum density of about 1.80 at ordinary temperature. Calcium chloride is sometimes used. Sinnat and Mitton (*67 IME 494*) used mixtures of carbon tetrachloride (sp. gr. 1.582 at 21° C.) and toluene (sp. gr. 0.8708). For sizes finer than 20-mesh McMillen and Bird (*Bul. 28, UW Ser. 61*) used a mixture of carbon tetrachloride with benzene or bromoform, according to whether densities below or above 1.58 were desired.

In changing solution strengths, the volume, x, of old liquid to be withdrawn and new solution to be added may be calculated by the equation, $x = (O - N)V/(O - A)$, where V is the volume of testing solution before and after the change in density, and O, N and A are the specific gravities of the old, new, and added solutions respectively. If the testing tank is of constant cross-section, x and V may be expressed in uuits of depth of liquid in the tank, if there is no appreciable amount of solid material in the tank.

Size of sample depends on the size of the particles. McMillan and Bird (*loc. cit.*) recommend 500 lb. for egg-size coal, $-3 + 1\frac{1}{2}$-in.; 250 lb. for nut-size, $-1\frac{1}{2} + \frac{3}{4}$-in.; 125 lb. for pea, $-\frac{3}{4} + \frac{3}{8}$-in.; 50 lb. for buckwheat, $-\frac{3}{8} + \frac{3}{16}$-in.; 25 lb. for birdseye, $-\frac{3}{16}$-in. + 20-mesh; and 0.5 lb. for -20-mesh. (See also Sec. 2, Art. 12.)

Apparatus. The essential elements of the apparatus for making tests conveniently are a large-enough container and means for removing the sink and float fractions separately.

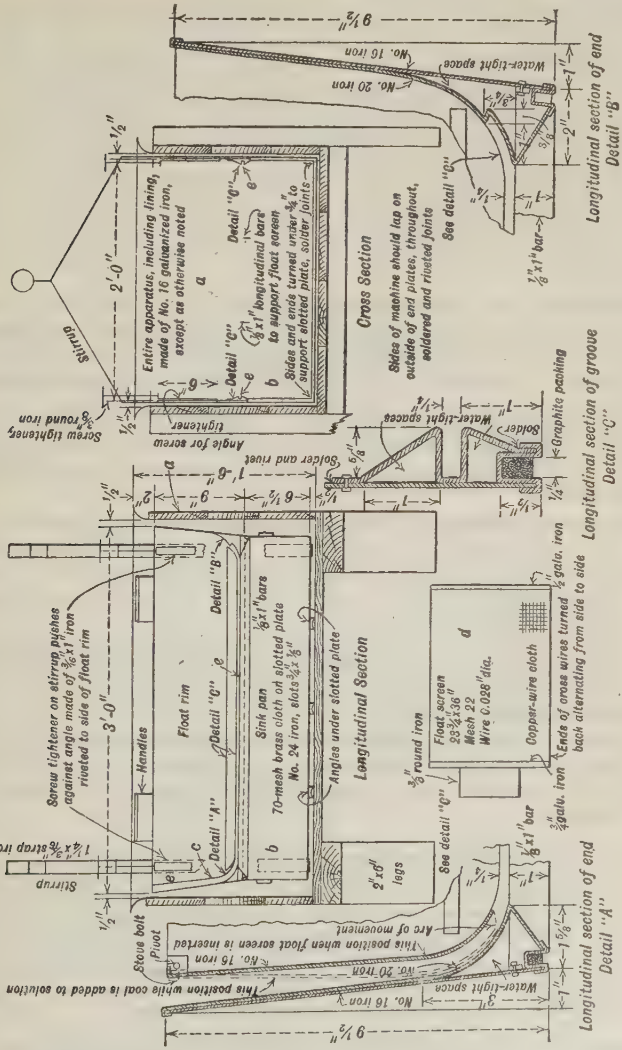

FIG. 22.—Apparatus for sink-and-float testing of coal.

Fig. 22 represents an apparatus for coarse sizes developed by the U. S. Bur. of Mines. It consists essentially of a wood or zinc-lined tank (*a*) and two perforated-bottom containers for removing the separated fractions. The sink pan (*b*) rests on the bottom of the tank and has a permanent perforated bottom and handles at the end. The float rim (*c*) rests on the upper edge of the sink pan. As set into place for a test it is merely a 4-sided rim

extending the sides of the sink pan above the surface of the liquid in the tank. After the charge has separated into sink and float fractions, a flexible screen (*d*) is slid down through and along the groove (*e, e, e*) in the float rim until it forms a perforated divider between the fractions and a support on which to lift out the float fraction when the float rim is removed. Details of construction are shown in the figure.

Procedure, especially when the feed contains impurities that disintegrate in water, is to start with the heaviest solution (1.70 sp. gr. for bituminous coals and 1.80 for anthracite will float all material of any value). The sample is shoveled into the assembled apparatus, float being skimmed as necessary to maintain the layer of float at not more than three particles deep. It is necessary to make certain, before any material is skimmed, that the specific gravity of the solution is exactly that or less than that at which separation is intended. Float should be stirred before skimming to prevent removal of entangled sink material. When all of the sample is in, the specific gravity of the solution should be brought to exactly the desired figure (using an accurate hydrometer for testing), the sink should be stirred to free any entangled float, and then the screen inserted into the float rim (Fig. 22) and the latter lifted out and placed on a suitable draining board arranged to collect drippings. The sink should then be removed, drained, washed free of heavy liquid and dried. Next reassemble the apparatus, dilute the solution to the next lower separating density, and re-treat the preceding float. Repeat until the desired number of cuts has been made.

Fine material. For material finer than 20-mesh a two-liter bottle makes a good separating container and carbon tetrachloride with benzene or bromoform good heavy solutions. Float material may be drawn into a two-liter vacuum flask by means of a glass tube. Separating solutions must be maintained at constant temperature in order to maintain constant specific gravity. The sample should be 200 gm. of air-dried (105° C.) coal which has been thoroughly wetted before separation. Twenty-four hours may be required for complete separation. The specific gravity of the solution must not be adjusted during a given separation.

Testing coal to determine a method of treatment involves the same principles as ore testing for the same purpose. The testing campaign should include sink-and-float tests, with ash and sulphur determinations; a sizing test with sink-and-float tests of the sizes will yield valuable information; and the microscope should be used freely.

The sink-and-float test on the whole feed will tell what yield and ash content of washed coal are to be expected; it will give information concerning the composition of the washed product and as to the possibility of taking an intermediate product for mine-plant fuel.

The sizing test with sink-and-float tests on the grades tells the size to which crushing must be carried to free the economic maximum of waste. The same information may be obtained by crushing different samples to different sizes and testing these.

Tables 13 and 14 present the results of two such tests on a coking coal. Table 13 indicates that further crushing from 1-in. to ⅜- freed some slate and distributed it principally in the coarser sizes of the − ⅜-in. product. The effect is more clearly shown in Table 14. There is more low-ash material and more free slate in the finer product. On the other hand, for a yield of, say, 90 per cent. (see Table 14), the 1-in. crushing gives a clean product containing about 7.3 per cent. ash against 6.5 per cent. in the − ⅜-in. product and the probability is that in actual washing the difficulties due to treating the finer product would prevent realization of this difference in the washery product and that the improvement in result, if any, would not pay for the increased treatment cost.

In general, to estimate from float-and-sink tests the amount of sulphur to be expected in washed coal, multiply the percentage of sulphur in the float by 0.9.

Microscopic examination will give an idea of the mode of occurrence of the ash and the possibilities of concentration (washing).

For methods of ash and sulphur determination see: *Methods of analyzing coal and coke*, F. M. Stanton and A. C. Fieldner, *TP 8, USBM*; *Standard methods of laboratory sampling and analysis of coal, A.S.T.M. Standards, 1921, p. 760.*

Following the small-scale tests, washing tests should next be made on a large hand jig (see Sec. 9, Art. 9) or better yet on a full-sized coal jig. These tests should be made at the mine, where there is sufficient material readily available for an exhaustive testing campaign and on a scale sufficiently large, in the case of a coking coal, to yield tonnage for full-scale coking tests. From these data a flow-sheet can be laid out intelligently.

It will generally be found in these tests that practically everything of less than 1.50 sp. gr. will go into the washed coal and everything heavier than 1.75 into the reject. The distribution of the material intermediate in specific gravity will depend on the type of washer (concentrator) and the way in which it is run. Tank, trough and tubular washers, unless run with the greatest care and not overloaded, will put much of this material into the cleaned coal. Jigs, unless badly overloaded or operating on too large a range of sizes can be made to deliver the bulk of this bony material either into the clean coal or

the refuse, especially if the jig is of more than one compartment or two jigs are run in series. Shaking tables will make a good separation if a middling product can be shaken out, otherwise the bone will distribute between both products. Except in the case of machines treating fine feeds the refuse should not contain more than 5 per cent. of clean coal and this should be well less than 1 per cent. of the feed to the machine.

Delameter (*22 CA 751*) gives, in considerable detail, the results of an elaborate series of tests to determine whether it was necessary or best to wash all of the coal and, if not, at what size it was best to split, jigging oversize and mixing the washed product back with the unwashed screenings. The results are summarized in Fig. 23. Plot *A* shows sizing-

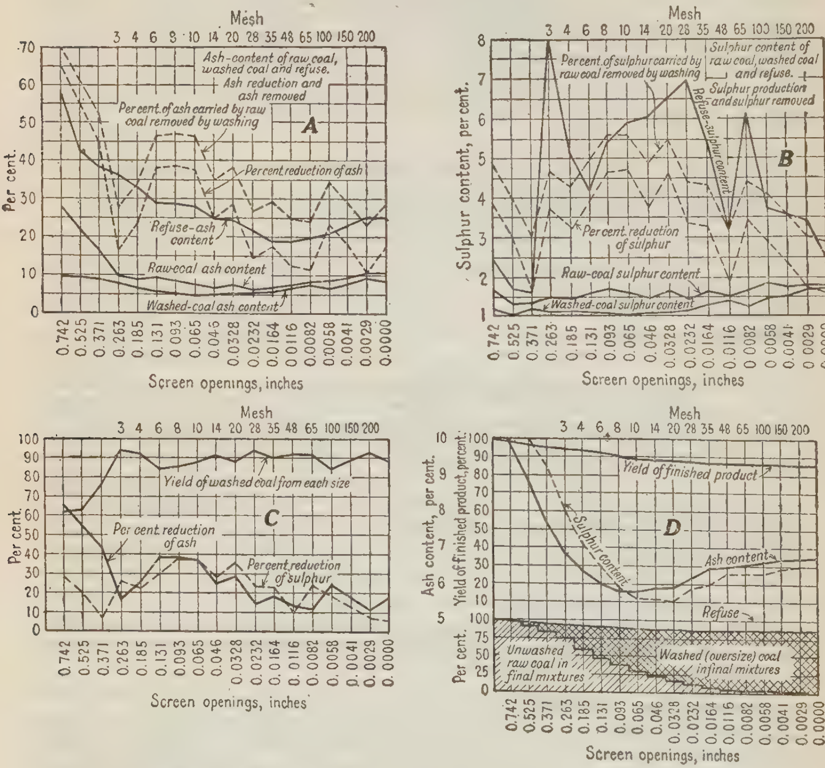

FIG. 23.—Results of washing tests on bituminous screenings (*after Delameter*).

assay tests giving the ash content of raw coal, washed coal and refuse in a representative run. *B* gives the same data for sulphur. *C* shows the relation between yield and ash and sulphur reduction. *D* shows the yield and the ash and sulphur content of the cleaned coal, assuming the raw coal (− 1.05-in.) sized on any given screen (abscissa), the oversize jigged and the unwashed undersize added to the washed oversize to make the final cleaned coal. According to this curve, if all of the − 1.05-in. coal is washed, the yield will be about 87 per cent., the ash content of the cleaned coal 6.7 per cent. and the sulphur content 1.15 per cent. On the other hand, by sizing on an 8-mesh screen and washing only the oversize, re-mixing unwashed undersize with the washed oversize, the yield would be 90 per cent., the ash content of the washed coal 5.8 per cent. and the sulphur 1.09 per cent. At this mine 1.2 per cent. of sulphur was allowable, which permitted the

separation to be made at 4-mesh, at which size the yield was between 93 and 94 per cent. and the ash content of the cleaned coal about 6.4 per cent. This is a rather surprising result in view of the fact that the fine sizes of the raw coal contained the most sulphur (see *B*) and not the least ash (see *A*).

Washery control. Sink-and-float tests form an excellent rule for judging the efficiency of the operation of any machine or operation. The feed and products of the machine or operation should be tested in a solution of PERMISSIBLE DENSITY, *i.e.*, the density pre-determined to yield a washed coal of allowable ash content. From the results, efficiency may be calculated by any of the methods of Art. 28. For this kind of work it is unnecessary to dry the sink-and-float fractions before weighing, since the results will be sufficiently accurate using moist weights, and the time saved is considerable.

11. Flotation

Testing flotation processes is more difficult than testing other methods of concentration for the reason that the controlling conditions are less well recognized and the phenomena, which are physico-chemical rather than strictly physical, are sometimes vastly affected by apparently slight changes in these controlling conditions. Minute amounts of foreign substances may exert enormous effect, temperature is of considerable importance, the character of the water and, in some cases, even, the material of which the machine is made may affect performance. It is particularly necessary, therefore, to make a careful, detailed record, *during the course of the test*, of every feature connected with the test, making special note of all conditions surrounding any unusual performance.

The conditions affecting froth flotation are: (1) the mineralogical character of the feed, the size and method of grinding; (2) the character and quantity of flotation agents; (3) the pulp thickness and the amount and character of suspended and dissolved organic and inorganic material in the water; (4) the kind of process; (5) the kind of apparatus; (6) the degree of agitation; (7) the duration of treatment; (8) the temperature.

The indicia of effect are copiousness and consistency of froth; size of bubbles; amount and kind of solid load; the degree of dispersion of the pulp; rate of flotation, and finally the recovery and grade of concentrate.

Record form. The record of tests is best kept on a printed or mimeographed form that will act as a check list for the information to be obtained. This form should include the following items: TEST; number, date, purpose. FEED; origin, history, approximate mineral composition, sizing test, assay, record of microscopic examination, weight. MACHINE; type, size. WATER; source, litmus reaction. REAGENTS; description, quantity, order of adding, method of mixing, duration of mixing period, pulp density and temperature and litmus reaction during mixing. ROUGHING (or concentrate-making) period; duration, degree of agitation or aeration; pulp density, temperature and litmus reaction; character of froth, including texture, size of bubbles at water line and overflow level, elastic or effervescent nature of bubbles, viscosity or tenderness of froth, persistence, mineralization, litmus reaction, percentage of solids. CLEANER (or middling-making) period: Collect the same data as in roughing period. ROUGHER TAILING; litmus reaction, degree of dispersion; rate of settling, temperature, density. CLEANER TAILING; the same. ASSAYS. METALLURGICAL RESULTS. NAME OF OPERATOR. It is well to define the meaning of certain of the descriptive terms. The following definitions are useful. TEXTURE: Examine the "grain" of the froth. Mental reference to the grain of a rock or other non-homogeneous mixture will help in choosing the proper descriptive term. The texture should be described as "even" when all, or a great majority of the bubbles in a given horizontal line against the glass walls of the testing machine are of approximately the same size; "uneven" describes the reverse condition. Texture should be described as "fine" when the average diameter of bubbles at ½ in. above the water line is ⅛ in. or less. CHARACTER OF BUBBLES: *Elastic* indicates that the surface bubbles in the machine are relatively

persistent, that they may be deformed considerably without bursting, and that they elongate markedly in overflowing. *Effervescent* bubbles burst with considerable violence soon after reaching the surface layer. QUALITY is *viscous* when patches of the froth act almost as solids and the body of froth is sluggish in the cell; *tender* describes a homogeneous, fluffy froth that is active on the surface of the cell. MINERALIZATION is best determined by examining a film under a low-power (15 to 20 ×) microscope. *Heavy* describes the mineralization of a film that is crowded with solid, opaque, and that draws back slowly when punctured; *light* describes the complete reverse of this condition; *medium* describes a wide intermediate range. *Gangue* and *sulphide* indicate the predominating mineral in the solid load. PERSISTENCE. *High* describes the fact that overflowed froth shows little or no tendency to break down after standing 10 min.; *medium* describes a froth that breaks down spontaneously to about one-half its volume in 10 min. after removal; *low* describes substantially complete breaking down in 10 min. SETTLING RATE of tailing gives a pseudo-quantitative measure of degree of dispersion. It is best measured by allowing one minute to elapse after flotation ceases, then measuring the distance from a fixed point on the side of the machine to the top of the subsiding solids and again measuring after the lapse of one minute. An experienced operator can keep this record with very little more time than is required for the test itself; it serves as a guide to methodical and careful observation; and makes it possible for persons who have not seen the test to visualize the performance and interpret the results.

Machines

For crude, small-scale tests by the agitation-froth process, agitation may be effected by hand shaking in a test-tube or a wide-mouth bottle, or in a milk-shake machine, and froth separated with a spoon or by overflow by introducing sufficient water through a tube below the pulp level. A separatory funnel may be used for shaking (*111 P 122*) in which case the tailing can be drawn off from the bottom without dilution. A motor-driven bar mixer with a small square glass jar is an excellent device for preliminary tests.

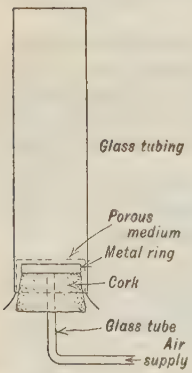

FIG. 24.—Tube for pneumatic flotation tests.

Preliminary pneumatic-process tests may be made with a small machine made of a short length (8 to 12 in.) of 1.5- or 2-in. tubing, a 1-hole rubber cork and a piece of finely porous cloth, arranged as shown in Fig. 24. Air may be supplied by a bicycle or automobile pump or at the worst an ordinary atomizer or syringe bulb. It is well to have a receiver made, say, of a 2-liter acid bottle, between the pump and cell, arranged so that the air supply to the cell can be regulated by means of a pinchcock.

These preliminary tests will be valuable principally to determine amenability and, perhaps, to give some idea of the grade of concentrate that can be made. They will not yield good recoveries.

The most convenient machines for laboratory work are single-cell models of mill machines taking charges of 500 to 1500 gm. of solid with provision for froth overflow and arranged for pulp circulation. Such machines yield results that are, in most cases, directly comparable to mill operations.

Parsons (*Bul 617, Canada Dept. of Mines, Mines Branch, 1923*) recommends that for differential-flotation tests a continuous-flow testing unit, consisting of a ball mill in series with the flotation machines, be used. He says that batch work gives better results than can be obtained in mill operation.

Janney mechanical machine (Fig. 25) is a miniature copy of one cell of the mill machine, differing therefrom in that the volume and area of the spitzkasten (*c*) are somewhat less in proportion to the size of the agitating compart-

ment (a) than in the larger machine and that the bottom of the spitzkasten of the laboratory machine is higher than the bottom of the agitating compartment, while the reverse is true of the mill cell. Pulp circulation is, of course,

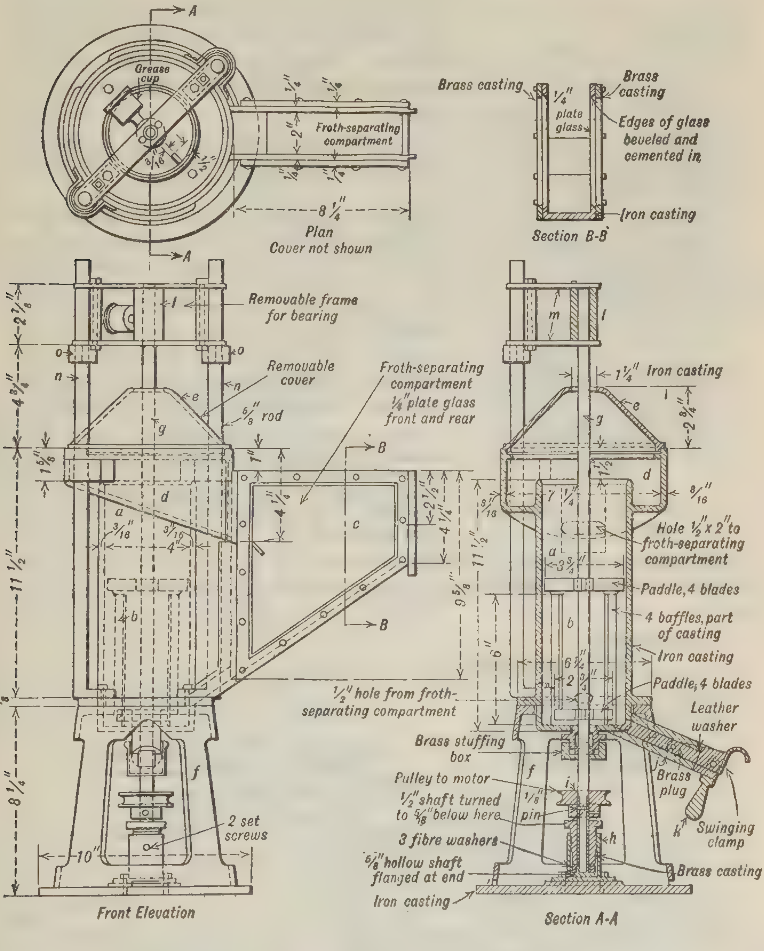

FIG. 25.—Janney laboratory flotation machine.

restricted to the one agitating compartment and one spitzkasten. The machine is made of cast iron or aluminum. A suspended impeller shaft, ¾-in. diameter, carried on roller bearings, is better than the under-driven type pictured.

A ¼-hp. motor capable of sufficient speed variation to give a range of agitator speeds

between 500 and 2400 r.p.m. should be provided. The ore charge for a pulp containing 20 to 25 per cent. solids is 500 to 600 gm.

Minerals Separation machine. A one-compartment model of the mill cell arranged for continuous pulp circulation is built by the Denver Fire-Clay Co., Denver, Col., under the name of Case laboratory machine. The form shown in Fig. 26 is just as satisfactory and is easily built in any mine shop.

A ¼-hp. motor giving the agitator a speed range from 800 to 2000 r.p.m. is desirable. The machine shown takes an ore charge of 750 gm.

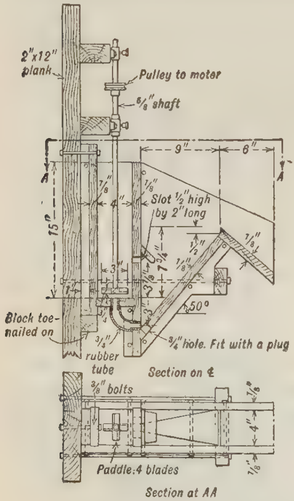

Fig. 26.—M. S. laboratory flotation machine.

Callow machine. General Engineering Co., Salt Lake City, Utah, makes a two-cell laboratory unit consisting of a rougher, 2 × 15 in., a cleaner, 2 × 7 in., a Pachuca tank for mixing, and an air-lift for circulating cleaner tailing back to the head of the rougher. The apparatus requires provision for 11 cu. ft. of free air per min. at about 5 lb. pressure. The ore charge is 1000 to 2000 gm.

The pneumatic machine shown in Fig. 27 can be built in any good mine shop. It can be arranged either for continuous or batch treatment, according to the position of the tailing-discharge slide. The ore charge for a pulp containing 20 to 25 per cent. solids is 1500 gm.

Sub-aeration machine (Fig. 28) is probably the most flexible of the laboratory types. It is not manufactured for sale but is easily made in any machine shop.

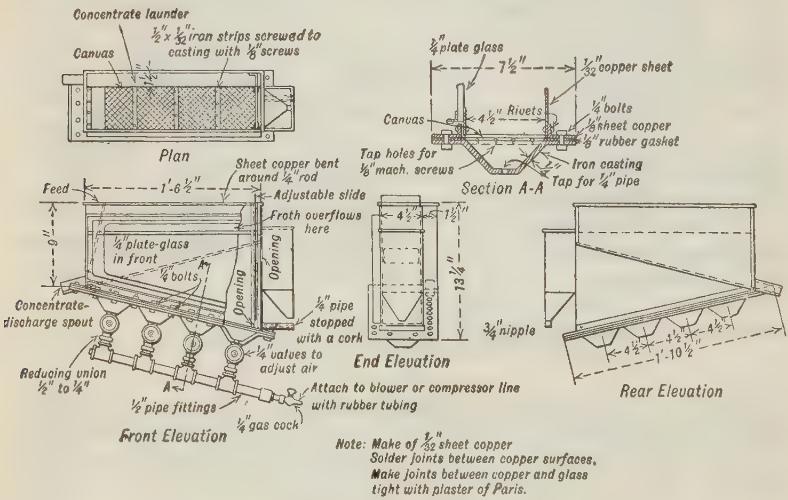

Fig. 27.—Laboratory-size Callow cell.

It requires a $\frac{1}{4}$-hp. motor which should give an impeller-speed range from 500 to 2000 r.p.m. The machine shown requires a charge of 750 gm. to give a pulp containing 20 to 25 per cent. solids.

Other testing machines. See A. F. Taggart, *Manual of flotation processes*, John Wiley & Sons, Inc., 1921.

Motors. An agitation-froth machine with 3- or 4-in. impeller requires a $\frac{1}{4}$-hp. motor. For direct current the General Electric Co. type DSD, constant-speed, shunt-wound motor, with a speed of 1700 r.p.m.; maximum voltage 250, drawing 1.25 to 0.63 amp., wired with a field rheostat in the armature circuit, is eminently satisfactory. Type SD is a similar motor for 110 volts. For alternating current Ralston (*112 P 8*) vouches for the satisfactory behavior of the General Electric Co. repulsion-induction motor, single-phase, 60-cycle, 1780 r.p.m. full speed, drawing 4.2 amp. at 110 volts or 2.1 amp. at 220 volts, either voltage being acceptable. Speed varies with the load and voltage and is controlled by a field rheostat in series with the motor.

Testing procedure

General. All apparatus should be scrupulously clean. Cleaning is best done by scrubbing with strong solution of sodium carbonate or sodium hydroxide, followed by a neutralizing wash with sulphuric acid solution and then by a blank run with finely-ground waste rock. If there is no frothing in the blank run the machine is clean and should then be washed free of solid in preparation for the ore charge.

It is most convenient to measure all quantities in metric units. Small quantities of mobile liquid reagents are readily measured with a Mohr pipette and the quantities converted into weights, taking into account the specific gravity; viscous liquids may be measured by counting drops, after the necessary calibration; solid reagents are best added in solution, if possible, otherwise they are weighed in.

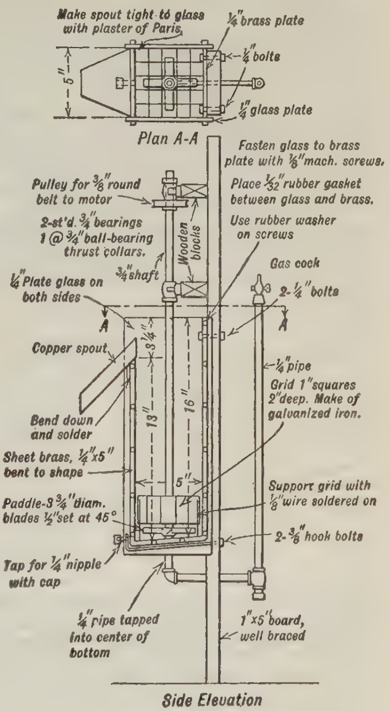

Fig. 28.—Laboratory sub-aeration machine.

The method of preparing the ore charge depends upon the ore, the nature of the test and the nature of the reagents. Dry grinding in a disk sample grinder or a small ball or pebble mill is most convenient, as it permits preparation of a large number of samples at one time, but the nature of such dry-ground material is not necessarily the same as that of the same ore wet-ground. Dry-ground particles may be of different shape from wet-ground, the relative average sizes of gangue and mineral will probably be different, and the heat developed in dry grinding together with the exposure to air may oxidize the surface of some of the floatable particles. Wright (*120 P 459*) says that wet-crushed samples have, in his experience, generally yielded recoveries from 5 to 10 per cent. higher than those from dry-crushed samples. The dispersion of viscous reagents is best effected in a thick pulp in a cylinder grinding mill. Hence wet grinding, simulating mill conditions, should be practiced unless it is established that dry grinding produces no essential difference in results.

In wet grinding the ore is first reduced to pass 10- or 20-mesh dry. The desired charge is then weighed into a small batch cylinder mill, water in an amount equivalent to 30 to 50 per cent. of the combined weight is added, flotation agent is put in, if desired, and the charge ground for the pre-determined time required to produce the desired size. A convenient form of batch-grinding apparatus may be made of a piece of 8-in. pipe, 10 in. long, with special caps with lugs for ease in unscrewing, to form the grinding cylinder; and two 4-in. pipe rollers with gudgeon ends in bearings, one roller driven and the other loose, in the same horizontal plane, spaced 9 in., on which the grinding cylinder is supported and rotated. The speed of the cylinder should be 40 to 50 r.p.m.

When the sample for test is a mill pulp, it should not be dried prior to testing.

In preliminary testing, as *e.g.*, in determining a suitable reagent, rough tests of metal content of the tailing may, with many ores, be made by vanning, and assays need not be made unless the vanning test indicates good recovery.

Methods of testing with the laboratory machines described are given in succeeding paragraphs. For methods of testing with other machines and by other processes see *Manual of flotation processes*.

Testing in agitation-froth machine. Start the impeller at slow speed. Add the charge of oiled pulp. (If feed has been dry ground, make a pulp in the machine to contain 50 per cent solids, add the collecting agent and agitate at full speed for one minute.) Bring the impeller up to full speed, add water until the level of the pulp stands one or two inches below the overflow lip, then add the frothing agent into the agitation compartment. Allow froth to build up until it stands ½ to 1 in. above the overflow lip, then scrape off as fast as it builds to this height. Add water as necessary to keep the pulp level at the proper height, which will increase as the test proceeds. Additional frothing agent may be added, if necessary to obtain froth toward the end of the test. Procedure varies somewhat according to the type of flotation flow-sheet that is being investigated. If this is of the rougher-cleaner variety, froth may be scraped deeply and removed rapidly during the roughing period in the endeavor to make clean tailing. Tailing is then removed from the machine and all of the overflow from one or more roughing operations, depending upon the amount of rougher froth produced, is charged back into the machine and frothed slowly to produce clean concentrate. The percentage of solids in the cleaning operation should ordinarily be between 6 and 12 at the beginning of the run. In a concentrate-middling test the first froth is removed slowly in an endeavor to make clean concentrate. Thereafter froth is removed as rapidly as possible and even a small amount of pulp may be overflowed in the endeavor to produce low-grade final tailing.

The rate of flow through mill machines is such that pulp remains in a given compartment of the primary machine for about two minutes. Hence each two-minute period in the test machine corresponds to treatment in one compartment of a mill-size machine and the probable mill installation can be estimated from the duration of the test run.

Collect concentrate, middling, tailing, and, if desired, the material that collects in the bottom of the agitating compartment ("untreated material") separately, weigh wet, dry and weigh, sample and assay.

Testing in pneumatic machine. Usually the feed is ground wet in a thick pulp with the collecting and dispersion agents. If dry-ground feed is used, 10-min. mixing with the agents in a 1 : 1 pulp in the batch-grinding mill with a light ball or pebble load is best. Thin the charge of pulp with water, add with frothing agent to the machine with air turned on slightly and tailing exit closed. Regulate the air in the different compartments so that there is no marked horizontal travel of air or bubble column, then add more water, if necessary, until froth overflows freely. Continue frothing until the residue in the cell shows marked impoverishment or until 8 or 10 min. have elapsed. This time corresponds to that required for the passage of pulp through a standard Callow cell under ordinary mill conditions. If no marked impoverishment occurs, it may be concluded that the particular flotation agents used are unsuited to the ore and others should be tried. In the case of a good roughing test, draw the tailing and return the rougher froth to the machine for cleaning. This operation requires only one-half to one-quarter the quantity of air used in roughing, the pulp should be quite dilute and the rate of overflow slow. Collect cleaner concentrate, cleaner tailing (middling) and rougher tailing separately, weigh wet, dry and weigh, sample and assay.

Testing in the sub-aeration machine is akin to testing in the pneumatic machine except that mixing is readily performed in the cell itself, as in the agitation-froth machine. Otherwise, with apparent modifications, the preceding instructions will serve for this machine.

Continuous tests in machines of the size described will not give satisfactory indications of mill results. Machines for such testing should have a capacity of several hundred pounds per hour and should be preceded by a ball mill and classifier. A flow-sheet consisting of a 3-ft. ball mill, in closed circuit with a simplex Dorr classifier sending overflow to a 1 × 5-ft. rougher Callow cell and a 6-in. × 3-ft. cleaner, with suitable accessory pumps and sampling apparatus will, however, treat ore at the rate of 5 tons per 24 hr., if already crushed to ½-in. size, and will give results that are comparable to mill performances. Several hundred to 1000 lb. of ore are required to charge such a plant and one or two hours running to allow it to settle down, so that at least one ton of sample is required for a test and two to five tons is safer. Flotation feed, unlike the feed in gravity concentration, cannot be made up of re-combined products from a previous run.

Purpose of flotation testing may be (*a*), to investigate the amenability of an ore to flotation, (*b*) to determine the best method of treatment, (*c*) to investigate a flotation agent, (*d*) to investigate a process.

Amenability. Actual flotation should be preceded by microscopic examination to determine the approximate qualitative mineralogical composition and state of the ore as regards oxidation. Preliminary examination with a binocular microscope followed by study of a polished section, supplemented, if necessary, by study of a thin section or some fragments with a petrographic microscope, will usually save time and permit much more intelligent prosecution of the actual testing work. If microscopic study shows unaltered sulphide associated with the ordinary rock-forming gangue minerals, it is a safe conclusion that the ore is amenable to flotation and actual tests in the machine may be directed rather toward determination of the best method of treatment than toward confirmation of amenability. If microscopic examination shows mixed sulphides, that fact will indicate low-grade concentrate and point the way toward differential flotation. If there are signs of oxidation, trouble is to be anticipated and the question of amenability cannot be answered without actual flotation testing.

The following classification of commonly-used flotation agents will serve as a guide in the choice of agents. It is not, however, to be looked upon in any way as rigid or complete, but merely as an aid to the beginner in flotation testing.

Frothing agents. (See p. 842.)

Agents that stiffen froths. Wood tar and wood-tar oils. Petroleum and petroleum derivatives.

Collecting agents. (See p. 842.)

Dispersion agents. (See p. 844.)

Agents for copper ores. Tars and their derivatives. Thiocarbanilid and xanthates. (See also p. 847.)

Agents for lead ores. Pine oil. Wood creosotes. Thiocarbanilid and xanthates. (See also 851.)

Agents for zinc ores. Pine oil. Coal-tar creosote. Thiocarbanilid and xanthates. Copper sulphate. (See also p. 851.)

Agents for differential flotation. See Sec. 12, Arts. 16 and 19–24.

Agents for oxide flotation. See Sec. 12, Art. 25.

Grade of concentrate can ordinarily be improved, if poor, by decreasing the rate of froth overflow. This may be accomplished by decreasing aeration, diluting the pulp, using less or a less-powerful frothing agent, by eliminating an agent that stiffens the froth, by choosing an agent that is more highly selective, or by the use of dispersing agents such as sulphuric acid, lime, and certain inorganic salts.

Recovery will usually be increased by increasing the rate of froth overflow. This may be done by increasing aeration, increasing the percentage of solids, using more frothing agent or a more powerful frothing agent, or adding a froth stiffener. Recovery may also be increased by increasing selection, either by the use of a different collecting agent or by adding a dispersion agent.

Tests for a method of flotation are in no way fundamentally different from tests for amenability; they differ only in that they are more thorough and exhaustive and should, ordinarily, be carried out on a larger scale. They should start with knowledge of amenability and of one method of treatment, and should comprise investigation of the effect of changes in flotation process, in grinding, dilution, reagents, temperature, water supply, etc., on recovery and grade of concentrate. The following facts should be kept in mind in this testing campaign:

(*a*) In the laboratory the agitation-froth process is easier to control and tests are more quickly run than by the pneumatic process.

(*b*) An ore that can be successfully concentrated by flotation in an agita-

tion-froth machine can be successfully concentrated, with certain changes in the accessory details of operation, in a pneumatic machine, and *vice versa*.

(*c*) Before a mill is built the process worked out in the laboratory should be tried out on something approximating a mill scale in a test plant.

(*d*) The flotation process operates most easily and with greatest leeway on a pulp containing from 15 to 20 per cent. solids. On the other hand, power consumption, mill equipment and reagent consumption are lessened as the percentage of solids in the pulp is increased.

(*e*) A change of reagents in an operating mill may be a serious matter, involving considerable laboratory experimental work and costly interference with mill operation. Hence the reagent chosen should be one of which a supply at a fair price is reasonably assured, and the reagents tried in the testing work should be of this class. The important members of the class are: pine oil, coal tar, coal-tar creosote, wood tar, wood-tar creosote, petroleum residuum, the low-grade kerosene commonly known as stove oil, thiocarbanilid, sodium and potassium xanthates, sodium sulphide, alkaline cyanides, sodium carbonate and bicarbonate, sulphuric acid, zinc and copper sulphates, xylidin, orthotoluidin. All of these substances are available at fair prices and in good supply. Certain other substances may be locally abundant and their use, temporarily at least, may be justifiable on that score, but a suitable flotation agent consisting of one or more of the above-mentioned substances should be determined and the best available supply investigated against the time when the supply of the local substance is exhausted.

Testing flotation agents. This is probably the most common type of testing at an operating plant. The first step is, of course, to find by actual test, first in the laboratory and then in the mill, whether the new agent will produce satisfactory recovery and grade of concentrate with the mill feed. In this investigation it is essential that the conditions of contemplated use be duplicated. This is not always an easy matter. For example, if the mill-flotation feed is re-ground residue from gravity concentration and reclaimed water is used in the mill and the new reagent is to replace one or more of the reagents in regular use, it is substantially impossible to obtain a sample for laboratory testing that has the size and mineralogical composition of mill-flotation feed and is uncontaminated with existing reagent. Under such circumstances the best approximation to mill conditions will be attained by taking some of the original ore, concentrating it in the laboratory by gravity treatment patterned on the mill scheme, then grinding the residue in the laboratory to mill size. It is not safe to take a sample in the mill and dry it to drive off mill reagents. Such dried pulp will almost invariable float more poorly than properly prepared fresh pulp.

Assuming favorable flotation results from the laboratory tests, the questions of quantity required, supply and price should next be investigated. Unless the potential supply is large, the price is sure to advance with adoption of the agent by other companies, and deliveries may be difficult, with resulting interruption to mill operation. The probable effect of storage at the mill should be looked into; the behavior in the water-recovery system; and the effect on flotation of such part of the reagent as comes back with reclaimed water. Some reagents that have been suggested have unpleasant or dangerous physiological effects, *e.g.*, amyl acetate, valerianic acid, hydrogen sulphide, sulphur dioxide, and alkaline cyanides. This fact must be given due weight.

When a new reagent is proposed to be used in combination with old reagents, the laboratory investigation should include parallel runs in which every con-

dition is the same except that in one run the proposed new reagent is present and in the other it is absent. A considerable number of reagents have been patented that will not stand this test.

Testing flotation processes involves no different principles, in so far as determining suitability for mill operation is concerned, from those already outlined. If the process is a new one, it is well to bear in mind that the inventor may know little about it himself and that, unfortunately, he does not always put all of that little into his patent. As a result the early trials may be a succession of failures. The history of the agitation-froth process typifies the first contingency. The discovery was made in treating high-grade zinc-bearing tailing in Australia. Great difficulty was encountered five years later in applying the process to Butte zinc ores, and its subsequent application to low-grade copper ores was established as the result of literally thousands of trials by mill operators in the face of statements by representatives of the patentees that their process was not suited to the treatment of such ores.

When testing is directed toward establishment of the physical and chemical phenomena underlying a flotation process, actual operation of the process is of little avail. The essential phenomena involved lie in the field of molecular physics and chemistry, and, in the operation of the complete process, are so complex and masked that it is impossible to segregate and observe them. Such testing requires resources both of equipment and personnel different from those available at a plant laboratory. The experiments usually bear but little apparent resemblance to the process. The danger to guard against is that of overlooking, in a simple experiment that involves only one of the elements, the effect of the simultaneous action of the other elements.

Oil testing. The usual purpose of oil testing in flotation work is to determine that the oil in question is similar in physical properties and, therefore, probably in its behavior in the flotation cell to a given prior shipment, or in order to set specifications for flotation oil purchase. For details see *Manual of flotation processes*. For results of tests on a number of oils see Sec. 12, Tables 15 and 16.

Interpretation of flotation-test results. Translation of laboratory results into terms of mill-scale operations is, in the usual case, less difficult in flotation than in gravity concentration, and in all cases more certain than where chemical reactions such as occur in leaching and precipitation operations are concerned. Any flotation result that can be obtained in a laboratory machine can be obtained in mill operation, if the essential laboratory conditions are duplicated. The converse of this statement is also true, except that the mill-sized machine is capable of handling a somewhat coarser feed than can be handled in the laboratory machine. Considering the essential elements of pulp treatment in detail, the translation from laboratory results to mill results will be as follows:

Average size of feed may be slightly coarser in the mill than in the laboratory or, if the grinding in the mill is carried to the same extent as in the laboratory, a somewhat better result, other conditions being equal, may be expected in the mill than in the laboratory.

Water may make a considerable difference between laboratory results and mill results and this difference may be either in favor of or to the detriment of the mill. The former will ordinarily be the case if a portion of the mill water is reclaimed and reused. Under these circumstances it will ordinarily be found that the flotation agent brought back by the mill water will lessen, to a considerable extent, the amount of new flotation agent that it is necessary to add,

and that froth will be more easily obtained with this reclaimed water mixed in. If, however, there is any considerable amount of soluble salts in the ore, or if the settling ponds are of considerable area and in an arid region and there is any considerable amount of dissolved solids in the new water, then the salts in the water may have a harmful effect on flotation.

Flotation agents in the mill will be the same as in the laboratory except that it will generally be possible in the mill to lessen, to some extent, the proportion of so-called frothing oil in the mixture.

The peripheral speed of the agitators in agitation-type machines may, in general, be somewhat less in the mill than in the laboratory.

The air consumption per cubic foot of pulp treated in pneumatic machines will usually be less in the mill than in the laboratory. The pressure on the under side of the blanket will be necessarily higher in the mill machine than in the laboratory machines described, on account of the greater head on the pulp side of the blanket.

Time of treatment necessary in the mill will be very closely the same for a given recovery and grade of concentrate as in the laboratory. The grade of final concentrate obtained in the mill will be close to that obtained in the laboratory. The recovery will come close to the indicated extraction calculated by the formula (10), p. 1236, from laboratory results, if, in the calculation, the figure for grade of concentrate is that obtained from the cleaner operation, the figure for rougher tailing is that obtained from the rougher operation, and the middling or cleaner tailing obtained in the laboratory is disregarded, provided that the grade of this middling product is not more than twice the grade of the original heads, and that the mineralogical character of the middling is not markedly different from that of the original feed.

Table 15 (*56 A 676*) shows comparison between laboratory tests and mill results. The first three columns compare mill results and two different laboratory results in miniature

Table 15. Comparison of laboratory tests with large-scale operations, Consolidated Nevada-Utah Corporation

	Mill results August 14, 1916	Miniature machine on feed, August 14, 1916, Salt Lake City water	Miniature machine results with head sample and mine water, August 14, 1916	5-ton laboratory test of April 15, 1916	Miniature results prior to 5-ton laboratory tests
Assay of feed, Zn per cent	17.20	17.56	17.56	17.54	17.53
Assay of total zinc concentrates, Zn per cent	41.80	40.48	40.17	42.41	41.91
Assay of total tailing, Zn per cent	5.60	4.89	4.89	3.64	4.71
Ratio of concentration	....	2.91	2.81	2.87	2.94
Recovery of Zn in zinc concentrate	77.80	78.58	79.07	84.12	81.48
Assay of all table zinc concentrate, Zn per cent	42.60	40.63	40.63	41.32	41.77
Assay of flotation zinc concentrate, Zn per cent	37.00	39.80	38.52	46.77	43.19
Assay of zinc in total iron concentrate, Zn per cent	10.10	14.30	....	12.88	10.06

machines on the same material. The last two columns compare miniature-machine (1000-gm.) results with 5-ton laboratory-machine results on the same sample. The discrepancy between the April and August tests is no more than is to be expected from different lots of ore, and the difference in miniature results on the two dates compared with difference between miniature results and larger-scale results on the same date, indicates that the discrepancy on the different dates is rather due to the ore than to the difference in scale of operation.

Mill tests. It cannot be too strongly urged that before a mill is erected, some testing work be done on mill-sized flotation machinery. This work should be done in a test mill at the mine, on ore whose prior handling corresponds as closely as possible with the scheme to be followed in the finished mill, and the water used should be as near as possible of the character of the water that is to be used in the operating plant. If such a test does no more than confirm the laboratory results, it will pay for itself in the information that it gives concerning mill operation on the ore and it may be that the test will bring up conditions which were overlooked in the laboratory testing work. Some of the equipment used in such a test can ordinarily be utilized in the final plant so that it need not all be charged against the testing work.

At Utah Copper Co. (Nov. 29, 1916) with Janney mechanical-air cells in the mill, a sample of mill pulp was taken and tested in the laboratory Janney mechanical machine. The mill machines averaged 0.120 per cent. Cu for the day, the laboratory-machine rougher tailing was 0.130 per cent. Cleaner concentrate was about 26 per cent. Cu in both places.

12. Magnetic and electrostatic concentration

For small-scale tests for permeability, to remove iron introduced in grinding small samples, or to remove magnetite from pan concentrate and the like, a small electromagnet such as that shown in Fig. 29 is satisfactory.

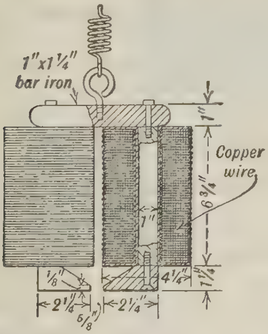

Fig. 29.—Electromagnet for laboratory testing (*after Richards*).

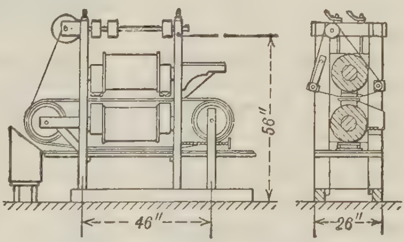

Fig. 30.—Laboratory-size Wetherill separator.

Cores and pole-pieces should be made of soft iron. According to *Richards*, the magnet shown, when wound with 5000 ft. of No. 21 cotton-covered copper wire on each pole, making a total of 6760 turns, carries a maximum of 0.8 amp. at 50 volts without undue heating. For continuous tests Richards recommends the small Wetherill-type machine shown in Fig. 30. Each magnet carries 100,000 ampere turns and with proper rheostat control can be used to treat minerals of both low and high permeability.

Electrostatic machine for laboratory testing is made by Huff Electrostatic Separator Co. to sell at about $1500. This apparatus is not justified in the ordinary testing laboratory.

Hydrometallurgy. See Sec. 15.

Sample dryers. A useful form for large samples is shown in Fig. 31. It consists of a large 3-walled rectangular pan with a steam chamber for a bottom, all mounted on a suitable framework at a convenient distance from the floor. The steam drying rack (Fig. 32) and gas dryer (Fig. 33) are suitable for smaller samples. An enclosing cupboard with good ventilation is essential to the best performance of both of these apparatus.

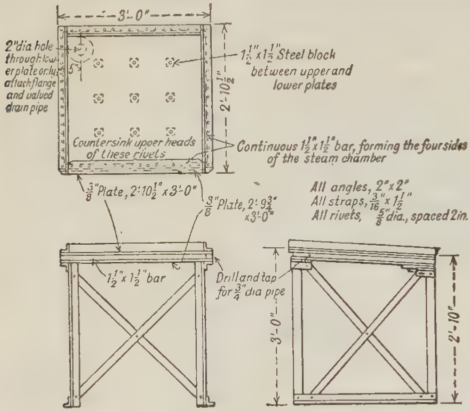

FIG. 31.—Steam drying plate.

13. Ore-dressing laboratory

General. The most desirable arrangement is a separate building with railroad spur for delivery of heavy machinery and ore samples and river, storm-sewer connection or the like for disposal of finely ground waste. The spur track should preferably approach the building at a sufficient elevation to permit gravity unloading of bulk-ore samples into a receiving bin and the unloading platform should be served by a crane that serves the milling room also. The building proper should consist of a large milling room and a number of small rooms for microscopic work, assaying, flotation testing, screen analysis, shop, small-sample storage, junk pile, etc. The best arrangement for the milling room is a large light room with high roof, preferably having, at one end or side, a strong skeleton framework with three or four floors at 8- to 10-ft. intervals, stepped back sufficiently to permit ready crane delivery, and a gallery around the rest of the room. The whole room should be crane-served. All but the heaviest apparatus should be set up as a self-contained portable unit, capable of being picked up by the crane and set down in the desired position on the floor or on the skeleton frame for use, and thereafter returned

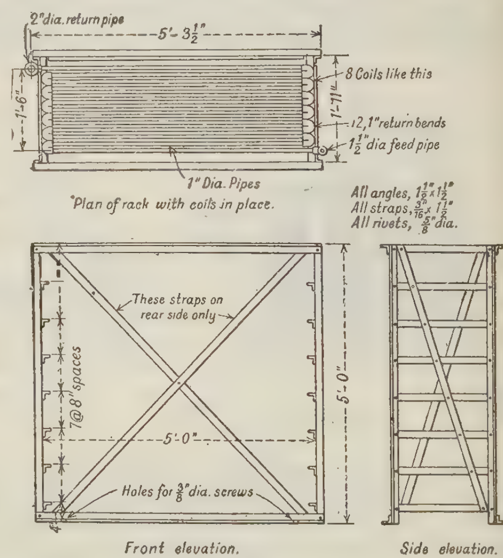

FIG. 32.—Steam drying rack.

to a place on the gallery for storage. The feed bins should discharge by feeders to a screen, oversize to a jaw crusher, undersize and crusher product to a conveyor and thence to a screen, oversize to a gyratory, undersize and crusher product to a conveyor to a screen, oversize to rolls, undersize and roll product to a bucket elevator to another screen returning oversize to the rolls and undersize to a compartmented fine-ore storage bin. The ideal condition would be to have each of the preceding crushers and screens so placed that it may be picked up and set down in the main milling room for individual test, but if this is not possible the arrangement must be such that each crusher is capable of individual test for capacity, power consumption and size of feed and product. There should be a bucket elevator in the main milling room delivering to the top of the skeleton frame and a battery of centrifugal pumps piped to deliver to any desired level of this frame. The fine-ore storage bins should be arranged for delivery to the elevator boot or to a rod or ball mill and the latter should, of course, be arranged for closed-circuit grinding, if in permanent locations, with finished product going to one of the centrifugal pumps. Set-ups for substantially any concentration or hydrometallurgical process with gravity flow of pulp can be made on the skeleton framework. This framework should be floored with removable slatted wooden sections about 2 ft. wide by 5 ft. long built up of 2 × 4-in. yellow pine. A dust-collecting system with suitable inlets at each permanent dry-crushing or screening-location and a service line into which temporary inlets may be connected is desirable although not essential. There should be a large sump in the floor of the main room, toward which the floor drains from all directions, with sufficient capacity to hold all excess water from a one- or two-hour concentrating run involving wet screening, hydraulic classification, jigging and tabling. The sump should discharge to waste by gravity either from bottom outlets or by decantation. A centrifugal pump should be provided to return water from the sump to the water-feed tank. This should be a tank about 6-ft. diameter by 6 ft. deep, located at the highest point of the laboratory, fed by the new-water system and by the sump pump, discharged into the laboratory-supply line by an outlet placed about 6 in. above the bottom, and having an overflow pipe of generous dimensions returning to the sump, a 1-in. tell-tale line returning with the overflow, and a small drain line from the center of a slightly-dished bottom. The water line from this supply tank should be of 3- or 4-in. diameter running around the walls of the laboratory, with permanent branch lines at strategic points and numerous plugged tees and valved outlets, a part of which should be fitted with ¾-in. and others with 1½-in. male hose bibbs. There should be a half dozen or more portable cylindrical tanks, 6- and 8-ft. diameter by 2 ft. high, of heavy galvanized-iron sheet, fitted with several 1½-in. outlets through floor flanges at one place on the rim and one such opening on the wall at the bottom. These are useful for collecting and dewatering sand products, or for holding dewatered slimes, and to keep solid matter out of the sump.

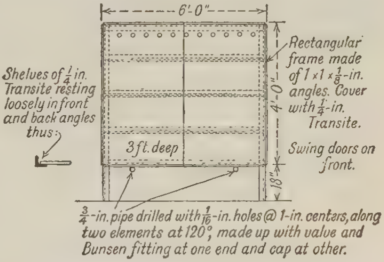

Fig. 33.—Gas dryer.

Cleaning up. All apparatus should be capable of complete and ready clean-up. Detail of the necessary arrangement to secure this end will vary with different apparatus, but in general all tanks and hoppers should have sloping bottoms where possible, all machines should be so placed that the material left-in-process can be washed or brushed into receptacles set under them, and all apparatus should be so designed that the amount of material left therein at the end of the run is a minimum.

Sampling and weighing equipment. Mechanical sampler for dry ore. Platform scales weighing in metric and common units to about 1000 lb., accurate to 0.5 lb. Druggist's trip scale weighing in metric and common units to 10 lb. with slide scale graduated to 10 gm. and ¼ oz., sensitive to 0.5 gm. Pulp balance weighing to 250 gm. and sensitive to 0.1 gm. Analytical balance. Suitable weights for the preceding. Square-edge D-handle shovels. Cross for cone-and-quarter sampling. Jones riffle with about 16 @ 1-in. chutes and another with about 16 @ 0.5-in. chutes. (The riffles should have an even number of chutes.) Galvanized ash cans, coal hods and pails. A cement sampling floor free from cracks or two @ ¼-in. steel sheets about 6 × 6 ft. Floor brush. Coffee mill. Disc pulverizer.

Assay laboratory with full equipment of apparatus and reagents for both wet and dry assaying. See a good book on assaying (p. 1181) for a check list. There should be gas-fired pot and muffle furnaces that will serve also as roasting furnaces for testing in magnetic concentration and hydrometallurgical work.

Microscope equipment. Hand lens, 10 × to 15 ×. Binocular microscope with interchangeable open-foot and stage mounting, 25-, 40- and 55-mm. objectives and 6 × and 10 × oculars. Petrographic microscope. Metallurgical microscope. Grinding and polishing laps. Mounting equipment. Apparatus and chemicals for microchemical work. See Chamot, Murdock, Davy and Farnham, Johannsen, p. 1192.

Equipment for sizing tests. Set of 8-in. Tyler standard sieve-scale testing screens to $\sqrt[4]{2}$ ratio up to 1.050 in. (see Table 1) and square-mesh wire screens in wooden frames about 18-in. square on approximately $\sqrt{2}$ scale from 1.05-in. to 4-in. Testing-sieve shaker. Sample pans, 2, 4, 6, 8 and 12 in. diameter (patty tins and pudding tins will serve). Scoops. Counter brushes. Round assay-button brushes. 1-in. flat camel's-hair brushes. Glazed paper. Paper bags and sample envelopes. Eye-piece and stage micrometers for the microscopes (see Microscopic sizing, Art. 4). Elutriation apparatus (see Art. 2).

Crushing equipment. Jaw crusher, Blake type; about 10 × 7 in. No. O gyratory crusher (see Sec. 3, Table 12). Crushing rolls, 12 to 16 × 10-in. Ball mill, not less than 4-ft. diameter, if feed is to be more than ½-in. maximum size; in no case less than 3-ft. diameter. Rod mill, preferably 24-in. diameter by 5 or 6 ft. long. This can also be used as a tube mill. Batch ball or pebble mill. The large crushing and grinding machines should be driven in such a way that reasonably accurate power readings can be obtained.

Grading equipment. Vibrating screen with good assortment of screen cloth. Glass classifiers, both free- and hindered-settling. Tank-type laboratory-size hindered-settling classifier. Mechanical classifiers of suitable size for the ball and rod mills. Diaphragm cones for feeding concentrating tables. 6 × 6-ft. Dorr thickener with diaphragm-pump discharge. Filter leaf. Drying rack.

Concentrators. Hand-jig sieves. Gold pan. Vanning plaque. Galvanized wash tubs. Laboratory-size Harz jig. Small shaking table (12 × 30-in. deck) with interchangeable decks and Wilfley, Garfield and Butchart riffling. Quarter-size shaking tables for sands. Slime table. Experimental film sizer. Miniature agitation-froth and pneumatic flotation machines. Larger flotation machines of about ¼ ton per hr. capacity. Blower. Electro-magnet. Dry-separating table.

Handling equipment. Trucks, conveyors, elevators for dry material and centrifugal pumps for fine wet material.

Feeders. Bins should be provided with automatic feeders with variable-speed control and movement-recording apparatus. Belt feeders with ratchet-and-pawl drive and revolution counters on the head shaft are most satisfactory. Self-contained portable vibrating or shaking-tray feeders mounted with small feed hoppers are best for feeding individual machines with dry or moist sands. An inclined trough along which a weighed quantity of dry or moist sand or slime is uniformly spread and from which a given length (weight) of charge is washed out per minute with a constant stream of water is the most satisfactory wet feeder for the laboratory. Travel of the feed-water stream may be made automatic by mounting the nozzle on a mechanically-driven screw.

Miscellaneous. Good equipment of tools for simple carpentry, plumbing, tin-smithing and machine work. Racks for storage of material and small samples. Room for barrel or bin storage of larger samples. Room for a junk pile.

14. Metallurgical calculations

Computations of performance in milling are complicated by the fact that it is a continuous rather than a batch operation, that the quantities of solid materials handled are large and usually mixed with water, hence difficult or impossible to weigh. Fortunately it is possible to determine many facts concerning performance without knowing weights, if the value of various constituents is known in some common unit, *e.g.*, the content of some particular metal or mineral, or of water, or of particles of a particular size or falling within some particular size range, or the like. Metal content may be expressed in per cent. by weight or volume, or in units of weight as oz. per ton, or even in units of value, as in dollars per ton, provided, in the latter case, that the value is in direct proportion to the metal content and not an artificial value dependent both upon metal content and lack of other content, as is frequently the case in valuation of concentrate.

Definitions and notation. The following notation and definitions obtain throughout all of the calculations.

C = weight of concentrate, expressed in any units, but necessarily in the same units as F. CONCENTRATE may be defined, for the purpose of these calculations, as any product of the treatment of a given feed that is richer in content of a given ingredient than the feed.

c = Assay of concentrate. See notes to f.

c_a, c_b, c_c. See notes to f_a, substituting the word "concentrate" for "feed."

E = EFFICIENCY. This term is usually applied to a two-product classifier operation. So applied, it indicates the ratio of the weight of classified material in the overflow to the weight of classifiable material in the feed. See development of formula (38) for further discussion.

F = weight of feed. This may be expressed in any units. The word FEED applies to the material entering treatment in any machine or operation, *e.g.*, the ore entering a treatment plant, or the material entering an individual machine.

f = assay of feed. As stated in the introductory paragraph, this assay may be given in any units, *e.g.*, per cent. Pb, oz. gold per ton, lb. Cu per ton; dollars per ton, when the value is directly proportional to the weight of a given constituent, say gold or silver, but not when the value is the combined value of the gold and silver, unless the ratio of weight of gold to silver is the same in all products as in the feed; per cent. — 1-mm. material, per cent. moisture, per cent. ash (in coal), etc.

f_a, f_b, f_c, etc. When the feed contains more than one ingredient of value, assays are made for each, and these are expressed separately in the formulas, distinguished by the subscripts. Thus, in an ore containing zinc, lead, and silver, f_a might be chosen to represent the per cent. zinc in the feed, f_b the per cent. lead, and f_c the oz. silver per ton of feed.

K = RATIO OF CONCENTRATION. This term is defined as the ratio of the weight of the feed in a given operation to the weight of concentrate obtained from it; or, stated another way, as the number of tons of feed required to produce one ton of concentrate.

M = weight of middling, expressed in any unit, but necessarily in the same unit as F. MIDDLING is defined, for the purpose of these calculations, as that product of the treatment of a given feed whose content of a given ingredient lies between that of the tailing and that of the concentrate.

m = assay of middling. See notes to f.

m_a, m_b, m_c. See notes to f_a, substituting the word "middling" for "feed."

R. RECOVERY is the ratio, expressed as percentage, of the weight of the sought-for ingredient, in the finished product of a given operation, to the weight of the same ingredient in the material entering the operation. Thus if there are 20 lb. of copper per ton in the material entering a given mill and 19 lb. are obtained in the form of concentrate from each ton entering, the recovery, $R = 19/20 = 95$ per cent.

The terms EXTRACTION, INDICATED EXTRACTION, ESTIMATED EXTRACTION and ACTUAL EXTRACTION are sometimes used to indicate recovery. The terminology is so confused that the meaning of none of the terms can be safely assumed without indication of the method of determination. Some writers have attempted to distinguish between extraction and recovery, making the former term mean the value of R as calculated from assays of feed and products (see Formulas 10, 24, 34 and 35) while recovery indicates the ratio of the weight of metal in concentrate actually recovered (= actual weight of concentrate × assay of concentrate) to the actual weight of metal in the feed (= actual weight of feed

× assay of feed). Other writers use the term indicated extraction or estimated extraction to signify R from assays alone and actual extraction to signify the percentage of the total metal fed that is actually recovered in concentrate. In this book the word recovery is used generally to describe the result by either method of calculation and the term ACTUAL RECOVERY to distinguish, when necessary, the case in which calculation is based on actual weights.

T = weight of tailing, expressed in any unit, but necessarily in the same unit as F. TAILING is defined, for the purpose of these calculations, as that product of the treatment of a given feed which is distinctly impoverished in content of a given ingredient as compared to the feed.

t = assay of tailing. See notes to f.

t_a, t_b, t_c. See notes to f_a, substituting the word "tailing" for "feed."

15. Two-product formulas

The simplest case is that in which two products only, *viz.:* concentrate and tailing, are made from the treatment of a given feed. Under such circumstances:

$$F = C + T, \quad (1)$$

$$Ff = Cc + Tt. \quad (2)$$

Multiply equation (1) by t, eliminate T, and

$$C = F(f - t)/(c - t), \quad (3)$$

$$F = C(c - t)/(f - t), \quad (4)$$

By similar manipulation,

$$T = F(c - f)/(c - t), \quad (5)$$

$$F = T(c - t)/(c - f), \quad (6)$$

$$T = C(c - f)/(f - t), \quad (7)$$

$$C = T(f - t)/(c - f). \quad (8)$$

By definition, $K = F/C$, whence, from equation (3),

$$K = (c - t)/(f - t). \quad (9)$$

By definition, $R = 100Cc/Ff$, whence from equation (3),

$$R = 100c(f - t)/f(c - t). \quad (10)$$

16. Three products, one metal

When three products are made and assays are reported in terms of one ingredient only, if no weights are known, determinations of recovery and ratio of concentration are strictly indeterminate problems. If enough is known with respect to the performance of the ore to justify an assumption as to the effect of middling re-treatment on the assays of final concentrate and tailing, correction of concentrate and tailing assays may be made on the basis of the assumption, and the preceding formulas may then be applied. For an example, see Art. 7. If the assumption be made that re-treatment of middling will result in distribution of the same into concentrate and tailing of the same assays as the corresponding products made in the operation that pro-

duced the middling, then if X and Y represent the final weights of concentrate and tailing respectively from the original and re-treatment operations,

$$C + M + T = X + Y, \qquad (11)$$

and

$$Cc + Mm + Tt = Xc + Yt. \qquad (12)$$

Eliminating Y,

$$X = [C(c - t) + M(m - t)]/(c - t) \qquad (13)$$

and

$$Y = 1 - X = [(c - t)(1 - C) - M(m - t)]/(c - t) \qquad (14)$$

Equations (3) and (5) will, however, give the same result.

If two of the weights F, C, M, T are known in addition to the assays, the other weights and the recovery and ratio of concentration may be calculated by manipulation of the two following equations:

$$F = C + M + T \quad (15) \qquad \text{and} \qquad Ff = Cc + Mm + Tt \quad (16)$$

The resulting equations are:

$$C = \frac{F(f-t) - M(m-t)}{(c - t)} = \frac{T(m-t) - F(m-f)}{(c - m)} = \frac{T(f-t) - M(m-f)}{(c - f)}; \qquad (17)$$

$$M = \frac{F(f-t) - C(c-t)}{(m - t)} = \frac{F(c-f) - T(c-t)}{(c - m)} = \frac{T(f-t) - C(c-f)}{(m - f)}; \qquad (18)$$

$$F = \frac{C(c-t) + M(m-t)}{(f - t)} = \frac{T(m-t) - C(c-m)}{(m - f)} = \frac{M(c-m) + T(c-t)}{(c - f)}; \qquad (19)$$

$$T = \frac{C(c-m) + F(m-f)}{(m - t)} = \frac{F(c-f) - M(c-m)}{(c - t)} = \frac{C(c-f) + M(m-f)}{(f - t)}. \qquad (20)$$

$$c = \frac{f - Mm - Tt}{1 - M - T}, \qquad (21)$$

$$m = \frac{f - Cc - Tt}{1 - C - T}, \qquad (22)$$

$$t = \frac{f - Cc - Mm}{1 - C - M}. \qquad (23)$$

$$R = 100\left[\frac{c(f - t)}{f(c - t)} - \frac{Mc(m - t)}{Ff(c - t)}\right] = 100\left[\frac{c(m - f)}{f(c - m)} - \frac{Tc(m - t)}{Ff(c - m)}\right]$$

$$= 100\left(1 - \frac{Tt}{f}\right) = 100\left[\frac{Cc(f - t) + Mm(f - t)}{Cf(c - t) + Mf(m - t)}\right]. \qquad (24)$$

$$K = \frac{F(c - t)}{F(f - t) - M(m - t)} = \frac{F(c - m)}{T(m - t) - F(m - f)}$$

$$= \frac{C(c - t) + M(m - t)}{C(f - t) + M(f - t)} \qquad (25)$$

Other equations for K and R may be written by manipulation of equations 15 to 20, but the simpler procedure is to solve for weights of feed and concentrate, after which solutions of K and R are obtainable from the definition equations.

17. Three-product formulas

(For 3-product formulas involving one ingredient only, see Art. 16.) When a feed containing, say, metal "a" and metal "b" is so treated as to make three products, *e.g.*, concentrate rich in metal "a," another concentrate (or middling) rich in metal "b," and a tailing impoverished in both "a" and "b," equations may be written that express the recoveries and ratios of concentration in terms of assays alone, and the weights of the different products in terms of assays and the weight of the feed.

Thus:

$$F = C + M + T, \qquad (26)$$

$$Ff_a = Cc_a + Mm_a + Tt_a, \qquad (27)$$

$$Ff_b = Cc_b + Mm_b + Tt_b. \qquad (28)$$

Then, from the solution of these simultaneous equations (most readily made by the method of determinants),

$$C = F\left[\frac{(f_a - m_a)(m_b - t_b) - (f_b - m_b)(m_a - t_a)}{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}\right]; \qquad (29)$$

$$M = F\left[\frac{(c_a - f_a)(f_b - t_b) - (c_b - f_b)(f_a - t_a)}{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}\right]; \qquad (30)$$

$$T = F\left[\frac{(c_a - m_a)(m_b - f_b) - (c_b - m_b)(m_a - f_a)}{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}\right]; \qquad (31)$$

where C = weight of concentrate rich in metal "a" and M = weight of concentrate rich in metal "b."

Ratio of concentration with respect to metal "a" is, by definition, $K_a = F/C$. Substituting in this equation the value of C from equation (29):

$$K_a = \frac{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}{(f_a - m_a)(m_b - t_b) - (f_b - m_b)(m_a - t_a)}. \qquad (32)$$

Similarly, $K_b = F/M$, and from equation (30):

$$K_b = \frac{(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)}{(c_a - f_a)(f_b - t_b) - (c_b - f_b)(f_a - t_a)}. \qquad (33)$$

Recovery of metal "a" in C is given by the equation $R_a = 100\,Cc_a/Ff_a$. Substituting in this equation the value of C from equation (29)

$$R_a = \frac{100\,c_a[(f_a - m_a)(m_b - t_b) - (f_b - m_b)(m_a - t_a)]}{f_a[(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)]} \qquad (34)$$

Similarly, $R_b = 100\,Mm_b/Ff_b$ and from equation (30)

$$R_b = \frac{100\,m_b[(c_a - f_a)(f_b - t_b) - (c_b - f_b)(f_a - t_a)]}{f_b[(c_a - m_a)(m_b - t_b) - (c_b - m_b)(m_a - t_a)]} \qquad (35)$$

Instead of working from the formulas, the weights of the products may be solved for by writing equations (26), (27) and (28) with the assay values written in and solving directly by determinants.

Example. Given assays as follows: Feed, 7.7 per cent. Pb and 11.9 per cent. Zn; lead concentrate, 50 per cent. Pb and 5 per cent. Zn; zinc concentrate, 50 per cent. Zn and 10 per cent. Pb; tailing, 1 per cent. Pb and 2 per cent. Zn. Write three simultaneous equations as follows:

Weights: $F = C + M + T$ (C = lead conc., M = zinc conc.)
Lead assays: $7.7\ F = 50\ C + 10\ M + T$
Zinc assays: $11.9\ F = 5\ C + 50\ M + 2T$.

Write and solve the determinant for C (see Sec. 24, Art. 14):

$$C = \frac{\begin{vmatrix} 1 & 1 & 1 \\ 7.7 & 10 & 1 \\ 11.9 & 50 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 1 & 1 \\ 50 & 10 & 1 \\ 5 & 50 & 2 \end{vmatrix}} = \frac{\begin{vmatrix} 2.3 & -9 \\ 38.1 & -48 \end{vmatrix}}{\begin{vmatrix} -40 & -9 \\ 45 & -48 \end{vmatrix}} = \frac{232.5}{2325} = 0.10.$$

Similarly write and solve the determinant for M:

$$M = \frac{\begin{vmatrix} 1 & 1 & 1 \\ 7.7 & 50 & 1 \\ 11.9 & 5 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 1 & 1 \\ 10 & 50 & 1 \\ 50 & 5 & 2 \end{vmatrix}} = \frac{\begin{vmatrix} 42.3 & -49 \\ -6.9 & -3 \end{vmatrix}}{\begin{vmatrix} 40 & -49 \\ -45 & -3 \end{vmatrix}} = \frac{-465}{-2325} = 0.20.$$

Since $F = 1$, $T = 1 - (0.10 + 0.20) = 0.7$

Recovery of lead in lead concentrate $= \dfrac{0.1 \times 50}{1 \times 7.7} = 64.9$ per cent.

Recovery of zinc in zinc concentrate $= \dfrac{0.2 \times 50}{1 \times 11.9} = 84.1$ per cent.

Ratio of concentration: lead $= F/C = 1/0.1 = 10$; zinc $= F/M = 1/0.2 = 5$.

18. N-product formulas

When any number of products, say n, are made, formulas giving the weights of each in terms of the weight of feed, the recovery, and the ratio of concentration, may be written by the method illustrated in the preceding article, and these formulas may be solved provided accurate assays of the feed and all of the products are given in $n - 1$ independent ways. The formulas, however, become so long and involved that it is usually simpler to write the simultaneous equations with the numerical values inserted and solve for the percentage weights by determinants, as illustrated in the preceding paragraph. Thus for four products C, S, M, T whose corresponding assays in three metals a, b and c are c_a, c_b, c_c; s_a, s_b, s_c; m_a, m_b, m_c; t_a, t_b, t_c; made from a feed F whose assay is f_a, f_b, f_c, the formula for C is

$$C = F\left[\frac{\left\{\begin{aligned}&(s_c-t_c)(m_a-f_a)(t_b-m_b)-(t_a-m_a)(s_c-t_c)(m_b-f_b)\\ &\quad+(m_b-f_b)(t_c-m_c)(s_a-t_a)-(m_a-f_a)(t_c-m_c)(s_b-t_b)\\ &\quad+(t_a-m_a)(s_b-t_b)(m_c-f_c)-(t_b-m_b)(s_a-t_a)(m_c-f_c)\end{aligned}\right\}}{\left\{\begin{aligned}&(s_c-t_c)(m_a-c_a)(t_b-m_b)-(t_a-m_a)(s_c-t_c)(m_b-c_b)\\ &\quad+(m_b-c_b)(t_c-m_c)(s_a-t_a)-(m_a-c_a)(t_c-m_c)(s_b-t_b)\\ &\quad+(t_a-m_a)(s_b-t_b)(m_c-c_c)-(t_b-m_b)(s_a-t_a)(m_c-c_c)\end{aligned}\right\}}\right]. \qquad (35)$$

The formulas for S, M and T may be written from equation (36) by symmetry, *e.g.*, $S = F[X/Y]$ in which X is obtained from the numerator of (36) by substituting f for s, wherever the latter appears and substituting c in place of f. Thus the first term of the numerator becomes $(f_c - t_c)(m_a - c_a)\ (t_b - m_b)$.

By similar substitution, the first term in the formula for M, is $(s_c - t_c)$ $(f_a - c_a)\ (t_b - f_b)$, and for T it is $(s_c - f_c)\ (m_a - c_a)\ (f_b - m_b)$. Y is the same as the denominator of equation (36) in all cases.

Example of the use of determinants for a 4-product problem follows: Given assays as in Table 16, write the equations in the following form:

Table 16. Specimen assays for 4-product determinant solution

	Per cent. Pb	Per cent. Zn	Per cent. Cu
Feed	7.1	5.7	2.26
Lead concentrate	60	1	1
Zinc concentrate	1	40	1
Copper concentrate	2	2	10
Tailing	1	2	0.1

	Feed		Lead conc.		Zinc conc.		Copper conc.		Tailing
Weight equation:	F	=	C	+	S	+	M	+	T
Lead equation:	7.1 F	=	60 C	+	S	+	2 M	+	T
Zinc equation	5.7 F	=	C	+	40 S	+	2 M	+	2 T
Copper equation:	2.26 F	=	C	+	S	+	10 M	+	0.1 T

Then

$$C = \frac{\begin{vmatrix} 1 & 1 & 1 & 1 \\ 7.1 & 1 & 2 & 1 \\ 5.7 & 40 & 2 & 2 \\ 2.26 & 1 & 10 & 0.1 \end{vmatrix}}{\begin{vmatrix} 1 & 1 & 1 & 1 \\ 60 & 1 & 2 & 1 \\ 1 & 40 & 2 & 2 \\ 1 & 1 & 10 & 0.1 \end{vmatrix}} = \frac{\begin{vmatrix} -6.1 & 1 & -1 \\ 34.3 & -38 & 0 \\ -1.26 & 9 & -9.9 \end{vmatrix}}{\begin{vmatrix} -59 & 1 & -1 \\ 39 & -38 & 0 \\ 0 & 9 & -9.9 \end{vmatrix}} = \frac{\begin{vmatrix} 197.5 & -38 \\ -53.64 & -0.9 \end{vmatrix}}{\begin{vmatrix} 2203 & -38 \\ -531 & -0.9 \end{vmatrix}} = \frac{2216.07}{22160.7} = 0.10$$

Similarly $S = 0.10$, $M = 0.20$ and $T = 0.60$. From these values the recovery of each metal in its respective concentrate and the respective ratios of concentration may be written.

Limitations of multi-product formulas. The formulas above given are theoretically correct, but the accuracy of the answers that they give is, of course, wholly dependent upon the accuracy of the sampling and assaying. The formulas for two-product treatment are not particularly sensitive to small errors in data or calculation, hence recovery and weight of concentrate should check smelter returns (or their equivalent). If they do not check, mill operation should be examined for spills, losses, hold-backs as in tanks, etc., and shipping and smelter sampling should be carefully analyzed.

The formulas for three or more products are more sensitive to small errors both in data and calculation, especially when one of the products is of relatively small weight and low assay.

Fry (*114 J 493*) cites an example of the effect of such errors. His actual assays and assumed erroneous assays together with weights of products calculated from both by determinants, using the four possible equations three at a time, are shown in Table 17. The

Table 17. Possible effect of small errors in assaying and sampling on calculated weights in 3-product concentration. (Assays from *Fry, 114 J 493*)

	Pb, per cent.	Zn, per cent.	Ag, ounces per ton	Calculated weights, per cent., Data used(a) WLZ	WLS	WZS	LZS
Actual assays:							
Feed	11.34	31.85	13.2	100.69	100.4	100.0	102.84
Lead concentrate	21.4	9.1	25.1	39.93	40.4	40.0	39.74
Zinc concentrate	5.4	56.2	6.2	50.9	50.0	50.0	49.68
Tailing	0.8	1.1	0.6	9.86	10.0	10.0	13.42
Possible erroneous assays:							
Feed	11.3	31.8	13.3	99.93	100.07	....	....
Lead concentrate	21.3	9.0	25.0	39.93	12.17	....	....
Zinc concentrate	5.4	56.0	6.3	50.2	172.2	....	....
Tailing	0.7	1.0	0.7	9.8	−84.3	....	....

a W weight equation. L Lead equation. Z Zinc equation. S Silver equation.

calculated weight of feed in the columns whose heading contains the letter *W* (which indicates that one of the simultaneous equations was $F = L + Z + T$) should, of course, be 100.0. The difference is due to slide-rule discrepancies, which, in some cases may become very important. The difference between the calculated weight and 100 in the last column measures the effect of both assays and slide rule. It will be noted that the errors that Fry assumed made but little difference in calculated weights in the case where the silver assay was not used, but that impossible results were obtained when the erroneous silver assays were included in the calculation.

Graphical solution. Fig. 34 shows a method, proposed by Fry, for a graphical solution designed to point out inaccuracies in sampling and assaying and at the same time average them, if they are not too large to be averaged. The chart is constructed as follows: Assume two values for the weight of tailing (T), one less than the probable, the other more. Using these assumed values, *e.g.*, in the case of the erroneous assays given, 5 and 15 per cent., write equations in L (weight of lead concentrate) as follows:

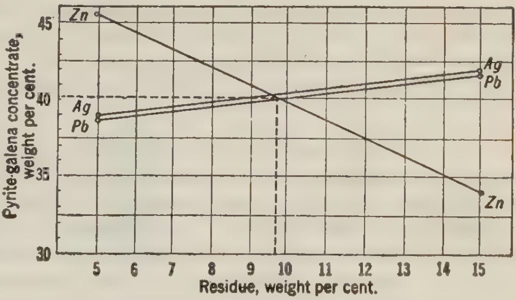

FIG. 34.—Graphical solution of 3-product problem.

Using the zinc assays,

$$31.8\ (100) = 9L + 56\ (95 - L) + \ (5)\ (1),\text{ from which } L = 45.6.$$
$$31.8\ (100) = 9L + 56\ (85 - L) + (15)\ (1),\text{ from which } L = 33.9.$$

Using the lead assays,

$$11.3\ (100) = 21.3L + 5.4\ (95 - L) + \ 5\ (0.7)\text{ from which } L = 38.6.$$
$$11.3\ (100) = 21.3L + 5.4\ (85 - L) + 15\ (0.7)\text{ from which } L = 41.6.$$

Using the silver assays,

$$13.3\ (100) = 25L + 6.3\ (95 - L) + \ 5\ (0.7)\text{ from which } L = 38.9.$$
$$13.3\ (100) = 25L + 6.3\ (85 - L) + 15\ (0.7)\text{ from which } L = 41.9.$$

Plot the assumed values of T as abscissas and the derived weights of L as ordinates and connect the corresponding values with straight lines. Read the mean of the two intersections as mean values of L and T. In this case L was read off as 40.1 and T as 9.65 which gave Z (weight of zinc concentrate) 50.25 by difference.

19. Applications of formulas

The most usual applications of the formulas are to control the operations of individual machines and of the whole mill and to check smelter returns. If feed is weighed in automatically and accurate moisture determinations are made, the calculated weight of concentrate over a period such as a month should check dry weight of concentrate shipped within reasonably close limits, and, over a period of a year should check very closely. Discrepancy in one direction only should be closely investigated; differences should be both positive and negative over a period of time.

In mills where the feed is not weighed, tailing should be time-sampled. Weights of concentrate and tailing may then be calculated and the former weight checked against the shipping weight.

As indicated in the introductory paragraph, the two-product formulas may be applied to investigations of the performance of screens and two-product classifiers. (See also Sec. 5, Art. 2.) In these cases the assays are usually screen analyses. The size split for statement of assays should be a screen that gives 5 per cent., or more if possible, as the minimum assay used. Ordinarily cumulative percentages on or through the key screen are chosen as the assays rather than individual percentages. For another formula for investigating classifier performance, see equation (38).

In laboratory testing three products are usually made, *viz.*: concentrate, middling and tailing. As discussed in Art. 16, some assumption must be made with respect to middling distribution, if the two-product formulas are to apply. In flotation testing it is ordinarily justifiable to assume that retreatment of middling would not affect primary concentrate or tailing assays, but the same assumption cannot ordinarily be made in gravity concentration.

Efficiency of concentration. It is apparent from inspection of the two-product formulas for recovery and ratio of concentration that if all of the feed were merely shoveled to one side and called concentrate, the recovery would be 100 per cent. The ratio of concentration would be 1, which would, of course, tell what had been done. This shows that recovery and ratio of concentration, or, at least, assay of concentrate, must be stated together in order that the figures may give a measure of the efficiency of the concentrating operation. Several proposals (see Art. 28) have been made to combine the numerical values of recovery and ratio of concentration, or ratio of assay of concentrate to assay of feed or tailing into one number called an efficiency index. Hancock (*19 MM 144*; *109 J 842*) proposes a number derived like that for classifier efficiency (E) (Art. 20). No proposal, however, shows a logical method of combination or one that has a physical significance that can be visualized. Hence it is better to give the two numbers, as is usual.

20. Formulas for classifier efficiency

Equation (10) may be, and ordinarily is used, together with equation (9) to give an idea of the relative amounts of sand discharge and overflow. Dean proposed defining CLASSIFIER EFFICIENCY as the ratio, expressed as percentage, of the weight of classified material in the overflow to the weight of classifiable

material in the feed. Overflow having the same sizing test as the feed is not said to be "classified material." Thus, if the separating size were 35-mesh and 100 tons of classifier feed contained 50 per cent. of −35-mesh material while the 50 tons of classifier overflow contained 90 per cent. −35-mesh, the 5 tons of +35-mesh in the overflow plus 5 tons of −35- mesh would comprise 10 tons of overflow of the same size composition as the feed. The net classified material in the overflow would, then, be 40 tons and efficiency, $E = 100 \times 40/50 = 80$ per cent. This can be expressed in terms of assays alone as follows: Let $100 - f$ = per cent. of oversize in feed, and $100 - c$ = per cent. of oversize in overflow. Then actual weight of oversize in overflow $= (100 - c)C/100$, and

$$E = \frac{C - \dfrac{(100 - c)C}{100 - f}}{\dfrac{fF}{100}} = 100\frac{C}{F} \cdot \frac{(c - f)}{f(100 - f)}. \quad . \quad . \quad . \quad (37)$$

But $C/F = (f - t)/(c - t)$. Substituting this value for C/F in equation (37),

$$E = \frac{100(c - f)(f - t)}{f(100 - f)(c - t)}. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (38)$$

In the example in the preceding text $c = 90$, $t = 10$ and $f = 50$, whence $E = 80$ per cent. If the finished product contains only desired material, *i.e.*, $c = 100$, this equation becomes the same as the two-product recovery formula (10).

If this formula is used for concentrating operations, assays should be expressed as percentages of valuable mineral rather than as percentages of metal, otherwise the operation is penalized (*i.e.*, efficiency is low) because it does not separate metal from the chemically-combined elements.

Screen efficiency. Usual method of determination is to apply formula (10). Formula (38) may also be used.

21. Tonnages in milling circuits

Tonnages may frequently be determined by application of the two-product formulas (9) and (10). Fig. 35 shows four typical closed crushing circuits.

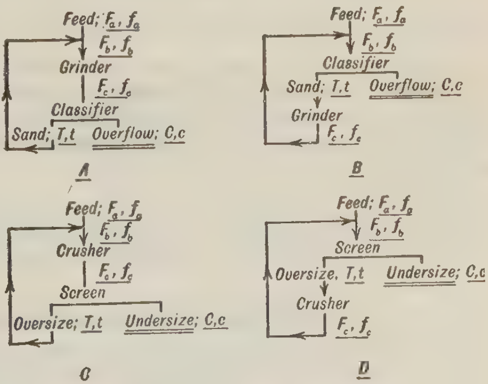

Fig. 35.—Typical closed crushing circuits.

In Fig. 35, *A*: $K = F_c/C = (c - t)/(f_c - t)$ from Eq. 9. But $C = F_a$. Hence, $F_c = F_a(c - t)/(f_c - t) = F_b$. And,

$$T = F_c - C = \frac{F_a(c - t)}{(f_c - t)} - F_a = \frac{F_a(c - f_c)}{(f_c - t)}.$$

Also $f_b = (F_a f_a + Tt)/(F_a + T)$.

In Fig. 35, B: $K = F_b/C = (c - t)/(f_b - t)$ from Eq. 9. But $C = F_a$, hence $F_b = F_a(c - t)/(f_b - t)$; and

$$T = F_c = F_b - C = F_b - \frac{F_b(f_b - t)}{c - t} = \frac{F_b(c - f_b)}{c - t}.$$

$$f_b = \frac{F_a f_a + F_c f_c}{F_a + F_c}. \qquad F_c = \frac{F_a(f_a - f_b)}{f_b - f_c}.$$

From inspection of the figure, $F_a f_a + F_c f_c = T_t + C_c$. But $F_c = T$ and $F_a = C$, hence $T(f_c - t) = F_a(c - f_a)$, and $T = F_a(c - f_a)/(f_c - t)$.

Adding C to both sides of the preceding equation, $T + C = F_a(c - f_a)/(f_c - t) + C$. But $T + C = F_b$ and $C = F_a$,

hence $F_b = F_a \left(\frac{c - f_a}{f_c - t} + 1\right)$.

By inspection of Fig. 35, B: $F_b f_b = F_a f_a + F_c f_c$.

$$f_b = \frac{F_a f_a + F_c f_c}{F_b} = \frac{F_a f_a + \frac{F_a(c - f_a) f_c}{(f_c - t)}}{F_a\left(\frac{c - f_a}{f_c - t} + 1\right)} = \frac{c f_c - t f_a}{c - f_a + f_c - t}.$$

$$f_c = \frac{F_a(c - f_a - t) + F_b t}{F_b - F_a}.$$

$$f_a = \frac{f_c(f_b - c) + f_b(c - t)}{f_b - t} = c + (f_c - t)[1 - F_b/F_a].$$

By equation (10) the value of R in Fig. 35, B, is $R = c(f_b - t)/f_b(c - t)$. Substituting in this equation the value of f_b, $R = \dfrac{c(f_c - t)}{c f_c - t f_a}$.

Tonnages in closed circuits may be estimated from sizing tests of the feed and product of a crusher on single pass by reckoning the percentage (r) of the original feed weight (a) requiring crushing (*i.e.*, with fines eliminated) that failed to be reduced on the first pass, by means of the formula for the sum of a geometric series, *viz.*: $S = a/(1 - r)$.

Thus if 100 tons per day feed to a set of rolls contained 30 tons undersize of the limiting screen, $a = 70$, and if the product of a single pass showed 65 tons undersize, $r = 35/70 = 0.5$, and S (total feed to the rolls per 24 hr.) $= 30 + 70/(1 - 0.5) = 170$. If the screen returns some undersize with the oversize, r must be increased accordingly. For another method of calculation, see *112 J 1050*.

22. Formulas involving sorting, roughing, etc.

The following formulas are useful to determine the monetary saving to be expected from sorting, roughing or other treatment in which a finished product, either concentrate or tailing, is to be removed in advance of the place that it is removed in the treatment scheme taken as standard.

Removal of concentrate. When the material to be removed is finished concentrate, let H and h = weight in tons and assay respectively of original feed; P and p = weight in tons and assay respectively of the concentrate to be produced by the proposed new operation; M and m = weight in tons and assay respectively of the residue from the proposed new operation, T = tons of final mill tailing without the new operation, T' = tons of final

mill tailing to be produced from M tons of residue from the new operation, C = tons of mill concentrate under normal operation and C' = tons of mill concentrate to be produced from M tons of residue from the new operation; c and t = assay respectively of C, C' and T, T'; V = value in dollars per unit of metal in concentrate to be produced by the new operation; V' = value in dollars per unit of metal in mill concentrate produced by either operation, R = cost of new operation in dollars per ton of concentrate produced thereby (P); S = cost in dollars per ton of milling H tons of original ore; and S' = cost in dollars per ton of milling M tons of residue from the new operation.

The assumption that the assays of tailing and concentrate made from original and sorted ore would be the same is justified by experience to the effect that relatively small changes in the tonnage or assay of mill feed have little effect on the assays of mill products. The values assigned to V and V' should be net and should take full account of penalties, freight, smelting charges, etc.

If the proposed operation is employed, the net return from P tons of concentrate so produced is its value less its cost of production $= PpV - PR$. Return from milling M tons of residue $= C'cV' - MS'$, and total return $= P(pV - R) + C'cV' - MS'$.

If the operation is omitted and the total feed is subjected to the same treatment that M is subjected to above, the return $= CcV' - HS$.

The saving in dollars (or loss, if the sign is negative) to be expected from adoption of the proposed operation

$$= [P(pV - R) + C'cV' - MS'] - (CcV' - HS).$$

The SAVING PER TON OF ORIGINAL FEED is

$$= \frac{P}{H}(pV - R) - cV'\left(\frac{C}{H} - \frac{C'}{H}\right) - \frac{M}{H}S' + S. \quad . \quad . \quad . \quad (39)$$

But $P/H = (h - m)/(p - m)$, from (9); $C/H = (h - t)/(c - t)$, from (9); $M/H = (p - h)/(p - m)$ (from the relation $M = H - P$); $C' = M(m - t)/(c - t)$, from (9). Then

$$\frac{C'}{H} = \frac{M}{H}\left(\frac{m - t}{c - t}\right) = \left(\frac{p - h}{p - m}\right)\left(\frac{m - t}{c - t}\right),$$

whence, by substitution of the above values in equation (39) the SAVING PER TON OF ORIGINAL MATERIAL to be expected from installation of the proposed process

$$= \frac{(h - m)(pV - R) - (p - h)S'}{p - m} - cV'\left[\frac{h - t}{c - t} - \frac{(p - h)(m - t)}{(p - m)(c - t)}\right] + S. \quad (40)$$

Removal of waste. If, instead of concentrate, W tons of waste assaying w is discarded at a cost of R dollars per ton discarded, then when the new operation is employed, the loss due to discarding waste is $= WwV' + WR$, and the return from milling the remainder $= C'cV' - MS$. Net return $= C'cV' - MS - W(wV' + R)$.

If the proposed operation is omitted, the net return $= CcV' - HS$, whence saving (or loss, if of negative sign) to be expected from installation of the new operation $= C'cV' - MS' - W(wV' + R) - CcV' + HS$.

SAVING PER TON OF ORIGINAL MATERIAL

$$= S - cV'\left(\frac{C}{H} - \frac{C'}{H}\right) - \frac{M}{H}S' - \frac{W}{H}(wV' + R).$$

Substituting assay values, as in the preceding development, the saving per ton of original material

$$= S - cV'\left[\frac{h-t}{c-t} - \frac{(m-t)(h-w)}{(c-t)(m-w)}\right] - \frac{(h-w)S' + (m-h)(wV'+R)}{m-w}. \quad (41)$$

Saving (or loss) to be expected from cleaning a salable product instead of shipping directly may be obtained by a similar method of analysis.

Let H' = tons of material, h' = assay of H', C' = tons of cleaned product, c' = assay of C', T' = tons of material that will be reject of the cleaning operation, t' = assay of T', R = cost of treatment in dollars per ton of H', V = value, in dollars per unit of metal, of C'; V' = value, in dollars per unit of metal, of H'.

If the material is shipped directly, the return $= H'h'V'$. If cleaning is practiced, the return $= C'c'V - H'R$.

Saving (or loss, if negative) to be expected from the proposed cleaning operation $= (C'c'V - H'R) - H'h'V' = C'c'V - H'(R + h'V')$.

Saving per ton of original material

$$= \frac{C'c'V}{H'} - (R + h'V') = \frac{c'V(h'-t')}{c'-t'} - (R + h'V'). \quad . \quad . \quad (42)$$

Saving to be expected by further treatment of a tailing product is the excess value of the concentrate produced by the treatment over the cost of treatment.

If H'' = tons of original tailing, C'' = tons of additional concentrate produced by further treatment of H'', T'' = tons of cleaned tailing, h'', c'', t'' = assays of H'', C'' and T'', respectively, R = cost of treatment per ton of H'', V = value in dollars per unit of metal in the concentrate C''.

Then profit (or loss, if of negative sign) to be expected from the proposed additional treatment $= C''c''V - H''R$

Profit per ton of original material (H'')

$$= \frac{C''}{H''}c''V - R = \frac{c''(h''-t'')}{c''-t''}V - R. \quad . \quad . \quad . \quad . \quad (43)$$

23. Specific-gravity assay

When an ore is a mixture of two minerals only or of one valuable mineral and a mixture of gangue minerals whose relative proportions are substantially constant, it is possible to make rapid approximate assays of a mixture of valuable mineral and gangue by determining the specific gravity of the mixture, provided the individual specific gravities of valuable mineral and gangue are already known. The usual method is by use of a specific-gravity flask.

Weigh the flask empty and when full of water. Dry the flask, introduce the ore sample, weigh; fill with water, taking care to remove all air bubbles, and again weigh. In centimeter-gram units, if S_o = specific gravity of ore, S_m of "mineral" and S_g of gangue; F = weight of dry flask, W = weight of water required to fill the flask, O = weight of dry ore, and T = total weight of flask + ore + water, then the weight of water required to fill the flask, with ore in it $= T - (O + F)$ = volume of water in flask, and volume of ore in flask $= W - [T - (O + F)]$.

$$S_o = \frac{O}{W - [T - (O+F)]} = \frac{O}{F + W + O + T} \quad . \quad . \quad . \quad (44)$$

If m = per cent. of "mineral" in ore = weight of mineral per unit weight of ore; $1 - m$ = per cent. of gangue; m/S_m = volume of "mineral" per unit weight of ore; $(1 - m)/S_g$ = volume of gangue per unit weight of ore; $1/S_o$ = volume of unit weight of ore.

Then $\dfrac{m}{S_m} + \dfrac{1 - m}{S_g} - \dfrac{1}{S_o} = 0$, and

$$m = \frac{S_m(S_o - S_g)}{S_o(S_m - S_g)}. \qquad (45)$$

24. Cyanidation

Let F weight of feed = 1; C = weight of concentrate (if made), T = weight of tailing from concentrating operation (= F, if no concentrate is made), A = weight of sand feed, B = weight of slime feed, X = weight of sand tailing and Y = weight of slime tailing, all expressed as decimal parts of F; and f, c, t, a, b, x and y = respective assays of the above products.

Then $F = C + T$; $T = A + B$; $f = cC + tT$; $Tt = aA + bB$; $Tt = f - cC$. But $T = F - C = 1 - C$. Hence $(1 - C)t = f - cC$ and

$$C = (f - t)/(c - t). \qquad (46)$$

Similarly

$$T = (c - f)/(c - t). \qquad (47)$$

$Aa = Tt - Bb$. But $B = T - A$, hence $Aa = Tt - (T - A)b$, and $A/T = (t - b)/(a - b)$. Substitute value of T from (Eq. 47), then

$$A = \frac{(c - f)(t - b)}{(c - t)(a - b)}, \qquad (48)$$

$$B = T - A = \frac{c - f}{c - t} - \frac{(c - f)(t - b)}{(c - t)(a - b)} = \frac{(c - f)(t - a)}{(c - t)(b - a)}. \qquad (49)$$

$R = [Cc + (Aa - Xx) + (Bb - Yy)]/Ff$. But $F = 1$, and for all practical purposes, $A = X$ and $B = Y$. Hence, substituting A for X and B for Y and then substituting for C, A and B their equivalents in terms of assays above given, and clearing

$$R = \frac{c(f - t) + \dfrac{c - f}{a - b}[(t - b)(a - x) - (t - a)(b - y)]}{f(c - t)}. \qquad (50)$$

25. Voids

Let w = weight of solid per unit volume. If material is moist, let w include also the weight of moisture. Let S = sp. gr. of dry solid, p = per cent. solids, V = PERCENTAGE OF VOIDS = percentage of unit volume unoccupied when that volume contains the weight w of solid or solid + water; B = per cent. of unit volume occupied by air, H = per cent. occupied by water and T = per cent. occupied by air + water. Quantities p, V, B, H and T are expressed as decimal parts of the unit, and gram-centimeter units are most readily used.

For dry material,

$$V = 1 - w/S. \qquad (51)$$

For wet material pw = weight of dry solid in unit volume; pw/S = volume of solid; and

$$T = 1 - wp/S. \qquad (52)$$

The weight of water in a weight w of wet material $= w - pw$. Since the numbers representing weight and volumes of water are interchangeable in gram-centimeter measure,

$$H = w(1 - p). \qquad (53)$$

$$B = T - H = \frac{wp(S - 1) - S(w - 1)}{S} \qquad (54)$$

Voids in broken rock smaller than 3-in. range between 40 and 45 per cent. when fines are present and 45 to 50 per cent. with fines removed. (*Bul. 5 UI No. 23.*)

Specific volume is defined as the weight of dry solid per unit volume of broken solid and is commonly stated in lb. per cu. ft. If Q = specific volume in gram-centimeter units, m = percentage of moisture in the mass of broken solid by weight, and v = percentage moisture by volume, then the volume of actual solid + water per unit volume of broken material $= 1 - V$ and the actual solid in this weight is $Q = S(1 - V)(1 - v)$. But $v = \dfrac{mS}{mS + 1 - m}$ (from Eq. 66), hence

$$Q = S(1 - V)\left[\frac{1 - m}{m(s - 1) + 1}\right] \qquad (55)$$

In common units this becomes

$$Q = 62.5S(1 - V)\left[\frac{1 - m}{m(S - 1) + 1}\right] \text{ lb. per cu. ft.} \qquad (56)$$

26. Pulp consistency

Let p = PER CENT. SOLIDS = weight of solids in unit weight of pulp; D = DILUTION, = water-solid ratio = parts water, by weight, per part of solid, usually written, *e.g.*, 6 : 1, 3.2 : 1, etc.; S = specific gravity of dry ore; d = specific gravity of pulp.

Then p/S = volume of solids in unit weight of pulp, $1 - p$ = volume of water in unit weight of pulp, $1/d$ = volume of unit weight of pulp, and $p/S + 1 - p = 1/d$, from which

$$d = \frac{S}{p + S(1 - p)} = \frac{S}{S - p(S - 1)} = \frac{D + 1}{D + \frac{1}{S}}, \qquad (57)$$

$$p = \frac{S(d - 1)}{d(S - 1)} = \frac{1}{D + 1}, \qquad (58)$$

$$S = \frac{dp}{1 - d(1 - p)} = \frac{d}{1 - D(d - 1)}, \qquad (59)$$

$$D = \frac{1 - p}{p} = \frac{S - d}{S(d - 1)} = \frac{1}{p} - 1. \qquad (60)$$

The relations between p, S and d are shown graphically in Fig. 36.

If Z = SOLID FACTOR = tons solid per FLUID TON (= 32 cu. ft.) of pulp; G = fluid tons of pulp per ton of dry solids; and q = per cent. solids by volume, then, since the weight of 1 cu. ft. of pulp = 62.5 d lb., the weight of one fluid ton = 32 × 62.5 d and

$$Z = \frac{32 \times 62.5d \times p}{2000} = pd. \qquad (61)$$

By substitution in equation (61) of values of p and d from equations (57) to (60),

$$Z = \frac{d}{D+1} = \frac{pS}{S - p(S-1)} = \frac{S}{DS+1} = \frac{S(d-1)}{S-1} \quad . \quad . \quad (62)$$

By definition $G = 1/Z$. Hence, by equations (61) and (62)

$$G = 1/pd = (D+1)/d. \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (63)$$

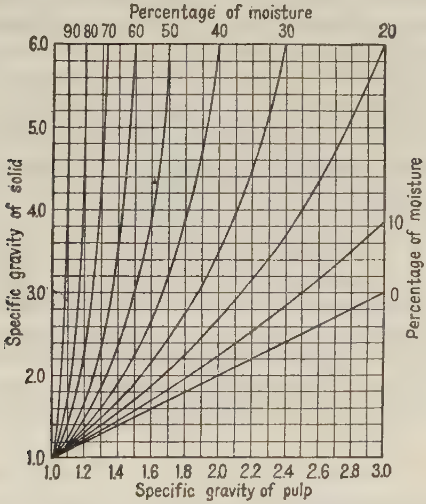

FIG. 36.—Relation between percentage of solids and specific gravity of ore pulps.

By definition $q = \dfrac{Z(2000)}{S(62.5 \times 32)} = Z/S$, hence, by equations (57) and (62),

$$q = \frac{d-1}{S-1} = \frac{p}{S - p(S-1)}. \quad . \quad . \quad . \quad . \quad (64)$$

27. Counting assay

If all particles are of substantially the same shape (that they are of substantially the same intermediate dimension may be assured by sizing), the volume percentages are equal to the number percentages. If there is a distinct difference in average shape of particles, the number percentages must be adjusted by factors expressing relative volumes of the mean shapes, in order to get volume percentages. If v = per cent. by volume of "mineral" in sample = volume per unit volume and S_m and S_g = specific gravities of "mineral" and gangue respectively, then weight of "mineral" in a unit volume of sample = vS_m and weight of gangue = $(1 - v)S_g$. The percentage of mineral by weight is

$$m = \frac{vS_m}{vS_m + (1-v)S_g} = \frac{vS_m}{v(S_m - S_g) + S_g}, \quad . \quad . \quad . \quad . \quad (65)$$

$$v = \frac{mS_g}{mS_g + S_m(1-m)} \quad . \quad . \quad . \quad . \quad . \quad (66)$$

These formulas are applicable to the case of mixtures of solid and water, in which case, if m and v are taken as percentages of solid, S_m is specific gravity of solid and $S_g = 1$.

28. Efficiency in coal washing

In coal washing, efficiency is judged on somewhat different grounds from those used in metal concentration and hydrometallurgy. In these latter processes the valuable material is a definite substance (metal) that can be accurately measured by assay, and, so measured, has definite significance. But the combustible material in coal is not so definitely measurable and it is never, practically, completely separable from the non-combustible, so that clean coal is not clean combustible but rather a mixture of "middlings" of varying fuel value from the cleanest that can be obtained to the dirtiest that can be sold.

Recovery. The assays made are usually for impurities, *i.e.*, ash and sulphur. If sulphur is reckoned as combustible,

$$R = \frac{(1 - c_1)(t_1 - h)}{(1 - h_1)(t_1 - c_1)}, \quad \ldots \ldots \quad (67)$$

where h_1, c_1, and t_1 are assays for ash in raw coal, washed coal and refuse respectively. If sulphur is reckoned as non-combustible, h_1, c_1 and t_1 must be taken as the sum of the percentages of sulphur and ash in the respective products.

Tonnage calculations may be made by the formula

$$X = \frac{t_1 - h_1}{t_1 - c_1}, \quad \ldots \ldots \quad (68)$$

where X = percentage weight of washed coal. $100/X$ = the ratio of concentration (page 1235).

Dodds (*23 CA 635*) points out that if sulphur and ash concentrate in different proportions in the washing process the tonnages calculated by equation (68) will differ according to whether ash or sulphur or the sum of the assays is used and that the latter gives the correct result.

Percentages of reduction of ash and of sulphur effected are used as measures of efficiency. These percentages are expressed as the difference between the respective percentages in raw and clean coal divided by the percentage in raw coal. It is not possible to effect 100 per cent. reduction of either substance by mechanical means.

Sink-and-float tests. On the basis of sink-and-float tests (Art. 10), the percentage of the total raw coal that will float in a solution, the specific gravity of which is that of the maximum specific gravity of salable coal (PERMISSIBLE DENSITY) represents the highest possible percentage recovery of salable coal, and the percentage of total combustible therein contained represents maximum recovery of combustible. No commercial process of extraction will reach this maximum and, therefore, if it is set equal to 100 per cent., the actual performances may be stated as percentages thereof.

Drakeley efficiency formulas. If X = weight of washed coal expressed as percentage of raw coal; a = weight of CLEAN COAL (*i.e.*, float in the solution whose specific gravity is such that it floats a coal of maximum salable ash content) expressed as a percentage of the weight of raw coal treated; and

b = percentage weight of clean coal in the washed coal (determined by a sink-and-float test), recovery

$$R' = 100Xb/a. \qquad (69)$$

This number according to Drakeley (*54 IME 428*) is the QUANTITATIVE EFFICIENCY. Drakeley suggests the term QUALITATIVE EFFICIENCY (Q) to express the relation

$$Q = 100(b - a)/(100 - a), \qquad (70)$$

and the term GENERAL EFFICIENCY to express the relation

$$G = R'Q/100. \qquad (71)$$

This attempt to combine recovery and a number akin to the ratio of concentration in metal concentration, is similar to attempts that have been made in the latter art, and no more successful. Such a number has no physical significance but merely relative value, and its magnitude, depending although it does on the product of two significant numbers, may be the same with a low value of R' and high value of Q or the reverse or with intermediate values of both, and is, therefore, not even numerically significant.

Delameter efficiency formulas. If E = percentage efficiency, a = percentage weight of raw coal floated on the PERMISSIBLE BATH (heavy solution that floats coal of permitted ash content), b = ratio of weight of washed coal to raw coal, expressed as percentage, d = percentage of ash in raw coal, e = percentage of ash in permissible float from raw coal, and f = percentage of ash in washed coal, Delameter proposes (*5 CA 723*) the following formulas for efficiency.

(1) If $f > e$ and $b = a$; $$E = (d - f)/(d - e). \qquad (72)$$

(2) If $f > e$ and $b > a$; $$E = \frac{1}{2}\left(\frac{b - a}{100 - a} + \frac{d - f}{d - e}\right). \qquad (73)$$

(3) If $f \ll e$ and $b \ll a$; $$E = \frac{1}{2}\left(\frac{f}{e} + \frac{b}{a}\right). \qquad (74)$$

(4) If $f > e$ and $b < a$; $$E = \frac{1}{2}\left(\frac{d - f}{d - e} + \frac{b}{a}\right). \qquad (75)$$

Formula (72) gives a true efficiency number based on percentage ash reduction. The first term in the numerator of formula (73) is roughly the percentage weight of the total sink fraction of the raw coal that appears in the washed coal. For perfect work the first term of the numerator should be zero and the second term one, in which case $E = 1/2$. This is clearly not a significant efficiency number since the same value for E would be obtained if both terms in the numerator equaled 1/2, which would, of course represent very poor work. Equation (74) gives $E = 1$ corresponding to perfect work and is, to that extent, a significant efficiency number. It also measures, within the limits set, the approach to two important goals in washing operations. Equation (75) likewise gives $E = 1$ for perfect work.

The great weakness of the equations is the fact that it is necessary to specify which equation has been used in determining the efficiency number stated for any given operation and also to give the values for a, b, d, e and f, in order that their relative effects may be judged; hence the efficiency number alone is in no case significant.

Fraser and Yancey. (*69 A 456*) propose the efficiency formula

$$E = \frac{YR}{Y_1R_1} = \frac{(c - a)(a - b)}{B(c - b)(a - f)}. \qquad (76)$$

where Y = the actual yield of washed coal = (*weight of washed coal*)/(*weight of raw coal*); Y_1 = standard yield = (*weight of raw-coal float*)/(*weight of raw coal*); R = actual ash reduction, per cent.; R_1 = standard ash reduction, based on sink-and-float test on raw coal, per cent.; a = per cent. of ash in raw coal; b = per cent. of ash in washed coal; c = per cent. of ash in refuse; f = per cent. of ash in raw-coal float; and B = weight of raw-coal float.

This number suffers from the disadvantage that, although perfect work gives $E = 1$, the same value may be obtained when $R/R_1 < 1$, if, at the same time $Y/Y_1 > 1$, both of which suppositions will commonly occur.

Hamilton (*69 A 475*) proposes

$$E = \frac{a(100 - c)}{b},$$

where a = per cent. of ash in raw-coal float, b = per cent. of ash in washed coal, and c = per cent. of clean coal lost = per cent. of refuse $\times$ per cent. of float in refuse. When $a = b$ and $c = o$, which represents perfect work, $E = 100$.

The weakness of this equation lies in the fact that it does not measure the recovery of combustible and that loss of clean coal does not penalize the efficiency number to anything like the same extent that it is penalized by failure to reduce ash.

Hancock (*69 A 476*) proposes the formula

$$E = \frac{I_r - YI_w}{I_r}, \quad \ldots\ldots\ldots \quad (77)$$

where I_r = per cent. of a given impurity in the raw coal, I_w = per cent. of the same impurity in the washed coal and Y = yield = (*weight of washed coal*)/(*weight of raw coal*).

This formula merely measures the efficiency of the operation in reduction of impurity with no penalty for loss of coal, in fact, if $Y = 0$ in the equation, $E = 1$.

Lincoln (*11 Bul. UI, No. 9*) suggests assaying the washed products by sink-and-float methods and calling half of the sum of the percentage float in the coal and sink in the ash the efficiency.

When the figure thus obtained is high, it has definite and useful significance, but otherwise it does not tell whether the performance fails to be good by reason of low-grade coal or high-grade refuse.

29. Statistical calculation

Numerical data covering mill operations rarely involve two variables only and for that reason the relation of effect to cause cannot be found by the ordinary methods of two-variable investigation such as plotting to rectangular co-ordinates, etc. If the ordinary methods are employed to determine the relation between any two of a number of variables, the investigation involves such doubtful assumptions with respect to the other variables (the usual assumption, *e.g.*, being that their effect is negligible) that the relation evolved is probably wrong and certainly untrustworthy. Thus in any ordinary mill operation of the flotation process, in which the quantity of oil per ton of feed varies from day to day and recovery also varies, direct comparison of recovery with oil quantity involves neglect of other elements of the operation, likewise variable, such as percentage of solids in feed pulp, fineness of grinding, mineral content of feed, grade of concentrate, etc., each of which has an effect on the recovery that cannot, justifiably, be neglected. The method of STATISTICS attempts to solve a situation such as that presented by supplying a

number called the COEFFICIENT OF CORRELATION, that is a measure of the extent of the directness or linearity of the relation between, say, oil quantity and recovery, if all of the other above-mentioned variables were held constant; another number, called the PROBABLE ERROR OF THE PARTIAL COEFFICIENT, that is a measure of the reliability and significance of the first; a third number, called the COEFFICIENT OF MULTIPLE CORRELATION, which measures the approach to directness or linearity of the relation between, say, oil quantity, and all of the other variables considered together; and a fourth number, called the PROBABLE ERROR OF THE MULTIPLE CORRELATION, that measures the reliability and significance of the third.

Notation. Coefficients of partial correlation are indicated by r with suitable subscripts indicating the variables considered. The arrangement of the subscripts is indicative of the nature of the coefficient, thus r_{12} is a SIMPLE OR ZERO-ORDER COEFFICIENT of partial correlation between variables *1* and *2*, in finding which the effect of all other variables has been neglected. When the calculation has been extended, as is explained later, to eliminate the effect of one of the neglected variables, the notation for the FIRST-ORDER COEFFICIENT thus obtained is $r_{12.3}$, etc.

The number $r_{12.3\ldots n}$ is called the coefficient of partial correlation between the variables *1* and *2*, say oil quantity and recovery; $e_{r_{12.3\ldots n}}$ is the probable error in $r_{12.3\ldots n}$; $R_{1(2,3\ldots n)}$ is called the coefficient of multiple correlation between the variable *1* (*e.g.*, oil quantity) and all of the other variables; and $e_{R_{1(2,3\ldots n)}}$ is the probable error in $R_{1(2,3\ldots n)}$.

Coefficient of partial correlation. With data available, as *e.g.*, in Table 18, which represent daily performances of a copper-flotation plant covering the period from Aug. 7, 1916 to March 12, 1917, incl., the first step is to copy these data on cards, one card for each set of figures, *i.e.*, one day in the present case. This is done for ease in compiling the subsequent calculations. Next arrange the cards in order of increase of one of the variables to be investigated.

For example, in the present calculation, the first relation investigated was that between "Lb. of oil per ton" (O) and "Dilution" (D), and the cards were arranged in order of increasing amounts of oil. With the cards thus arranged, Table 19 was built as follows:

The difference between maximum and minimum oil quantities was divided by a number between 15 and 30, chosen primarily to give a quotient easy to add and subtract. The maximum and minimum oil quantities were 3.8 and 0.6 respectively. The difference, 3.2, was divided by 16, which gives a common difference of 0.2. Seventeen classes with this difference embrace the entire range of oil quantity. Table 19 proper was, therefore, divided into 17 vertical columns headed 0.65, 0.85 . . . 3.85 lb.oil per ton as shown. The column headed 0.65 embraces all quantities of oil between 0.55 and 0.75, that headed 0.85 embraces all quantities from 0.75 to 0.95, etc. The cards were next arranged in order of increasing dilution, the range was found to be from 4.8 to 15.8, and an interval difference of 0.4 gave 28 classes or horizontal columns. A blank sheet was next ruled as in Table 19, providing for five columns or lines to the left of and above the double rulings respectively and 17 vertical columns and 28 horizontal lines in the space below and to the right of the double ruling. Vertical columns were headed with the determined oil-quantity means and horizontal lines by dilution means as shown in line O and column D respectively. All cards with values of O between 0.55 and 0.75 were next grouped into values of D corresponding to the means in column D and the number of cards in each group entered in the rectangle corresponding to the corresponding values of O and D. Thus on Aug. 17, Jan. 7 and Jan. 27 the amounts of oil used were 0.7, 0.7 and 0.6 lb. per ton respectively, which group under $O = 0.65$, and the corresponding dilutions were 6.0, 5.4 and 5.2 respectively. These group as one occurrence under $D = 6.1$ and two under $D = 5.3$. The numbers 1 and 2 were, therefore, entered in the corresponding rectangles as described and shown in the table. By similar procedure the other FREQUENCIES were entered in the proper places. The numbers in column "f_D" are the sums of all of the frequencies in the same horizontal line and the numbers in line "f_O," the sums of all the frequencies in the corresponding vertical columns. From inspection of columns "D" and "f_D" the mean value of D is apparently in the range $D = 6.1$. Similarly, the mean value of O appears to be in the range $O = 1.45$.

a Same oil throughout. *b* 100 ÷ per cent. solids.

Assuming, for the present, that these are the correct means, the individual deviations of the other values of D and O, by number of groups, are set down in corresponding files in the vertical column and the horizontal line marked "d_D" and "d_O" respectively. For example, the first number in column d_D is -3, indicating a deviation by three groups, of 0.4 value each, of $D = 4.9$ from $D = 6.1$, the assumed mean. The files marked "fd" show the products of the corresponding values of f and d and the numbers in the files marked "fd^2" are derived from those in files "fd" by multiplying by the corresponding values of d. The DEVIATION (c_O) OF THE TRUE MEAN of the values of O from the assumed mean may now be found by dividing the algebraic sum of file "f_Od_O" by the total number of observations $N(=\Sigma f)$ or $c_O = \Sigma f_Od_O/N = \Sigma f_Od_O/\Sigma f = +8/198 = +0.04$. Similarly $c_D = \Sigma f_Dd_D/N = \Sigma f_Dd_D/\Sigma f = +65/198 = 0.328$. The STANDARD DEVIATIONS, σ_O and σ_D respectively are obtained from the general equation

$$\sigma = \sqrt{\frac{\Sigma fd^2}{\Sigma f} - c^2}. \qquad (78)$$

Totals	198		+65	1929																			901 32 32

Hence $\sigma_O = \sqrt{\frac{1380}{198} - 0.0016} = 2.64$ and $\sigma_D = \sqrt{\frac{1929}{198} - 0.1074} = 3.10$. The coefficient of partial correlation (r) is derived from the equation

$$r = \frac{p}{\sigma_O \sigma_D}, \quad \ldots \quad (79)$$

in which

$$p = \frac{\Sigma f d_O d_D}{\Sigma f} - c_O c_D. \quad \ldots \quad (80)$$

The individual values of fd_Od_D, with appropriate signs, are shown in small figures in the small co-ordinate rectangles with the corresponding frequencies. These figures are summed horizontally and the totals shown in the last vertical file, and these semi-totals are then summed vertically, yielding the total $\Sigma fd_Od_D = 869$, for the present set of observations. Then $p = 869/198 - 0.04 \times 0.328 = 4.37$, and $r_{OD} = 4.37/2.64 \times 3.10 = 0.535 \pm e_{r_{OD}}$.

Probable error in partial coefficient, $e_{r_{12.3\ldots n}}$ is derived from the formula

$$e_{r_{12.3\ldots n}} = \frac{0.6745(1 - r^2_{12.3\ldots n})}{\sqrt{N}}. \quad \ldots \quad (81)$$

In the present case $e_{r_{OD}} = 0.6745(1 - \overline{0.535}^2)/\sqrt{198} = 0.034$; hence $r_{OD} = 0.535 \pm 0.034$.

Significance of $r_{12.3\ldots n}$ **and** $e_{r_{12.3\ldots n}}$. The numerical value of $r_{12.3\ldots n}$ ranges between -1 and $+1$ as limits, a negative value indicating an inverse relation between the variables 1 and 2 and a positive value a direct relation. The absolute value of r is, however, the significant matter. If $r = 0$, entire lack of correlation is indicated. The significance of other values is not capable of mathematical demonstration, but is based on experience in the use of the method. Rugg (*Statistical methods applied to education, Houghton-Mifflin Co.*) states that in educational statistics a value or r between 0 and $|0.15|$ or $|0.20|$ indicates negligible correlation, a value from $|0.15|$ or $|0.20|$ to $|0.35|$ or $|0.40|$ indicates that correlation is present but of low degree, a value between $|0.35|$ or $|0.40|$ and $|0.50|$ or $|0.60|$ indicates marked correlation, while a value greater than 0.60 corresponds to a high degree of correlation. When the data are numerous, when they may be selected so as to exclude one or more variables that would enter into a consideration of unselected data, and when rejection of obviously erratic values is possible, as is frequently the case in metallurgical data, a more exacting standard of significance of values of r obtains. For such data the following scale is more suitable: 0 to $|0.25|$, negligible correlation; $|0.25|$ to $|0.5|$, low; from $|0.5|$ to $|0.7|$, medium; $|0.7|$ to $|0.9|$, high; $|0.9|$ to $|0.95|$, very high; and $|0.95|$ to $|1.00|$, practically perfect.

The significance of r is also affected by the relative magnitude of r and e. From the definition of e it follows mathematically that 50 per cent. of all values of r will fall between $r + e$ and $r - e$ and that 99+ per cent. will fall between $r + 4e$ and $r - 4e$. If, therefore, e is large with respect to r (r being positive), $r - 4e$ may well be a negative number, from which it follows that the value of r may be zero or thereabouts, indicating negligible or no correlation. In the present problem $r + 4e = 0.669$ and $r - 4e = 0.401$ and medium correlation is indicated.

MULTIPLE CORRELATION

Zero-order coefficients. The coefficient of partial correlation r_{12}, as above developed gives, by definition, an indication of the linearity of the rela-

tion between the variables 1 and 2, on the assumption that the variables 3 . . . n are constants. Since 3 . . . n are, however, variables, this partial coefficient is insufficient basis for judgment as to the actual approach to linearity of the relation between 1 and 2, and it is necessary to go through a further series of operations in which the effect of each variable on the relation between each of the other pairs is eliminated. The first step in this operation is to determine the other coefficients of partial correlation of the zero order, *e.g.*, r_{13}, r_{14}, etc., or, in the present case r_{OA}, r_{AD}, etc., as in Table 20. This is done in the same way

Table 20. Coefficients of partial correlation of zero order (r_{12}, etc.)

$r_{OD} = 0.535 \pm 0.034$	$r_{OR} = -0.288 \pm 0.044$	$r_{CR} = 0.265 \pm 0.045$
$r_{DA} = 0.794 \pm 0.018$	$r_{AR} = -0.196 \pm 0.046$	$r_{CA} = -0.371 \pm 0.041$
$r_{AD} = 0.434 \pm 0.039$	$r_{DR} = -0.070 \pm 0.048$	$r_{OC} = -0.444 \pm 0.038$
	$r_{CD} = -0.124 \pm 0.047$	

A Pounds of acid per ton of ore. *C* Grade of concentrate, per cent. copper. *D* Dilution (ratio of water to ore, by weight). *O* Pounds of oil per ton of ore. *R* Recovery of copper, per cent.

as r_{OD} was determined. The next step is the elimination of the effect of each variable, in order, and the establishment of second-degree coefficients $r_{13.2}$, $r_{12.3}$, $r_{23.1}$, etc., or, taking the data of the present problem $r_{OD \cdot A}$, $r_{OA \cdot D}$, etc. These are called FIRST-ORDER COEFFICIENTS. The first-order coefficient $r_{OD \cdot A}$ indicates the degree of linearity of the relation between lb. of oil per ton and dilution with the effect of acid quantity eliminated; $r_{OA \cdot D}$ similarly measures the relation between the quantities of oil and acid added when the effect of dilution is eliminated; etc., the assumption being still made, as above that the other variables are constant.

Derivation of partial coefficients of higher order is effected by suitable application of the general formula

$$r_{12.3 \ldots n} = \frac{r_{12.3 \ldots (n-1)} - r_{1n.3 \ldots (n-1)}\, r_{2n.3 \ldots (n-1)}}{\sqrt{1 - r^2_{1n.3 \ldots (n-1)}}\ \sqrt{1 - r^2_{2n.3 \ldots (n-1)}}}. \quad . \quad . \quad (82)$$

where n is the total number of variables considered at that step.

First-order coefficients. In the problem in hand the first-order coefficients are derived from those given in Table 20 by application of the general formula as follows, e.g.:

$$r_{OD \cdot A} = \frac{r_{OD} - r_{OA}\, r_{AD}}{\sqrt{(1 - r^2_{OA})(1 - r^2_{AD})}} = \frac{0.535 - (0.794)(0.434)}{(1 - 0.794^2)(1 - 0.434^2)} = 0.345.$$

Similarly the other first-order coefficient shown in Table 21 are calculated.

Table 21. Coefficient of partial correlation of the first order

$r_{OD \cdot A} = +0.345$	$r_{DR \cdot O} = +0.064$	$r_{DC \cdot R} = -0.109$
$r_{OA \cdot D} = +0.738$	$r_{DR \cdot A} = +0.017$	$r_{RC \cdot O} = +0.160$
$r_{DA \cdot O} = +0.015$	$r_{OD \cdot C} = +0.540$	$r_{RC \cdot D} = +0.259$
$r_{OD \cdot R} = +0.538$	$r_{OA \cdot C} = +0.756$	$r_{RC \cdot A} = +0.211$
$r_{OA \cdot R} = +0.786$	$r_{DA \cdot C} = +0.421$	$r_{AC \cdot O} = -0.035$
$r_{DA \cdot R} = +0.429$	$r_{OR \cdot C} = -0.197$	$r_{AC \cdot D} = -0.354$
$r_{OR \cdot D} = -0.298$	$r_{AR \cdot C} = -0.110$	$r_{AC \cdot R} = -0.338$
$r_{OR \cdot A} = -0.224$	$r_{DR \cdot C} = -0.039$	$r_{OC \cdot D} = -0.451$
$r_{AR \cdot O} = +0.055$	$r_{DC \cdot O} = +0.151$	$r_{OC \cdot A} = -0.266$
$r_{AR \cdot D} = -0.184$	$r_{DC \cdot A} = +0.044$	$r_{OC \cdot R} = -0.398$

Second-order coefficients ($r_{12.34}$, $r_{13.24}$, etc.) are similarly calculated from the first-order coefficients, a typical example of the application of the general formula being

$$r_{OD \cdot AR} = \frac{r_{OD \cdot A} - r_{OR \cdot A}\, r_{DR \cdot A}}{\sqrt{(1 - r^2_{OR \cdot A})(1 - r^2_{DR \cdot A})}} = \frac{0.345 - (-0.224)(0.017)}{\sqrt{(1 - (-.224)^2)(1 - (0.017)^2)}} = +0.358.$$

The values of the second-order coefficients for the present problem are given in Table 22.

Table 22. Coefficients of partial correlation of the second order

$r_{OD \cdot AR} = +0.358$	$r_{OC \cdot DR} = -0.406$	$r_{DC \cdot AR} = +0.042$
$r_{OD \cdot AC} = +0.371$	$r_{OC \cdot AR} = -0.230$	$r_{AR \cdot OD} = +0.054$
$r_{OD \cdot RC} = +0.544$	$r_{DA \cdot OR} = +0.011$	$r_{AR \cdot OC} = +0.061$
$r_{OA \cdot DR} = +0.728$	$r_{DA \cdot OC} = +0.020$	$r_{AR \cdot DC} = -0.102$
$r_{OA \cdot DC} = +0.693$	$r_{DA \cdot RC} = +0.419$	$r_{AC \cdot OD} = -0.033$
$r_{OA \cdot RC} = +0.756$	$r_{DR \cdot OA} = +0.063$	$r_{AC \cdot OR} = -0.045$
$r_{OR \cdot DA} = -0.247$	$r_{DR \cdot OC} = +0.041$	$r_{AC \cdot DR} = -0.322$
$r_{OR \cdot DC} = -0.210$	$r_{DR \cdot AC} = +0.008$	$r_{RC \cdot OD} = +0.152$
$r_{OR \cdot AC} = -0.179$	$r_{DC \cdot OA} = +0.152$	$r_{RC \cdot OA} = +0.158$
$r_{OC \cdot DA} = -0.305$	$r_{DC \cdot OR} = +0.143$	$r_{RC \cdot DA} = +0.211$

Third-order coefficients ($r_{12.345}$, $r_{13.245}$, etc.) are similarly calculated from the coefficients of the second order. A typical example applicable to the present problem is

$$r_{OD \cdot ARC} = \frac{r_{OD \cdot AR} - r_{OC \cdot AR}\, r_{DC \cdot AR}}{\sqrt{(1 - r^2_{OC \cdot AR})(1 - r^2_{DC \cdot AR})}} = \frac{0.358 - (-0.230)(0.042)}{\sqrt{(1 - (-0.230)^2)(1 - (0.042)^2)}} = 0.379.$$

The values of the third-order coefficients in the present problem are given in Table 23.

Table 23. Coefficients of partial correlation of the third order

Symbol	Coefficient	Probable error
$r_{OD \cdot ARC}$	+0.379	±0.041
$r_{OA \cdot DRC}$	+0.692	±0.025
$r_{OR \cdot DAC}$	−0.197	±0.046
$r_{OC \cdot DAR}$	−0.267	±0.044
$r_{DA \cdot ORC}$	+0.017	±0.048
$r_{DR \cdot OAC}$	+0.040	±0.048
$r_{DC \cdot OAR}$	+0.144	±0.047
$r_{AR \cdot ODC}$	+0.060	±0.048
$r_{AC \cdot ODR}$	−0.042	±0.048
$r_{RC \cdot ODA}$	+0.154	±0.047

Significance of $r_{OD \cdot DRC}$ and $e_{r_{OD \cdot ARC}}$, etc., in Table 23 is, according to the standard set up on p. 1259, as follows:

1. The correlation between oil and acid is medium-high. This was, of course, to be expected from the facts of plant operation, where the usual tendency of the operators was to increase both oil and acid when froth overflow became sparse and to decrease the two together when froth overflow was too rapid.

2. The correlation between oil and dilution is low but distinct. Physically this low correlation is in part explained by the fact that changes in oil lagged behind the cause that required changes. Increase in dilution, if the quantity of oil fed remains constant, causes decrease in frothing and in carrying power of the froth, or what the flotation operator describes as an under-oiled condition, and increase causes the reverse condition, which he describes as over-oiling. But these changes in machine performance lag considerably behind the changes in dilution causing them, hence for certain periods high dilution and low oil quantity go together and for certain other periods low dilution and high oil, notwithstanding that the operator endeavors to maintain high oil with high dilution and *vice versa*. Mathematically, also, the correlation suffers in that grade of feed, which is another variable affecting oil quantity, is not considered in the correlation. If it were considered and properly eliminated, the effect should be to raise $r_{OD \cdot A} \cdots$

3. Correlation between quantity of oil and recovery and that between quantity of oil and grade of concentrate is in the zone of low to negligible, according to the data analyzed. The interpretation of this result is that under the conditions of the mill operations studied, changes of one- or two-tenths of a pound of oil made little difference in recovery or grade of concentrate. The negative sign of these two coefficients indicates, in so far as the low value of the coefficient permits any distinct indication, that increase in oil in the particular operations resulted in decrease in both grade and recovery.

4. Negligible correlation is indicated in all of the other cases.

Coefficient of multiple correlation is a number (R) that measures the degree of completeness with which the variations of any one variable are accounted for by consideration of the other variables entering into the calculation. The value of R for any variable ranges between 0 and +1. In any problem its value must be greater than the absolute value of the greatest of the partial coefficients involving the same variable. It is obtained from the formula

$$R = \sqrt{1 - (1 - r^2_{12})(1 - r^2_{13.2})(1 - r^2_{14.23}) \ldots (1 - r^2_{1n.234) \ldots (n-1)}} \quad (83)$$

In the present example

$$\begin{aligned} R_O &= \sqrt{1 - (1 - r^2_{OD})(1 - r^2_{OA\cdot D})(1 - r^2_{OR\cdot DA})(1 - r^2_{OC\cdot DAR})} \\ &= \sqrt{1 - (1 - \overline{0.535}^2)(1 - \overline{0.738}^2)(1 - [-0.210]^2)(1 - [-0.267]^2)} \\ &= 0.844. \end{aligned}$$

Other values of R are:

$$R_D = 0.553; \quad R_C = 0.487; \quad R_R = 0.333; \quad R_A = 0.795.$$

Multiple correlation is very high if R is larger than 0.90, high from 0.75 to 0.90, medium from 0.60 to 0.75, low from 0.30 to 0.60, and negligible below 0.30.

Reliability of coefficient of multiple correlation is to be judged from the probable error, obtained by the formula

$$E_R = \frac{k(1 - R^2)}{\sqrt{N}}, \quad (84)$$

where k is a coefficient given by Table 24 (Pearson, *6 Biometrika 59*).

Table 24. Value of coefficient k in equation for E_R

$n' - 1$	k
1	0.674
2	1.177
3	1.538
4	1.832
5	2.086
6	2.313
7	2.519
8	2.710

n', Number of values of R investigated.

For E_{R_O}, $K = 1.832$, $R_O = 0.844$, $N = 198$ and

$$E_{R_O} = \frac{1.832(1 - \overline{0.844}^2)}{\sqrt{198}} = \pm 0.037.$$

$$E_{R_D} = \pm 0.090; \; E_{R_C} = \pm 0.099; \; E_{R_R} = \pm 0.116 \text{ and } E_{R_A} = \pm 0.048.$$

Hence the final values for R are $R_O = 0.844 \pm 0.037$; $R_D = 0.553 \pm 0.090$; $R_C = 0.487 \pm 0.099$; $R_R = 0.333 \pm 0.116$; $R_A = 0.795 \pm 0.048$. These figures indicate that the variations in oil and acid are accounted for with a high degree of completeness and that the values of R are reliable; variations in dilution and grade of concentrate are not particularly well accounted for, and the data are highly incomplete in so far as the investigation of recovery is concerned.

SECTION 23

DESIGN AND CONSTRUCTION OF ORE-TREATMENT PLANTS

BY

JOHN M. CALLOW

CONSULTING ENGINEER; PRESIDENT, THE GENERAL ENGINEERING COMPANY

1. Situation of mill with respect to mine

General Principles. Since one of the main purposes of concentration is to reduce the expense of delivering mine product to the smelter, a concentrating mill should ordinarily be situated as close as practicable to the source of its ore supply. In general those mines at which the ratio of concentration is high are most benefited by placing the mill near the mine, but this conclusion may be modified by one or more of the following facts: (*a*) freight rates of public carriers usually advance in direct relation to the unit value of the material carried (see Table 10); (*b*) mill concentrate produced by wet methods may carry from 4 to 15 per cent. water, even after draining or filtering; (*c*) the site near the mine may lack adequate supply of mill water with low expense for elevation; (*d*) suitable space for tailing disposal, and (*e*) advantageous topography for a mill site. Examples of a variety of practices are given in Table 1.

In the case of a large-scale operation, the ability to move great tonnages by the most efficient available motive power over privately owned track to a mill adjacent to or in the direction of the smelter, may offset some of the advantages of proximity of mill to mine. Some notable examples of long hauls are given in Table 2.

Of the mills cited, those of ANACONDA, NEVADA CONSOLIDATED, and RAY CONSOLIDATED are closely adjacent to smelters; water supply was an important consideration in selecting sites for the CHINO, COPPER RANGE, and NEVADA CONSOLIDATED mills; while the disposal of tailing contributed largely to the selection of sites for NEVADA CONSOLIDATED and the

Utah Copper Co.'s mills. In no case, however, was the decision based upon one favorable condition alone.

Placing a mill near the mine it serves, tends to minimize irregularities in receipt of ore. The ill effect of mill stoppage for lack of ore can be guarded against to a limited extent by providing storage bins, but it is seldom practicable to store more than two or three days' supply, and in the case of some

large mills, operations would cease if the ore supply were interrupted for a single day (see Table 12).

METHODS OF TRANSPORTING ORE TO MILL

The following means are available: 1. Mine-car or other small-car tramming: (*a*) hand; (*b*) animal; (*c*) cable; (*d*) storage-battery locomotive; (*e*) trolley locomotive; (*f*) gasoline locomotive; (*g*) narrow-gage steam locomotive; (*h*) mono-rail system. 2. Wagon or truck haulage: (*a*) animal; (*b*) motor trucks; (*c*) tractors and trailers. 3. Belt conveyors. 4. Aerial tramway: (*a*) reversible; (*b*) continuous. 5. Standard-gage railroad.

Hand tramming is frequently adopted at small mines for distances up to 300 ft., especially when the mine cars themselves can be conveniently trammed to the mill. For such surface tramming, the track can usually be maintained in better condition than underground, and can be laid to the most advantageous grade, say 0.6 per cent. in favor of the loaded run. On well-graded track, and with the usual metal-mine car in good condition, one man can push a net load of 2000 lb. at speed of 1½ miles per hour (130 ft. per min.); maintaining the same speed on the return trip would give an ore-carrying capacity of 0.75 ton-mile per hour *in motion*. Dumping time, which is approximately ½ min., will range from 40 per cent. of the total working time (excluding loading) on a 50-ft. tramming distance, to 10 per cent. on a 300-ft. tram. Loading time will vary between the extremes of 2 min. (from chutes) to 30 min. per ton (shoveling from rough bottom). (For further data on loading and tramming by hand, see *Peele*.)

Animal tramming is applied to trains of mine cars, and also to one or several cars of large size receiving ore from a dumping or storage pocket. The method is not more efficient than hand tramming over short distances and for traffic of less than two ore-ton-miles per hour, but competes favorably with mechanical systems up to 25 ore-ton-miles per hour, at distances up to ½ mile and with grades below 1.25 per cent. On good track, with moderate grades in favor of the load, one mule can pull a gross load of 7 to 12 tons, and haul

from 2 to 4 ore-ton-miles per hour of total working time at distances of 700 to 3000 ft. The tractive force of an average horse, at 2.5 miles per hour for 8 hours, is 125 lb.

Cable haulage may be applied to gravity plane, engine plane, or tail-rope system.

Gravity plane. Loaded cars, of modern design and well lubricated, will run freely down a grade of 2 per cent., but if empty cars are to be hauled up by the action of the descending loads, transmitted through a cable, 5 to 5½ per cent. is about the minimum grade that will operate with a plane 500 ft. long; longer planes require steeper grades, up to 10 or 15 per cent. Cars or skips discharging automatically into a receiving bin at the bottom of the incline are frequently used.

Engine plane may be operated on any grade steep enough to allow the empty trip to descend by gravity, while overcoming the added friction of cable and engine drum. In practice, 3½ per cent. has been found to be the minimum satisfactory grade.

The NIPISSING low-grade mill, at Cobalt, receives part of its ore by an engine plane 2200 ft. long, hauling a trip of 4 cars, or 3.85 tons of ore, up a steady grade of 10 per cent., with a 30-hp. electric hoist and a ½-in. cable. Operating at 90 per cent. capacity, the plane makes one trip in 25 min. The total cost of operation (1922) was 34.2¢ per ton hauled, or 82¢ per ton-mile. The cost of installation, in 1913, was $6500. At the TROJAN mine, S. D., one electric hoist is used both to haul trips of eight 1.5-ton cars up a 1500-ft., 6 per cent. slope out of the mine, and to lower them 2000 ft. down a 15 per cent. incline to a gathering station from which they are hauled to the mill by gasoline locomotive.

Tail-rope system is best adapted to nearly level or irregular grades, and can be applied to curved track; it is commonly used at coal mines.

A well-known application to surface tramming in the United States is in the TRI-STATE DISTRICT, hauling ore from one or more outlying shafts to a central mill, an average distance of 800 ft., with ½ mile as a maximum (10-ton steam and 5-ton gasoline locomotives are used for the same service). Track is 36-in. gage with 40-lb. rail, and cost (1923) an average of $1.56 per ft., including grading, laying, and all track materials. Cars are of steel, with roller bearings, and of 2.5- and 3.5-ton capacity (44 and 62 cu. ft.). At GOLDEN ROD mill (*H. H. Wallower, PC*) a 14-car train with gross weight of 60 tons is hauled by a tail-rope system a distance of 1800 ft. over level track containing frequent curves. The driver is a band-friction, tandem, double-drum hoist, belt-driven by 75-hp. motor; after starting, little power is needed. The cost of this method is compared with that of steam-locomotive haulage on the same property during 1923 in Table 3.

Table 3. Haulage costs at Golden Rod Mill, 1923

	Cable system	Steam locomotive
Distance, ft.	1800	2600
Grades	Level	900 ft. @ 1% (Remainder level)
Tons trammed	144,019	114,179
Cost per ton, cents:		
Labor	4.09	6.06
Power	0.27	0.93
Supplies	1.82	3.54
Total	6.18	10.53
Total cost per ton-mile, cents	18.13	21.40

Limitations of the tail-rope system as to grades and distances have not been reached in the Tri-State district; curves present slight difficulty.

Storage-battery locomotives might be advantageous to haul trains of ore cars directly to the mill from a mine in which battery locomotives for any reason are preferred underground. Gages range from 18 to 44 in. In general, battery locomotives are equipped with motors aggregating 4 hp. per ton of total weight; the range is from 2.5 to 8 tons. On clean rails they exert a drawbar pull of one-fourth their weight when moving at 3½ miles per hour; they have been operated effectively on grades up to 10 per cent., but in general they give best results on moderate grades.

In the BUTTE & SUPERIOR mine, in narrow, tortuous drifts with irregular grades (*123 P 751*), a 3½-ton locomotive, exerting a draw-bar pull of 1500 lb., at 4 miles per hour, hauls a train of 10 roller-bearing cars, each of 2250 lb. gross weight. During 1919, nine locomotives hauled 737,787 cars of ore and waste an average distance of 790 ft., at cost per car-trip of: power, 0.41¢; locomotive repairs, 3.21¢; motorman and helper, 6.90¢; total, 10.52¢.

Exhaustive tests at COPPER QUEEN showed that battery locomotives required 1.6 kw.-hr. at the power house per ore-ton-mile. In the UNITED VERDE mine (*66 A 177*) Baldwin-Westinghouse 3-ton locomotives gave a drawbar pull of 800 lb. at 3½ miles per hr. Batteries (80 Edison A–4 cells) were re-charged after each shift, with 250-volt current. Hauling 215 tons ore per shift, a distance of 200 ft. up 0.4 per cent. grade, the cost in cents per ton was (1918): Labor (1 motorman and 2 loaders), 8.4; power (25 kw.-hr. per shift), 0.4; depreciation of motor, 0.6; repairs and inspection, 0.2. Total, 9.6.

Trolley locomotives, in addition to hauling trains of ore cars direct from mine workings to the mill, where this is possible, are often installed independently for surface haulage from a loading pocket at the mine, as at ALASKA GASTINEAU, BRITANNIA, HEDLEY, MELONES, TONOPAH EXTENSION, BUNKER HILL & SULLIVAN, and many other mines. For this purpose, more powerful and wider-gage locomotives are applicable than for mine haulage and higher voltages are permissible. Trolley locomotives are usually equipped with motors aggregating 10 hp. per ton of total weight (which ranges from 3 to 30 tons), and give a draw-bar pull, with steel-tired wheels, estimated at 25 per cent. of the total weight of the locomotive.

At UNITED VERDE mine, Jerome, Ariz. (*66 A 177*) in the Hopewell main-haulage tunnel, 25-ton Baldwin-Westinghouse locomotives are used, equipped with two 75-hp. 250-volt, direct-current motors and exerting a draw-bar pull of 12,500 lb. at 7.1 miles per hr.; total haul, 8900 ft. Bottom-dump, standard-gage cars of 220-cu. ft. nominal capacity are loaded from chutes with 280 cu. ft. or 20 tons of heavy sulphide ore. The trains are 14 cars, making 425 tons gross per locomotive. The cost in cents per ton for 1918, on 861,250 dry tons, was: Labor, including loading and dumping, 5.4; supplies, 0.1; power, 0.5; repairs, 3.5. Total, 9.5, or 5.6¢ per ore-ton-mile. At ALASKA-JUNEAU (*120 P 251*) the mine output was hauled two miles down a 0.5-per cent. grade, 30-in. gage, double-track, 32-car trains; each car weighed 3 tons empty and carried 10 tons of ore; total weight of train, 96 tons empty, 416 tons loaded. The locomotive was in two sections, of 9 tons each, having two direct-current Westinghouse No. 905 motors in each unit and was small enough to pass through a rotary car dump discharging four cars at a time. The front section of the locomotive could be quickly detached and used for switching. Power for operation was obtained from two 300-kw. rotary converters, each with an individual 6-phase transformer.

For other data on performance and operating costs of trolley locomotives, see *Peele*.

The BUTTE, ANACONDA & PACIFIC RY. transports ANACONDA ore (over 5,000,000 tons per year) from mines on Butte Hill to the Washoe concentrator at Anaconda; total haul, 32 miles (*Elec. Ry. Jour.*, Mar. 14, 1914). The General Electric locomotives used weigh 80 tons, have 1050-hp. continuous rating, and exert a tractive force of 25,000 lb. at 15 miles per hr. Trolley wire is No. 0000 and carries 2400 volts direct-current. The cars weigh 18 tons and carry 50–53 tons of ore; two locomotives per train. Operating data are given in Table 4.

This road, formerly steam-operated, was electrified during 1912–13, at a cost of $1,-201,000; the first year's electric operation indicated a saving of 36 per cent. in direct costs, as shown in Table 5. In the item of power alone, the saving was 48 per cent. compared with steam operation. The saving in trainmen's wages was due principally to the higher speed and greater regularity in train movement.

Table 4. Haulage of Anaconda ore by Butte, Anaconda and Pacific Ry.

	On Butte Hill, Mines to Rocker	Main Line, Rocker to E. Anaconda	On Smelter Hill, E. Anaconda to Concentrator
Distance, miles	4.6	20.1	7.2
Average grade, loaded	−2.5%	−0.3%	+1.1%
Cars in train	30	65	20
Gross train load, tons	2000	4620	1400
Speed, miles per hour	12	16–21	16

Table 5. Comparative costs of steam and electric haulage at Anaconda

	1913, steam	1914, electric
Locomotive operation only (fuel or power, oil, crew, maintenance, etc.)	$594,921	$357,339
Trainmen's wages	147,632	116,486
Total direct operation	$742,553	$473,825
Ton-miles hauled, net	158,917,720	172,855,856
Cents per ore-ton-mile	0.467	0.274

Gasoline locomotives are built up to 15 tons in weight, with draw-bar pulls of 20 per cent. their weight and geared to speeds of 6 to 12 miles per hour. The makers estimate gasoline consumption at 0.1 gal. (0.6 lb.) per hp.-hr.; tests have indicated 0.73 to 1.2 lb. of gasoline per brake hp.-hr. at full load and full speed, 1.2 to 2.2 lb. at half load and half speed, and higher consumptions for reduced loads.

At numerous bituminous-coal mines and a few metal mines of the United States (*Peele*) with hauls of 1800 to 3400 ft., the operating cost varies from 2.5 to 5¢ per mineral-ton-mile.

At the New York Zinc Co., Edwards, N. Y. (*W. R. Wade, PC*), a Fate-Root-Heath 25-hp. gasoline locomotive hauls a train of 2 or 3 cars, each weighing 3000 lb. empty and carrying 3 tons of ore, an average distance of 800 ft. down a 0.5-per cent. grade at a speed of 15 miles per hour. The track is 3-ft. gage with 25-lb. rails. The locomotive also hauls waste (about one-fourth of the ore tonnage) an average distance of 400 ft. In a 9-hr. shift, it averages 250 tons ore and waste. Gasoline consumed, 1 gal. per hour; estimated operating expense (excluding wages), $2 per shift; repairs, not over 0.1¢ per ton. Allowing wages of $4 a day for one engineer, the estimated total direct cost for haulage only is 17.7¢ per ton-mile. The first cost of the locomotive was $1815. At the Trojan mine, S. D., a Milwaukee gasoline locomotive hauls trains of eight 1.5-ton cars a distance of 2000 ft. to the mill at cost of 6¢ per ton (1922) or 15.8¢ per ton-mile.

Narrow-gage steam locomotives are found in many districts, hauling for long distances, where rough topography makes construction of standard-gage roadbed unjustifiably expensive. A simple steam locomotive consumes 4.5 to 8 lb. of coal or 2 to 5 lb. of fuel oil, and 27 to 32 lb. water per hp.-hr. while in motion; the total fuel consumption, covering delays, may be 50 to 100 per cent. greater.

At Bawdwin mines, Burma, the total length of narrow-gage line is 46 miles with grades of 4 to 5.5 per cent. in places and numerous sharp curves. Gage is 2 ft. The principal traffic is down-grade, 33 miles, at a cost of 7¢ per ton-mile.

Mono-rail system, well developed in Europe, has only one noteworthy installation in the United States, *viz.*: near Searles Lake, Cal. (*116 J 100.*)

The total length is 28 miles, of which 8 miles is level but the remainder traverses extremely rugged country, requiring sharp curves and grades of 8 to 10 per cent. The wooden

framework supporting the rail is seldom more than 3 ft. high. Estimated cost was $8000 per mile. A specially fitted Fordson tractor makes 10–15 miles per hour on the level, and 8 miles per hr. up grade. Cost of transportation was estimated at less than $1 per ton.

Horse-drawn wagon haulage. For general data on loads, speeds, grades, tractive resistance, road surfaces, etc., see *Peele.*

At Philipsburg, Mont., the ALGONQUIN mine formerly shipped manganese ore 2.7 miles to the mill by 6- or 8-horse wagon and trailer carrying together 5 to 6 tons. The team made two round trips per day. In the DOLORES district, Colo., picked vanadium ore is hauled on contract by 4- or 6-horse wagon and trailer 50 to 90 miles to Placerville. The average load is 1000 to 4000 lb. per horse, depending on grades and road condition. Speed on rough roads, 16 miles per day; on good roads, 22 to 25 miles per day. During the early development of the MAGMA mine (1914) the rate for wagon haulage of supplies, 32 miles up-grade from Webster, was $10 per ton; when the wagons hauled both ways the rate was $8 up, $5 down.

Motor trucks of 1- to 6-ton capacity are rapidly supplanting horse-drawn wagons where the roads are suitable.

In the vanadium district of SOUTH-WEST COLORADO, 5-ton trucks, generally overloaded, make from 50 to 80 or 90 miles per day over roads in fair condition.

At the SILVER DYKE mine, Neihart, Mont. (*W. E. Wampler, PC*), teaming contractors haul concentrate 3.5 miles down a mountain road having an average grade of 4 per cent. for $1.50 per ton, returning with freight, against a maximum adverse grade of 7 per cent., at $2 per ton; they use wagons, sleds, or motor trucks, according to the condition of the road. The motor trucks are 3-ton International, but are usually loaded with 5 tons; they make three round trips in an 8-hr. shift, loaded both ways. Driver's wages, $5.50 per shift; gasoline consumption, 8 gal. per shift; oil, 1 quart. The original cost of the truck (1923) was $3600.

Contractors hauling supplies to the MOGOLLON mines from Silver City, N. M., 75 miles over good roads, use White trucks of 2- and 5-ton capacity (*72 A 533*). The total freight hauled in 1922 was 1484 tons at a cost of 26.5¢ per ton-mile. The contractors haul concentrate by motor trucks from the BETTY O'NEAL mill, Lewis, Nev., to Battle Mountain, over 12 miles of dirt road in good condition, except during rains, for $5 per ton, or $0.42 per ton-mile (*117 J 449*). ARMSTEAD mill, Talache, Id. (*A. H. Burroughs, Jr., PC.*), ships concentrate to Eagle, 6.5 miles over good gravel road down an average grade of 2.5 per cent. with maximum of 6 per cent., in 2½-ton Standard motor trucks usually loaded with 3 tons. During 1923, 4160 tons of concentrate was hauled down and 2000 tons freight up. Contract price, $1.80 per ton in summer, $2 in winter (aver. 30¢ per ton-mile). More recently, a 5-ton GMC truck has proved cheaper to operate.

Tractors and trailers move at relatively slow speed, but can haul heavy loads over roads rough enough to be damaging to motor trucks.

At Philipsburg, Mont., the ALGONQUIN mine shipped manganese ore 2.7 miles to the mill in trains of five 6-ton trailers drawn by a 75-hp. Holt caterpillar tractor, making 3 trips or 90 tons a day, at a cost of 72¢ per ton, or 27¢ per ton-mile. TREADWELL-YUKON Co., Mayo district, Yukon Terr., employs a 10-ton Holt caterpillar tractor to haul 4 sleds loaded with 33 to 54 tons of sacked ore a distance of 42 miles down very rough mountain road, with frequent grades that require splitting the load. During 5 months (November, 1922, to Mar., 1923) the train made 54 round trips (4636 miles) delivering 2501 tons ore (46 tons per trip). The temperature ranged from $+10°$ to $-50°$ F. and snow was 4 ft. deep on the level but there was no interruption to tractor service. The loaded trip required 20 to 24 hr., the return trip with a light load of supplies, 16 to 20 hr. Gasoline consumption was 2 gal. per mile loaded; 1 gal. per mile returning. Total cost (fuel, oil and wages, including return trips) was $2.60 per ton, or 6.2¢ per ore-ton-mile.

Belt conveyors are frequently used for bringing ore into a mill from a hoist pocket, train-dump pocket, or coarse-crushing plant. They may also serve for hand-picking of the ore in transit, and to elevate to the top of the mill. For details of construction, see Sec. 20, Art. 1. With a 36-in. belt, and material of 100 lb. per cu. ft., 1 ton-mile of transport on level ground requires 1.25 hp.-hr. of work; in general, for lighter materials and narrower belts, 1 hp.-hr. moves 1 ton 1 mile, on a level haul.

A down-hill belt conveyor was installed by the MOUNTAIN COPPER Co. to convey the pyrite output of its Hornet mine, crushed to 4-in. maximum size, a vertical distance of 189 ft. from mine level to railroad track in a horizontal distance of 300 ft. The two terminal bins and an intermediate tower bin supplied all but 60 ft. of the vertical drop, which was divided between two conveyors. The upper, 24 in. wide, sloped 9° 40′ and traveled 125 ft. per min., governed by a small motor and two sets of spur gears; the lower, 20 in. wide, sloped 14° 40′, traveled 150 ft. per min., and was connected to the same shaft that drove a trommel (*119 P 638*). In a similar manner, at the ENGELS mill (*123 P 183*) flotation concentrate (70 tons, dry, per day) carrying 10 to 15 per cent. water is lowered a vertical distance of 100 ft. on a 12-in. belt sloping 34°.

Reversible aerial tramways are designed for distances up to 2000 ft., and bucket loads of 400 to 2500 lb. Intermediate supports may be used, but the speed is then limited to 1000 ft. per min.; on an unsupported span, 1500 ft. per min. is safe. There may be one or two carrier cables; in the latter case the economical limit is approximately 20,000 ft.-tons per hour; for a single cable the capacity is less than 10,000 ft.-tons per hour. (*Peele*). Data supplied by the American Steel and Wire Co. are given in Table 6.

Table 6. Capacities and weights of reversible tramways

Load per bucket, lb.		400	800	1500	2000	2500
Diameter of track cable, in.		⅞	1⅛	1⅜	1½	1⅝

2000	....	12.10	16.65	20.90	24.00	26.70

a Based on travel of 600 ft. per minute, with allowance of 40 to 50 sec. for loading and dumping. *b* Weight may be used for estimating cost of equipment at factory, since unit price per pound is practically constant throughout the stated ranges of length and capacity; in 1917 it was quoted as 19¢ per pound.

At the OTTAWA mill, near Slocan, B. C., a two-bucket reversible gravity tram 200 ft. long, with rated capacity of 10 tons per hour, cost $8000 in 1921, including the erection of terminals and clearing of way. Rugged country and local scarcity of timber added to the expense. Cost of tramming was 10¢ per ton.

Continuous aerial tramways often afford the only practicable means of conveying ore from the mine or concentrates from the mill in steep or rough

districts. The economical minimum limit of capacity is 10 tons per hour; the maximum limit varies from 100 tons per hour in general to 200 tons under exceptionally favorable conditions. They are not usually warranted for distances of less than 1000 ft. and the maximum length of a unit is about 4 miles; two or more units can be erected in tandem, with transfer of buckets for greater distances. Anchor and tension stations must be situated at intervals of 3000 to 5000 ft. Loads per bucket range between 500 and 2000 lb., and three buckets per minute is about as rapidly as they can be handled at terminals; two buckets per minute is nearer the average. (For additional data see *Peele*.) Structural and general operating data supplied by the American Steel and Wire Co. are given in Tables 7 and 8. Data on specific operations are given in Table 9.

Table 7. Trenton-Bleichert continuous tramways

Capacity, tons per hour	Cable diameter		Carrier buckets			Weight of line and buckets, pounds per 100 ft. (*b*)	Weight of Terminal equipment, tons (*c*)	Weight of anchor and tension stations, tons (*d*)
	Tracks	Traction	Load, pounds (*e*)	Spaced, ft.	Number per hour (*a*)

a Goes over a high point 1020 ft. above loading terminal. *b* During winter, with heavy snow, men and all supplies are carried by this tram, necessitating extra guards. *c* Concentrate down; coal and all other supplies up. *d* 10% water. *e* Including bins. *f* Excluding bins.

Standard-gage steam locomotives are employed by the largest mines, not only for long hauls of ore but also for disposal of waste. In many cases, the tracks form part of the mine equipment; in others, the roads serve as public carriers operated by organizations subsidiary to the mining companies; while in others, the ore traffic runs partly or entirely over independent roads, sometimes under a trackage license. A few notable examples of relatively long hauls over standard-gage railroads were given in Table 2. Examples of rates charged by common carrier railways in the West are given in Table 10.

Copper Queen, since 1921, has hauled waste rock from Sacramento Hill down grade to a dump two miles away (*68 A 251*). Of 15 standard-gage Porter locomotives used (4 driving wheels and saddle tanks), three weigh 53 tons each and exert a tractive force of 20,436 lb.; the other 12, with superheaters, weigh 54.5 tons each and exert 23,063 lb. pull; gage pressure, 175 lb. in both cases. Cars are all-steel with compressed-air dump, have capacities of 20 and 25 cu. yd., and weigh, respectively, 55,400 and 60,700 lb. The average performance per locomotive-shift is 450 cu. yd. (solid; estimated at 1035 tons) at a cost of 17.7¢ per cu. yd., or 3.8¢ per ton-mile.

Shay geared locomotive affords the only practicable motive power for numerous railroads in mountainous districts, and could be used advantageously elsewhere as a pusher for slow-moving traffic on grades not too steep for ordinary locomotives. In addition to negotiating sharp curves, it has the advantage of small weight in proportion to its tractive force, since all its weight rests on driving wheels, and its force is well maintained even on steep grades; in the example noted below, on a 6 per cent. grade the Mikado locomotive loses more than one-half of its level draw-bar pull while the Shay loses only 32 per cent.

Greenbriar, Cheat & Elk R.R., with 115 miles of track in W. Va., having 7 per cent grades and 32° curves, uses 150-ton, 3-truck, 3-cylinder (17 × 18-in.) Shay locomotives,

At Mountain Copper Co., a narrow-gage Shay locomotive with seven 20-ton cars delivers ore from mines on Iron Mt. to the mill at Minnesota, a descent of 800 ft. in 5 miles, or 3 per cent. average grade.

Storage bins are almost invariably provided at some point between the mine workings and the mill, or that part of the mill where the major crushing operations are conducted. This storage not only obviates the necessity for stopping the mill when delays occur at the mine or on the transport system, but also makes it possible to operate mine or traffic on part time while the mill runs continuously. Conversely, delays in the mill need not affect the continuity of mining or transportation. At many mines, the ore receives its first reduc-

tion at an independent crushing plant, in some cases remote from the mill, which is equipped with its own receiving and discharging pockets, and is thereby enabled likewise to work intermittently, if desired. In general, the storage capacity should suffice to maintain the mill in operation during any mine or traffic interruption that is at all probable; it will therefore be roughly proportioned to the milling capacity, and to the difficulties inherent in the method of conveying the ore into the mill. In the case of mills served by standard-gage railroads, the loaded cars in transit afford a notable volume of storage. At mills of large capacity, especially those at which the crushing is performed in a centralized machine, as in the LAKE SUPERIOR copper mills, structural difficulties may prevent the erection of storage bins to hold more than a few hours' supply of ore. Table 12 gives data on a few modern mills.

2. Situation of mill with respect to water supply

General considerations. All wet concentrating mills require so large an amount of water that securing an adequate supply often becomes an important engineering problem; in many cases, it has been the deciding factor in the selection of a mill site. Where railroad connections permit cheap haulage, it has often proved economical to bring the crude ore many miles to a convenient source of water instead of pumping the required amount of water to a mill in the neighborhood of the mine. Even with an abundant supply of water in proximity to the mill, if this must be pumped to storage sufficiently elevated above the mill to afford rapid flow, the pumping of 4 to 40 tons of water, compared with elevating 1 ton of ore, becomes an important factor in the design and location of a mill. For mills using flotation, the chemical composition and uniform character of the water supply are matters of prime importance.

Water requirements in the milling circuit depend primarily on the nature of the process and equipment; jigs and tables require the most; flotation a less amount; cyaniding and other lixiviation processes the least volume of water. The supply of new water depends upon the facilities employed, if any, for recovering clarified water from tailing, concentrate, or intermediate products in the mill. The practice of recovering water is naturally most common in districts where water is scarce; also at those flotation mills in which soluble reagents have a value; but the desirability of clarifying and recovering water at any convenient stage in the milling system, at an elevation above that of final discharge, always deserves investigation as to its possible economy in pumping. Data on the water requirements of representative mills are given in Table 13.

Gravity supply is an important advantage when obtainable. The water may be conducted by ditch, flume, or pipe-line; the latter often permits the selection of a shorter route, and may be constructed of wood in manufactured sections, wood-stave pipe assembled on the ground, riveted steel pipe, or heavier forms of metal if great pressures must be carried, as at the bottom of an inverted siphon.

Ditches. See Sec. 27, Art. 30.

Flumes are commonly of rectangular section, for ease of construction and repair with local materials; the width is usually twice the wetted depth. Sills and posts should be spaced not more than 4 ft., and 3 ft. is better. No lumber less than 1½ in. thick should be used. According to *Wilson* a 3 × 3-ft. flume with 3 × 4-in. sills, posts and caps, requires 139,600 bd. ft. of lumber per mile, including battens and walk-way, but not the longitudinal stringers and trestle work. Semi-circular flumes of wood or steel, having the advantage of conforming more closely to the best principles of hydraulic flow, are in the market; their principal drawback is the inconvenience of repairs.

Table 12. Storage-bin capacities at representative mills

Mill	Daily capacity, tons	Storage capacity				Ore received via

a 34% from tailing pond, 48% from settlers in mill. ***b*** From settlers and filters See page 1280. ***c*** 1.56 tons from thickeners, 0.32 ton from tailing pond. ***d*** From tailing dam. ***e*** From slime pond. ***f*** None from tailing. 2.5 tons recovered inside the mill. ***g*** In three 50-ft. Dorr tanks. ***h*** From thickeners and settling ponds.

Manufactured wood pipe is available in inside diameters of 2 to 48 in., piece lengths of 6 to 25 ft., and to withstand heads up to 400 ft. of water. ADVANTAGES: light weight, ease and rapidity of laying, resistance to corrosion even in acid water, and small frictional resistance to flow. Comparing 16-in. pipes under heads up to 6 ft., a riveted-steel and a new cast-iron pipe will deliver respectively 80 and 85 per cent. as much as a wooden pipe; the frictional resistance in the latter, furthermore, does not tend to increase with age. The woods commonly employed are cypress, white pine, Douglas fir, and California redwood. Bondings are of wire or steel ribbon; the wood is commonly treated with creosote, and the outside protected with asphalt.

Wood-stave pipe, assembled on the job with specially formed staves and rod bands, is suitable for diameters of 16 in. to 20 ft., and hydraulic heads of 150 ft. for the larger up to 400 ft. for the smaller diameters. ADVANTAGES are: ease and rapidity of construction, applicability to rough country, ability to form curves of radius 60 times the pipe diameter, resistance to corrosion, low frictional resistance. A pipe buried in clean soil has longer life than one lying on the surface; decay from the outside seems to be promoted by dents and abrasions given by rough workmanship during construction. Initial leakage can be stopped quickly by introducing bran at the inlet of the pipe.

Nevada Cons. mill, at McGill, Nev., receives most of its water by gravity from a reservoir on Duck Creek, 9.5 miles away and 105 ft. higher than the receiving tank at the mill, through a 32-in. pipe of which 40,000 ft. was laid with Douglas fir staves and ½-in. round bands; sills were spaced at 3 ft. (*109 J 857*). The total first cost (1907), including 10,000 ft. of 32-in. riveted-steel pipe in the line, was $180,000, or $4 per ft. Flow capacity, 20 to 21 cu. ft. per sec. In 1920, the ends of the staves were found to be rotted; repairs were made by enclosing the affected portions of the pipe in concrete jackets, about 6 in. thick and reinforced with small rods; the total length thus repaired was 1500 ft. This line was still in use early in 1924 and was expected to last 2 years longer (*C. B. Lakenan, PC*).

Sheet-metal riveted pipe is of two general types: longitudinal lap or butt jointed, and spiral jointed; the former is generally adopted for large lines and high heads, the thickness of metal and the manner of riveting being selected to suit the pressure, while the latter has a wider application to smaller flows and pressures. The spiral-riveted lap seams give the pipe added strength as a beam, thereby reducing the amount of support to be provided when laying a line over the surface; it is lighter than cast-iron pipe of corresponding size and strength, and is practically equal in flow capacity to cast-iron or smooth steel pipe when the latter has become tubercular. Riveted pipe sections are connected by slip joints, for light pressures, or by bolted flanges or other special forms of bolted joints which permit a slight deflection.

Spiral-riveted pipe is available in diameters of 3 to 42 in., sectional lengths up to 20 ft. for galvanized and 40 ft. for asphalted, steel thicknesses from 16 gage to ¼ in., and for withstanding bursting pressures of 400 to 900 lb. per sq. in. for the larger diameters up to 1800 lb. for smaller pipes. A safety factor of 5 is commonly employed. Table 14 gives data

Table 14. Spiral riveted pipe

Inside diameter, inches	Thickness, U. S. gage	Weight per foot, asphalted, pounds	Approximate bursting strength, pounds per square inch
6	14	6.6	1560
7	14	7.7	1340
8	14	8.8	1170
9	14	9.9	1045
10	14	11.0	935
11	14	12.0	850
12	14	13.0	780

14	12	22.2	940
15	12	23.7	875
16	12	25.2	820
18	12	27.6	730
20	12	30.6	660
22	10	42.2	765
24	10	45.7	705

(The data relate to sizes of intermediate, or "Extra Heavy" weight; each size listed is also made in lighter and heavier sheet metal.)

selected from publications of the American Spiral Pipe Works. Prices per pound for plain-ended pipe were quoted in 1924 at 12.2 to 13.2¢ for asphalted, and 17.1 to 18.5¢ for galvanized, the higher price applying to the lighter-gage metal.

Couplings most commonly used, other than slip joints for small pressures, are flanges, preferably of forged steel, and bolted sleeve joints with rubber packing. On a line of asphalted pipe, in 40-ft. sections, flanges attached at the factory will cost an additional 30 per cent. over the price of the plain pipe in sizes from 6- to 30-in.; bolted sleeve joints cost 13 per cent. the price of plain pipe. For a line of galvanized pipe, in 20-ft. sections, galvanized flanges attached at the factory will cost 50 to 60 per cent. the price of the plain

pipe, and bolted sleeve couplings (not galvanized) will amount to 15 to 20 per cent. the cost of plain pipe in the line.

The Nevada Consolidated Copper Co., in connection with its central reservoir on Duck Creek (*109 J 857*), laid 54,800 ft. of feeder lines to convey water from four tributary streams and thereby maintain their flow during the winter. Of this total, 45,000 ft. (at three tributaries) consisted of 8- and 12-in. riveted, slip-jointed, light-weight pipe in 20-ft. sections, made in the company's shop at a cost of 7¢ per lb., and asphalted. The lines were laid so as to develop little pressure. Joints were made by warming the larger end to expand it and soften the asphalt; the small end of the next section was then driven in by a ram supported on a light tripod. Three men laid 1500 to 2000 ft. of 8-in. pipe in this manner per day. The total cost of these three lines was 62¢ per ft. for the 8-in. and 75¢ per ft. for the 12-in. line. The fourth line, 9800 ft. of 6-in. pipe designed to carry 150 lb. per sq. in., cost $1.53 per ft.

Flow in pipes and open channels. See Sec. 27, Arts. 29 and 30.

Other sources of water. Mine water is often available for milling purposes; its composition may require correction, especially for flotation processes. Springs, wells, tunnels in water-bearing strata, streams, ponds, lakes, and the ocean have all been drawn upon for mill water.

Nevada Consolidated Copper Co., just below its main gravity storage dam on Duck Creek, drove a tunnel 1150 ft. long across the valley at the bottom of gravelly soil, 40 ft. deep, resting on hardpan. This intercepted 2 cu. ft. per sec. of the seepage from the reservoir, which was raised by a hydraulic ejector operated by a high-pressure gravity line. McGill springs, at the Nevada Consolidated smelter, deliver 9 to 12 cu. ft. per sec. This was formerly pumped to mill-supply tanks by two motor-driven centrifugal pumps, each with capacity of 4.9 cu. ft. per sec., at cost of 0.77 to 1.04¢ per ton of water. One triple-expansion steam pump, with maximum capacity of 12 cu. ft. per sec. against 480-ft. head did the work at about half the cost of the electric installation (*109 J 857*). New Cornelia's water comes from a 2-compartment shaft 600 ft. deep, sunk for the purpose at a point eight miles northeast of Ajo. A duplex, double-acting pump, direct-connected to a synchronous motor, delivers 800,000 to 1,000,000 gal. per day through 6.7 miles of 10-in. iron pipe against a total head (including friction) of 1375 ft. (*60 A 22*). The 2000-ton Allenby mill of the Granby Consolidated, requiring 4.6 tons of water per ton of ore, is supplied from the Similkameen River, one mile away, by three centrifugal pumps (one in reserve) which have a capacity of 800 gal. per min. each, discharging through 5000 ft. of 14-in. pipe against 600-ft. static head (*115 J 989*). At Alaska-Juneau salt water was pumped from Gastineau channel, with two centrifugal pumps, 3000 gal. per min. each; each pump direct-connected to a 400-hp. squirrel-cage induction motor (*120 P 251*). At Alaska-Gastineau, treating 10,000 tons a day with 5.2 tons water per ton ore, there is sufficient gravity supply for five summer months; the remaining months salt water is pumped with three 2-stage Byron Jackson turbines of 1000, 2000, and 3000-gal. per min. capacity respectively against a head of 275 ft., with the expenditure of 700 hp. (*63 A 488*). Water for the Chino mill, Hurley, N. M., is obtained from wells and streams, respectively five miles south, one mile northeast, four miles and five miles west, the last two using the same steel pipe line. The pump stations are equipped with Aldrich electric-driven pumps (*104 P 464*). Storage at Hurley is 3,000,000 gal. New water amounts to 18 per cent. of the 7.1 tons in circulation per ton of ore.

At the 4000-ton Panda concentrator at Katanga water is pumped from the river, two miles distant, by two 3-stage centrifugal pumps, each of 3300 gal. per min. capacity and each direct-connected to a 525-hp. synchronous motor. The pumps deliver through 24-, 26-, and 28-in. spiral-riveted pipe against 300 ft. head. After passing through the powerhouse condensers, the water is elevated another 200 ft. by three 2-stage pumps, each driven by 350-hp. synchronous motors. The capacity of the two mill reservoirs is 3,820,000 gal. (*29 MM 137*).

Inspiration, treating 14,700 tons ore per day (1924) obtains its daily supply of 6,700,000 gal. (1.89 tons per ton of ore) of new water from six wells, 300 ft. to 1400 ft. deep in gravel, at a point 14,500 ft. from the mill (*G. H. Ruggles, PC*). Well pumps deliver through 1000 ft. of 10-in. pipe against a static head of 80 ft. to the station pumps operating against a static head of 520 ft. and delivering to a 3,000,000-gal. mill reservoir through a 20-in. pipe line. The line is partly of steel with leaded bell-and-spigot joints, partly of flanged pipe. Power requirements are 3.49 kw.-hr. per 1000 gal. The approximate total cost is 5¢ per 1000 gal. (= 2.2¢ per ton of ore). For recovery of old water see Art. 3.

At the Ray Consolidated mill, Hayden, Ariz., treating 10,000 tons of ore per day, 35,000 tons of water per day is pumped from wells near the Gila River through 9000 ft. of 26-in.

wood-stave pipe against head of 310 ft. (*W. S. Boyd, PC*). The initial cost of the water plant was $400,000. Power for pumping is 1.3 kw.-hr. per 1000 gal. (1.09 kw.-hr. per ton of ore) showing an over-all efficiency of 75 per cent.; the total cost of water is 3.4¢ per 1000 gal. (2.85¢ per ton of ore). No provision for recovery of water has been found necessary. The water circulation in the gravity section of the mill (jigs, tables, vanners) was 6 tons per ton ore.

At Miami, treating 7000 tons of ore a day with an average water circulation of 3.5 tons per ton of ore, 1600 gal. of new water per min. (1.4 tons per ton of ore) is pumped from wells and mine shafts four miles away, against a total head of 862 ft. with an expenditure of 3.5 kw.-hr. per 1000 gal. at a cost of 7¢ per 1000 gal. (2.3¢ per ton of ore). Old water to the amount of 2500 gal. per min. (2.1 tons per ton of ore) is reclaimed from the tailing dam, against head of 160 ft., with an expenditure of 235 hp. and at cost of 1.5¢ per ton of ore. (For methods of reclaiming, see Art. 3.) In 1922 Miami spent 4.6¢ per ton of ore for mill water, or 7.1 per cent. of the total cost of milling.

Chemical composition of the mill water may be important, especially when mine water is to be used. Mechanical troubles may be caused by the corrosion of metal by acid water, or by lime accretions deposited by hard water. Flotation is highly susceptible to variation in character of the water, with respect both to its soluble and its suspended matter, and certain special flotation methods require careful control of the character of water entering the mill.

In South-east Missouri it is common practice to use mine water as far as it goes, supplemented by pumping stations on Big River and Flat River. The water in circulation averages 7 to 11 tons per ton of ore, and a 3000- to 4000-ton mill can usually operate with a supply of new water amounting to 700 gal. per min. (4200 tons per day), the principal loss occurring with flotation tailing. The mine water often carries as much as 30 grains of calcium and magnesium salts per gal., and the piping, launders and tables of the mills require frequent cleaning (*57 A 322*). At Tul Mi Chung mill, Korea, concentrating a highly complex sulphide ore exclusively by flotation (*33 IMM 2*), water is obtained by pumping from a reservoir fed by a stream which, during nine months of the year, carries a large proportion of suspended clay in addition to dissolved salts corresponding to 44 parts total CaO and 12 parts MgO per million. Coagulation is effected by adding 300 lb. of lime to the 1700 tons of water consumed per day (0.18 lb. lime per ton) followed by settling before pumping. Undissolved lime is injurious to flotation of this ore, but free alkalinity of 0.0004 per cent. CaO is helpful. Lime is not added during the 3 months that the water is clear.

At Consolidated Coppermines milk of lime was added to the discharged tailing just before it enters the final Dorr thickener, in order to overcome interference with flotation caused by sulphuric acid and iron salts. All mine water used in the mill was first sent to the same thickener, which was thereby made to act as a water-treatment plant, the overflow being returned to the main supply tank, while precipitated calcium sulphate and iron hydroxides were discharged with the thickened tailings. By a similar arrangement of flow at the Utah Consolidated mill, constant character of mill water was maintained, although chemical treatment was not required. At the Utah Apex mill, acid salts in the mine-water supply were neutralized, and at the same time a desirable flotation reagent was introduced, by adding sodium sulphide at the fine-crushing mills and combining the flotation tailing and new mine water in the same Dorr tank, the overflow of which returned to the storage supply, while the thickened tailing, carrying also the precipitated impurities from the mine water, passed over concentrating tables and thence to waste.

Water conservation may become necessary or advisable: (*a*) to economize in the supply of new water, where the latter is scarce or expensive to procure; (*b*) to save cost in pumping new water, where the escaping water can be collected at an elevation above that of its original source; (*c*) to avoid loss of useful material in solution; (*d*) to escape prosecution for polluting streams.

The most notable examples of systematic conservation in the United States are found among the lead-ore concentrating mills of south-east Missouri, which recover 80 to 90 per cent. of the mill water; the zinc mills of the Joplin district, and the copper-flotation mills of the South-west, whose average return of water ranges from 70 to 85 per cent. The Sta. Barbara lead-carbonate concentrator in Mexico returns over 90 per cent. of its circulating mill water. (See Table 13.)

A tailing pond is the most common means for recovery, sometimes in combination with mechanical devices, but frequently alone. For methods of forming retaining dams, see Art. 3. Water is clarified by natural sedimentation, or by discharging the slime portion of the tailing on top of a growing pile of sand tailing, which acts as a filter (*57 A 332, 420*). This latter method was formerly the usual practice in South-east Missouri, but is now largely abandoned in favor of settling ponds.

Mechanical settlers, designed primarily for dewatering concentrate, sand tailing, etc., but incidentally yielding an overflow sufficiently clear to be returned to the mill circuit, can often be so placed as to afford considerable economy in returning water to the central supply tank. Devices of this type include the Allen, Boylan, Callow, Caldecott and similar settling cones, the Akins, Dorr, Esperanza, and other varieties of screw or scraper dewaterers, and Dorr settling tanks of the smaller sizes. Filter water is also suitable for returning. If not wanted where it can be immediately conducted by gravity, the clear water can be returned to the main supply system by pumps discharging directly into the main water pipes in the mill, thereby avoiding a separate column pipe from each pump to the main pressure tank.

Clarifying tanks, for the primary purpose of reclaiming water and discharging thickened slime, are now commonly of the Dorr type, having the advantage of large capacity with small loss of mill height. Tanks of the larger sizes, 50 to 200-ft. diam., are frequently placed out-doors (except in cold climates) set with the bottom below the general level of the ground.

Performance. See Table 13. At Phelps Dodge, Morenci branch, reclaimed water (2310 gal. per. min.) is returned from a common sump against a head of 235 ft. by pumps requiring 200 hp. At the Chino mill (see Table 13) the total power for water circulation is 1850 hp., including pumping of the original supply (see p. 1278). At Copper Queen (see Table 13) the water content of discharged tailing is reduced from 75 per cent. to 35 per cent. before discharging to the sand retaining dam, where an additional recovery of water is secured. Water recovery at Inspiration is described in Art. 3. South-east Missouri practice is, in general, to dewater sand tailing by drag scrapers or shovel wheels, thus obtaining clear water, and to impound slime tailing.

3. Situation of mill with respect to tailing disposal

General. The necessity of providing for the economical and satisfactory disposal of tailing, usually amounting to 75 per cent. and frequently approaching 100 per cent. of the tonnage delivered to a mill, has often been the deciding factor in selection of a mill site, especially for a large plant treating ore from a mine with an assured long life. Some of the factors that enter the problem are: (*a*) maximum economy requires gravity flow of the tailing to its destination; (*b*) gravity disposal involves the use of water as a carrier and not all of this can be recovered; (*c*) mechanical elevation of tailing and the accompanying water may be a necessary preliminary to gravity disposal; mechanical stacking of dewatered sand tailing is an alternative; (*d*) areas of land may have to be acquired solely for tailing disposal; (*e*) special precautions may need to be taken against pollution of streams by soluble or suspended matter; (*f*) special haulage facilities may be needed; (*g*) tailing from which it is hoped to extract valuable ingredients by subsequent operations will usually require additional expense for suitable storage; (*h*) in a few cases, the tailing has enough present market value to become a source of revenue, or at least to pay for disposal.

Direct loading into cars is a common method of disposing of coarse waste, especially that produced by hand sorting or by dry methods of concentration, as in Lake Superior "rock houses," Wisconsin zinc mills, coal washers,

magnetic iron concentrators, etc. At wet concentrating mills, the advantage of this method, even where gravity disposal is utilized for finer tailing, is that it avoids waste of the large volume of water that would be required to flush coarse material down a flume.

Former practice in SOUTH-EASTERN MISSOURI was to dewater sand tailing in an elevated tank from which the settled product passed through spigots into cars drawn to a dump by locomotive. This plan is now obsolete, but in modified form (tailing mechanically dewatered before transfer to a bin) is still practiced at ST. JOSEPH LEAD CO., Bonne Terre mill (*57 A 420*). At BUNKER HILL & SULLIVAN, sand tailing is occasionally diverted from an elevated gravity flume into railroad cars and hauled away for ballast. Tailing from the leaching vats at Ajo is loaded by truss excavator into the same cars that bring the crushed, raw ore to the plant. Unusual circumstances at the MOCTEZUMA mill formerly required conveyance of de-slimed sand tailing across a gulch by aerial tram; the tailing now is all slime and flows by gravity to settling ponds.

Gravity flushing of wet tailing of medium to fine size is always adopted if conditions permit; the method may require assistance of mechanical elevators, and is frequently employed in such a manner as to permit recovery of water. Design of a tailing launder requires special attention because: (*a*) it is usually longer than any launder inside a mill and, if given a grade steeper than is actually necessary, will sacrifice an undue amount of available head; (*b*) it carries a larger volume than individual mill launders and should be designed to do this without the addition of valuable water for flushing; (*c*) abrasion, while no more severe than in mill launders conveying the same material, demands more extensive renewals; linings should therefore be specially designed for durability and ultimate economy. (For general data on dimensions and slopes of launders, see Art. 6 and Sec. 20, Art. 10.)

At BUNKER HILL & SULLIVAN the sides of a wooden tailing launder, 24 in. wide, are lined with concrete slabs, 1 ft. square and 1.5 in. thick, or white-iron plates of the same size, 1 in. thick, or with discarded elevator belt with the rubber-protected side against the walls. The bottom is riffled transversely, at 24-in. intervals, with ¾-in. white-iron strips 6 in. wide, standing on edge; sand resting between the cleats prevents wear on the bottom (*S. A. Easton, PC*; *120 P 525*). The slope is ⅜ in. per ft. At UNITED EASTERN fine-crushed cyanide tailing (46 per cent. water) is distributed by gravity through 6-in. slip-jointed, iron pipe laid with 3° (⅝ in. per ft.) minimum slope.

Impounding of tailing has three purposes: (*a*) to save the solid for future treatment, as at Anaconda, Panda, and Chino; (*b*) to give opportunity for settling and recovering water, as in Missouri, the South-west, Mexico, and elsewhere; (*c*) to avoid pollution of streams, as at Engelmine, Cal., certain anthracite washeries, and at numerous cyanide mills. Tailing ponds may be formed by excavation in earth, as at Anaconda; by concrete dams, as at Engelmine; or, more commonly, by dams formed from the tailing itself; the latter is common practice in the South-west. Impounding dams are frequently used to catch the water remaining in the thickened product of mechanical dewaterers.

Tailing dams are built by discharging a stream of pulp from a launder elevated on a trestle of light construction, from which, as the pile accumulates, some of the horizontal timber can be recovered. To build a stable dam with maximum slope of face requires that slime be removed from the sand before the latter is placed. The slime, deposited separately above the sand dam, effectively fills the pores in the upper layers of sand, but does not increase the tendency of the dam to slide. De-sliming may be done in the mill, discharging the two tailings through separate launders, or in improvised or regularly-constructed classifiers, situated on the tailing-dam trestle, and delivering slime overflow at a distance from the sand. In some cases the topography permits the tailing sluice or pipe line to be laid on the surface.

At Old Dominion 700 tons per day of flotation tailing (practically all −48-mesh, and 56 per cent. −200-mesh) is carried by gravity in an unthickened pulp of 20 to 25 per cent. solids through 8-in. steel pipe having a minimum length of 1600 ft. and maximum of 3600 ft. (See Fig. 1.) The total head is 50 ft., and the pipe is laid at any convenient grade (*C. E. Chaffin, PC*). The pipe delivers to a Dorr duplex classifier at the face of the dam, mounted with its motor on a truck, periodically moved ahead on a 20-ft. section of track, when a corresponding section of pipe is introduced. (See Fig. 2.) Sands, constituting about one-third of the solids, are deposited ahead of the classifier, forming a long, narrow dam on a hillside, while slimes discharge sideways into the pond. The dam section in process of building is 12 ft. high and 12 ft. wide at the top, with side slopes of 45°. When a 12-ft. layer has been completed to the limits of its width (200 ft.), another layer is started on top. When the maximum height of the present dam, *viz.* 30 ft. above ground, has been reached, another will be started at a lower point. One man attends the classifier and shapes the dam. The cost of disposal, 2½¢ per ton, is relatively high because of the long, narrow shape of the dam. Water is not reclaimed, but overflows by a wooden standpipe and flume through the dam.

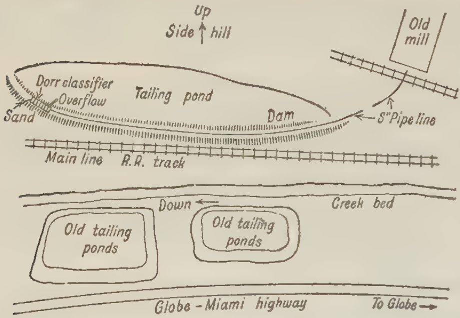

Fig. 1.—Plan of tailing dam, Old Dominion.

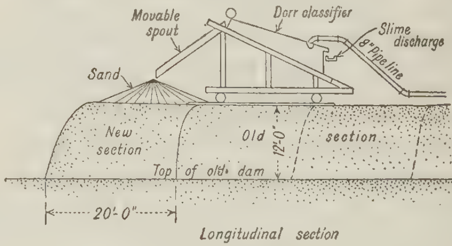

Fig. 2.—Old Dominion method of building tailing dam.

At Inspiration 14,200 tons per day of table and flotation tailing (94 per cent. −48 and 52 per cent. −200-mesh) is disposed of entirely by gravity (*C. E. Chaffin, PC*). All table tailing and part of the flotation tailing are thickened just outside the mill to recover water at as high a level as possible. The feed to the roughing tanks carries 22.(per cent. solids; the overflow going to the Dorr thickeners carries 22 per cent. solids. The total water recovered is 4600 gal per min., or nearly 50 per cent of the whole circulation. The final discharge to the tailing dam containing all thickened products and the unthickened portion o flotation tailing, averaged 31. per cent. solids during 1922 This flows in an open launde 3000 ft. to the nearest corner o the tailing dam, roughly squar in plan, and then in either on of two elevated launders, abou 5000 ft. long, each extendin half-way around the perimeter The launders are 4 ft. wid and 2 ft. deep, made of 2-in plank with battened joints and have a uniform grade of 14 in. per 100 ft. Collars a

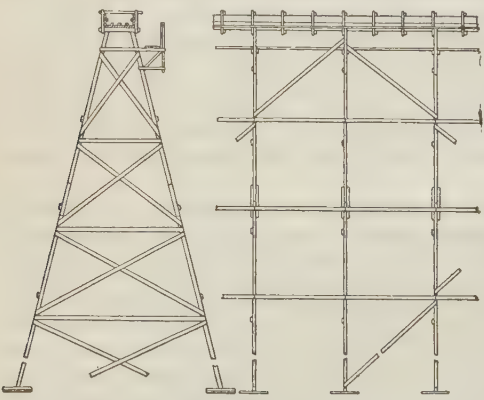

Fig. 3.—Tailing launder and trestle, Inspiration.

3-ft. intervals are made of 4 × 6-in. sill and 2 × 4-in. posts and cap. The trestle (Fig. 3) ranges from 30 to 70 ft. high. Bents are spaced 12 ft. For bents up to 50 ft. the legs and caps are 4 × 6-in., battered 3 in 12, transversely braced in 12-ft. panels with 2 × 6-in. cross braces. For higher bents, the posts are increased 50 to 100 per cent. in section. A walkway 2 ft. wide with hand-rail is carried at one side of the flume. Longitudinal bracing is effected by means of purlins spaced 12 ft. and slant bracing as shown in Fig. 3. The total load is 750 lb. per linear ft. Total lumber for a 30-ft. trestle is 900 bd. ft. per 12-ft. section.

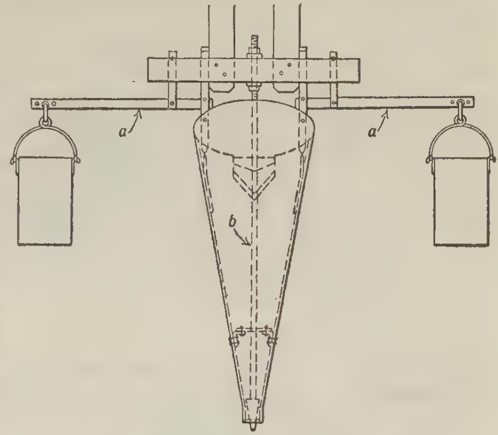

Fig. 4.—De-sliming cones, Inspiration tailing dam.

Sand is de-slimed in automatic cones (Fig. 4) 15 ½-in. inside diameter at the top, 2-in. diameter at the bottom, and about 3 ft. 2 in. deep, made of No. 20 galvanized sheet. The cone is suspended by straps from counterweighted levers (*a*). The valve rod (*b*) is fixed in position so that when the cone is filled with pulp at low density the valve is closed. As sand collects and the weight of the cone increases, it drops somewhat and the valve opens, discharging thickened sand.

The cones are spaced at 12-ft. centers along the trestle. They are fed through ¾-in. pipes inserted through the side of the flume. Sand and slime are discharged through short spouts, the former to a marginal pile and the latter to the enclosed pond. (See Fig. 5.) Of 400 cones installed, 250 are in use at a time; one man per shift watches 80 cones and 1000 ft. of flume. Other labor includes a boss and three men per shift. Wet sand settles to a slope of 1½ to 1. The marginal pile is raised to height of 40 ft., with a top width of 12 ft. When the enclosed area is filled with slime, a new trestle is erected on top and about 80 ft. back from the edge of the preceding pile; the resulting terraces are necessary to prevent leakage. In Feb., 1923, the fourth marginal pile had reached 126 ft. above the lowest point of ground, and was expected to impound two years' tailing; lower ponds will then be started, as no higher level can be reached without pumping. Table 15 gives costs. Prior to 1920, about the same annual tonnage was distributed to four smaller ponds at costs ranging from 2.65¢ to 3.71¢ per ton.

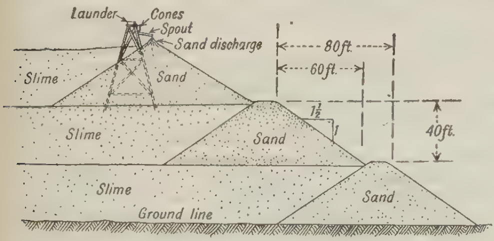

Fig. 5.—Section of tailing dam, Inspiration.

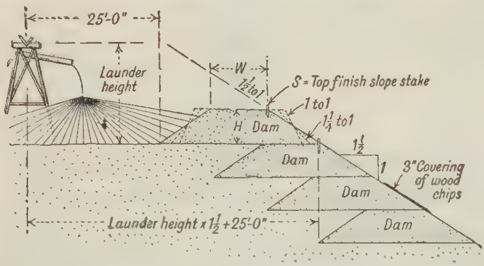
Table 15. Cost of tailing disposal at Inspiration mill (cents per dry ton)

Year	Tons solid	Launders and trestles	Drain	Operating labor	Miscel.	Total
1920	4,943,000	0.488	0.168	0.490	0.224	1.370
1921	884,950	1.420	0.463	0.539	0.168	2.690
1922	3,534,000	1.120	0.090	0.550	0.460	2.220
1923	4,957,730	1.620	0.100	0.570	0.120	2.410

See Table 13 for water recovery. Triplex pumps deliver the overflow of the thickene against a head of 125 ft. with power consumption of 0.801 kw.-hr. per 1000 gal. at a tot cost of 1.25¢ per 1000 gal. Water from the pond is returned by centrifugal pumps again a head of 280 ft., with consumption of 3.23 kw.-hr. per 1000 gal. at a total cost of 5¢ p 1000 gal.

MIAMI, since Dec., 1923, has disposed by gravity of a daily average of 7000 tons flotation tailing (98 per cent. −48- and 55 per cent. −200-mesh) in an unthickened pu carrying about 27 per cent. solids, or at the rate of approximately 3300 gal. per min. (*C. Chaffin, PC*). This flows through 4000 ft. of 18-in. redwood stave pipe under a head 26 ft. The pipe is large enough to allow sand to settle on its lower side and protect it fro wear. It lies on the ground, at no special grade (at one point passing over a low hill except where it crosses the slime pond on a trestle. When it is necessary to raise this trestl sand is allowed to flow through holes in the bottom of the pipe, forming a ridge across t middle of the pond. The pipe delivers to a distribution box from which two launders e tend, one for 2400 ft. and one for 1600 ft., in opposite directions along the face of the dar The launders are V-shaped, with 24-in. sides, made of 2-in. plank, set on a grade of to 3/16 in. per ft., and have V-notches to the full depth on the dam side at 20-ft. interval They are supported on a trestle (Fig. 6), 30 to 60 ft. high, 25 ft. back from the outer edge of t dam. The bents, 10 ft. apa are made of 4 × 4-in. pos and 2 × 4-in. braces. T entire flow in each launder discharged through its lowe notch, and directed towa the face of the dam by apron 9 ft. long, 4 ft. wide a 1 ft. deep, made of 1-in. boar The sands settle on the ban while slime flows inwardly t ward the pond. When t sands have accumulated to depth of 6 ft., the next high notch is opened, and the pro ess is repeated until a 6- layer has been deposited ba to the distribution box. T part of the operation requi 1 man per shift, with anoth man and a foreman on d shift, or 5 men per day. dam 6 ft. high is next formed along the outer edge of the pile by an American railw ditcher operated by three men and requiring 45 days (one shift) to complete a dam alo the whole length of the tailing pile. The outer face of this dam, sloping 1½ to 1, is co tinuous with the general outer slope of the whole pile; no terracing is necessary. O 6-ft. dam provides retaining space for 6 months, or 1,250,000 tons. The highest point the dam (early 1924) was 200 ft. above ground; additional height will require pumpi of tailing, as was formerly practiced when the mill discharged from a lower level. Wo chips, collected on screens attached to Dorr classifiers in the mill and amounting to 3 4 tons (dry) per day, are spread loosely in a 3-in. layer over the outer slope of the pile alleviate nuisance from blowing dust. The cost of gravity disposal (1923) including tres and launder building, ditcher operation, labor and maintenance was 1.61¢ per ton; t additional cost of collecting, transporting and spreading wood chips was 0.75¢ per t of tailing.



W = finished width of top when dry. *H* = height of dam for stacking dry sand. For stacking wet sand for finished top width *W*, place stake at *S*; for semi-wet sand move slope stakes in *H*/4 from *S*.

FIG. 6.—Section of tailing dam, Miami Copper Co.

Clarification of tailing water to avoid pollution of streams is required the laws of certain states.

At ENGELS, a concrete tailing dam, preceded by three Esperanza drag classifiers in ser and one 80-ft. Dorr thickener, is used. Lime is added in the proportion of 1.76 lb. C per ton of ore, to assist settling. The cost of clarification (1920) was 17¢ per ton of milled; water is not recovered (*123 P 183*). Settling ponds are frequently inadequate the desired degree of clarification at PENNSYLVANIA ANTHRACITE WASHERIES and electroly methods of coagulating fine suspended matter are under development.

Elevation of tailing is adopted, either to stack comparatively dry taili in a pile or to extend the radius of gravity disposal. The most commo

employed means of elevation are: (*a*) inclined trams, as at anthracite breakers and some So. African gold mills; (*b*) sand wheels, notably at some Lake Superior copper mills; (*c*) belt-bucket elevators, as in the Joplin district, and formerly at Chino; (*d*) inclined belt conveyors, as in south-east Missouri and more recently at Joplin; (*e*) centrifugal sand pumps, as at Bunker Hill and Sullivan, and formerly at Miami; (*f*) air-lifts, of which there is a noteworthy installation at the Chino mill.

Sand wheels up to 60-ft. diameter have been used in So. Africa and are still retained at Calumet and Hecla copper mills, for transferring tailing from the main concentrator to re-treatment works, on account of their simplicity, durability and efficiency. For details see Sec. 20, Art. 14.

Belt-bucket elevators are frequently used for tailing disposal in the Tri-State district but are gradually being replaced by inclined conveyors handling dewatered tailing (*H. H. Wallower, PC*). When the disposal space within reach of the mill elevator and its distributing launder is exhausted, a second elevator of the same height is erected on top of the first pile, receiving its pulp through launder from the top of the first elevator, and distributes its discharge by a second launder. The system is extended in this manner until as many as three or four intermediate " dummy " elevators are installed in addition to the mill elevator and the final stacker.

Owing to the grade (2 in. per ft.) required of the connecting launders, and an unavoidable drop of 6 ft. at the upper end of each elevator, the combined lift of the elevators will be about twice the height of the final pile, and all water required for flushing through the successive launders (1.7 tons per ton of tailing) must be elevated the same distance. An average mill of the district discharges 25 tons and a large mill 45 tons of tailing per hour. At an average mill, elevator belts are 8-ply, 24 in. wide, with buckets 24 by 7 in., made of 10-gage steel, spaced on 18-in. centers; this permits 3 shifts of buckets during the life of one belt, which is usually about 18 months. Average speed is 275 ft. per min.; average power for a system containing one or two dummies, 0.44 hp. per ton of pulp, equivalent to 1.18 hp. per ton of dry tailing deposited.

A new 60-ft. dummy elevator costs about $2000 complete, itemized as follows; 136 ft. of belt @ $3.85 = $524; 90 buckets @ $1.31 = $118; 1 spout, $40; 15-hp. motor and material and erection of elevator structure, $1318. Cost of operation of a system containing five elevators will average, per year: power (300 days of 20 hr., 75 hp. @ 1.5¢ per hp.-hr.), $6750; labor for maintenance and attendance, $250; total, $7000, equivalent to 4.7¢ per ton for a mill of average size, or 2.6¢ per ton for a large mill.

Inclined belt conveyors represent standard practice in the lead belt of south-east Missouri, where a single mill may dispose of 2000 to 4000 tons of sand tailing per day (*57 A 322*).

The sands are mechanically dewatered (shovel wheels are preferred) to 8 to 20 per cent. moisture and delivered to a rubber-covered belt conveyor, usually 24 in. wide, inclined 16°, and moving 300 to 350 ft. per min.; in one exceptional case, the speed was 475 ft. per min. up 23° slope; in general, 18 per cent. moisture will cause tailing to slide on a 16° slope. The belt is usually lengthened by units of 75 ft., as the pile gains height. Idlers for this wet work must stand hard usage. The standard 5-pulley grease-lubricated type is in general use, experiments with ball-bearing idlers having proved disappointing. Discharging from the belt may require assistance by air or water jets. Tailing is distributed from the end of the belt through semi-circular launders (9-in. radius) of No. 10 sheet iron in 4-ft. sections. They are laid on the pile with a slope of 2.5 to 3 in. per ft. Flow is assisted by water (formerly also by flotation tailing) pumped through a pipe from the mill to the upper end of the conveyor; in some cases part of this flushing liquid is dropped on the flank of the sand pile, washing out a cavity to be concurrently filled with sand from the conveyor. Slime tailing was sometimes filtered through sand piles, yielding clear water to the reclaiming pond, but impounding dams for slime tailing are now practically always used.

At certain mills of the Tri-State district (*H. H. Wallower, PC*) the tailing, previously dewatered by cones, drag scrapers, shovel wheels, screens, etc., is now stacked by inclined belt conveyors instead of by elevators. Fig. 7 illustrates one method of arrangement. One 250-ft. conveyor inclined at 20° will replace a mill elevator, final stacking elevator

and two dummies, with their connecting launders; the power consumption will be about one-third that for the four elevators, and the life of conveyor belt is 2½ to 3 times that of elevator belts; attendance is also reduced. At the GOLDEN ROD mill, one 450-ft. inclined belt replaced five elevators and avoided erection of a sixth and was expected to save $21,100 in a four years in addition to refunding the cost of the conveyor ($6300). The usual belt in the Tri-State district is 18 in. wide, inclined at 20°. Speeds are: 175 ft. per min. for 3[illegible] tons per hour; 220 ft. per min. for 45 tons; 230 ft. per min. and a 20-in. belt for 55 tons per hour. At one plant, stacking by a conveyor 260 ft. long rising 85 ft., requires 0.5[illegible] hp.-hr. per ton, including dewatering wheel, conveyor, and slime pump.

Tailing is distributed from the head of the conveyor with or without the addition of water. A common means for distribution without additional water is an auxiliary horizontal reversible conveyor, at right-angles to the elevating conveyor, and extending in both directions. The GOLDEN ROD mill will install a 40-ft. distributing conveyor pivoted at its feed end and supported by cable from an A-frame at the head of the inclined conveyor;

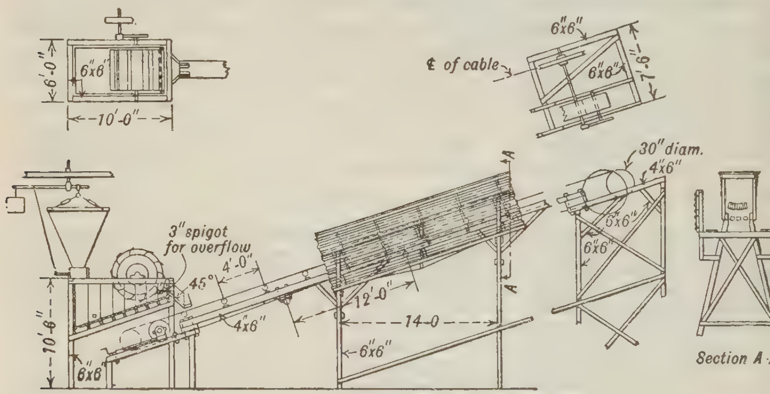


FIG. 7.—Tailing conveyor.

this can then swing 180° and may be inclined to afford additional elevation. In the we[illegible] method, the inclined conveyor discharges into a box which also receives flotation tailin[illegible] pumped up from the mill; the combined pulp then flows through a steel launder slopin[illegible] 2 in. per ft. The average mill, discharging 45 tons sand tailing per hour, will pump 25[illegible] gal. per min of flotation-tailing pulp the solids in which average 98 per cent. −100-mesh

Centrifugal sand pumps are now available in durable types and adequate sizes to stand the severe service of pumping large volumes of tailing. (For pumps in general mill service, see Art. 6; also Sec. 20, Art. 11.) Sands up to ⅛-in. size can be pumped safely, if carried by at least three parts of water; coarser sands are being pumped, but at the cost of excessive wear. Pulps below 48-mesh can be pumped at a dilution of 1 : 1; and, in general, trouble due to sedimentation is less likely to occur with thick than with thin pulps. Pipes through which coarse pulps are being pumped should be inclined at least 20° from the horizontal, to permit complete drainage when the pump stops.

At UTAH CONSOLIDATED 950 tons per day of tailing (80 per cent. −200-mesh) in pu[illegible] carrying 40 per cent. solids is pumped against a head of 35 ft., using a 6-in. Wilfley pum[illegible] BUNKER HILL & SULLIVAN lifts 600 tons of general tailing with 24,000 tons of water per d[illegible] against a 25-ft. head (to a gravity flume) with a 12-in. Byron Jackson pump direct-co[illegible] nected to a 75-hp. motor at 900 r.p.m. (*120 P 525*). MIAMI formerly used three 6-in. W[illegible] fley pumps (with three others always in reserve) to lift 3300 gal. per min. of tailing pu[illegible] carrying 22 to 27 per cent. solids (averaging 6000 tons dry solid per day crushed to 18 mes[illegible] against a total head of 46 ft. Each pump was driven at 1020 r.p.m. by belt from a 50-h[illegible] motor; the power requirement was 0.45 kw.-hr. per dry ton. The delivery pipe was 18 i[illegible]

diameter and was steel for a short distance from the pumps, the remainder redwood; total length, 1280 ft. The average pulp velocity was 4.2 ft. per sec. The expense per dry ton was: power, 0.594¢; labor and supplies for operation, 0.224¢; maintenance of pumping plant, 0.212¢; total, 1.032¢, not including labor on the dump. Wood pipe showed no wear after 18 months (*C. E. Chaffin, PC*). This system is now displaced, rearrangement of the milling process having made it possible to discard tailing by gravity from a higher level (see p. 1284).

Air-lifts were installed at the Chino Copper Co. in 1919 to raise 12,000 (dry) tons of tailing per 24 hr. to a height of 40 ft., delivering into a gravity launder (*J. M. Sully, PC; 112 J 806*). For details of construction and operation, see Sec. 20, Art. 15. The costs for the initial period of 16 months (Sept., 1919 to Dec., 1920), for 9 months of 1922 (resumed Apr. 1 after a year's suspension), and for the year 1923, are compared in Table 16.

Table 16. Operating cost, Chino tailing air-lift

	16 months, 1919–1920	9 months, 1922	Year, 1923
Ore milled, tons	....	1,416,869	2,785,564
Tailing lifted, tons	2,207,922	1,348,619	2,645,182
	Cents per dry ton	Cents per dry ton	Cents per dry ton
Steam power	0.687	0.675	0.721
Electric power (condenser auxiliaries)	.102	.091	.078
Compressor labor (operation and repairs)	.120	.063	.064
Plant labor (mostly repairs)	.022	.194	.111
Compressor supplies	.040	.059	.021
Plant supplies	.017	.261	.087
Total per dry ton lifted	0.988	1.343	1.082
Total per ton milled	....	1.278	1.028
Total per ton of pulp	0.148	....	....

During the first 16 months, a belt-bucket elevator in the mill was lifting a slightly greater volume of the same pulp to a corresponding height at total cost of 1.954¢ per dry ton (0.293¢ per ton of pulp). In addition to the indicated saving of nearly 50 per cent. in operating cost, the air-lift had the additional advantage of causing no delay for replacements, and of being more elastic in its power requirements. The air-lift was able to start and clear itself after the foot-piece had been buried under 32 ft. of settled slime. The estimated cost of a bucket-elevator installation for the same service as the air-lift plant was 33 per cent. greater than the estimated cost of the latter. During 1921, experiments demonstrated the possibility of air-lift elevation for tailing from the coarse-concentrating department, containing everything up to 1-in. size in a pulp with 50 per cent. solids in suspension.

Possibility of utilizing tailing may have a bearing on the selection of the method for temporary disposal. Common uses for mill tailing are: (*a*) mine filling, as at certain mines in the Lake Superior copper district, Butte, So. Africa, and West Australia; (*b*) for re-treatment, as at the Calumet & Hecla, Utah Copper, Anaconda, Chino, and Panda mills; (*c*) for road building, railroad ballast, and structural purposes; (*d*) for recovery of soluble constituents by natural efflorescence, as at certain cyanide mills; (*e*) for agricultural purposes, as at Mascot, Tenn.

Mine filling. At the Champion mine deficiency of coarse waste filling is made up by hauling mill tailing up to ¼-in. size in railroad cars and dumping into a raise connecting with the working levels. The sand is distributed in the stopes by blowing through pipes up to 250 ft. long from a tank holding a charge of 1.5 tons, using air at 75 lb. pressure. The cost is 2¢ per ton of sand moved. Burning stopes in the Leonard, Tramway and West Colusa mines, Butte, were filled with flotation tailing, both old and currently produced, of which 50 per cent. was −280-mesh. The material was sluiced through a 3650-ft. flume, 23 in. wide, on 2-per cent. grade, in a pulp carrying 20 to 50 per cent. solids and 250 to 600 gal. water per min. Pulp was conducted down the shaft in a 6-in. cast-iron pipe and dis-

tributed 800 to 1000 ft. laterally through 4-in. pipe (cast and wrought) with bends of 4-f radius. A head of 100 ft. was usually satisfactory for distribution (*68 A 61*).

Re-treatment of tailing by tabling, ammonia leaching, and flotation, forms an importar part of the present milling operations at CALUMET & HECLA (*117 J 277*), the material havin been formerly deposited under water and along the shore of Torch Lake, from which it reclaimed by suction dredges. (See pp. 78, 967.) At ANACONDA, when starting the mi in 1901, slime tailing was saved for future treatment by collecting it in six earth pond each 300 by 600 ft. in area and averaging 15.5 ft. deep, the flow, when possible, being cor tinuous through three ponds in series. Settled material was excavated by drag-line scrape and piled alongside the ponds (*46 A 249*). In subsequent years, this accumulation afforde notable amounts of cheaply recovered copper. At CHINO a similar plan was followe during early operations, and later a 1000-ton mill was erected to treat the accumulate tailing. At PANDA, 4000 tons per day of a copper-carbonate ore is concentrated by jig and tables. The tailing averages 5 per cent. Cu, easily recoverable by leaching, for whic treatment it is being impounded (*29 MM 137*, *5 MMt 55*). At the SWEENEY mill, Ke logg, Id., 1,200,000 tons of jig, table, and flotation tailing, −20-mm. in size and averagin 1.9 per cent. Pb, was re-treated. The pile had been formed by the Joplin method of eleva tors and launders (see p. 1285); it covered 20 acres, had maximum height of 70 ft., max mum slope of 20° 07′, a minimum natural slope of 4° 30′, and weighed 110 lb. per cu. f It was reclaimed by steam shovel, standard-gage cars and locomotive, and inclined be conveyor. (*119 P 289*.) At UTAH LEASING Co. (p. 99) old tailing (0.7 per cent. Cu a chalcopyrite) from the Cactus mill was reclaimed at the rate of 620 tons per day by stea shovel and 5-ton cars hauled 1000 ft. by a steam locomotive.

In general, when disposing of tailing in expectation of subsequent re-treatment, th following precautions should be observed, where practicable, even at some additional co (*58 A 178*): (*a*) when starting a mill, the earliest tailing should not be placed so that will be buried under later accumulation, which will probably be of lower grade; (*b*) mid dling should not be mixed with tailing; (*c*) tailing should be placed in a deep and narro rather than a broad and shallow deposit, to facilitate reclamation; (*d*) sand and slime tai ing should be separated; the latter is not only lower in grade but also needs no re-crushin before further treatment.

Road building and railroad ballasting consume important amounts of coarse mill tailin in the tri-state, south-eastern Missouri, Lake Superior, northern New Jersey and nume ous other districts situated near populous communities. At the RICHARD mine, Dove N. J., a large part of the hard, light-colored tailing from dry concentration of iron ore sold for structural purposes within a radius of 100 miles (*115 J 973*). Two coarse grade −2 + ¾-in. and − ¾ + ⅛-in., sell for $1 per ton, and sand − ⅛-in. for 80¢ per to The income from this source is a set-off against fine crushing for recovery of addition iron. The jig tailing from the AMERICAN ZINC, LEAD AND SMELTING Co. mill at MASCO Tenn. (⅝-in. maximum size), is re-screened and classified into sized products suitable fo various structural purposes; the largest consumption is for railroad ballast, but some shipped as far south as Tampa, Fla. A finer material (80 per cent. −200-mesh) is shippe as far as New Orleans, Memphis, and Washington, for use in street and road constructio (*H. I. Young, PC*).

Brick of excellent quality and high acid resistance is made from ANACONDA flotatio tailing, which averages 20 per cent. alumina; the same practice is applied to mill an cyanide tailing at the OPP mine, Oregon (*115 J 492*).

Agricultural uses. The fine limestone flotation tailing (85 per cent. −100-mesh at MASCOT finds a good local market as soil dressing because of its lime content.

4. Topography of mill-site

General. The slope of the ground selected for the mill-site is not only a de termining factor in the cost of construction, but also has an important bearin on the cost of operation. Classified with respect to the slope of the site, mi buildings are of four general types: (*a*) Terraced, on steep hillside. EXAMPLES Alaska-Gastineau, Britannia, Copper Queen, Engels, Kimberley (B. C. Le Roi No. 2, Liberty Bell, Nevada Consolidated, Panda, Silver Dyke, Silve King, Sunnyside, Utah Consolidated, Utah Copper. (*b*) Low, broad buildin on practically level ground. EXAMPLES: Armstead, St. Joseph Lead Co (Bonne Terre), Federal Lead Co. No. 3 (Flat River), American Z. L. & S. Co (Mascot), and the typical mills of the Joplin district. (*c*) Tall and relativel narrow structure on level or slightly sloping ground. EXAMPLES: man anthracite breakers, Bunker Hill & Sullivan, Calumet & Hecla, Northern O

Co. (Edwards, N. Y.), Richard. (*d*) Composite type, represented by United Comstock, Ray, Miami, and numerous other cyanide and flotation mills; in these, the coarse-crushers and screens are housed in a tall structure (sometimes separated by some distance from the concentrator) while agitators, settling tanks, tables or flotation machines are covered by a low broad building with little or no slope.

The CONSTRUCTION FEATURES most affected by slope of site and type of mill are: excavation, retaining and foundation walls, design and erection of frame, with special reference to support of heavy or vibrating machinery and snow loads; natural lighting, and ease of enlarging. The OPERATING FACTORS most strongly influenced are: elevation and re-elevation of ore and its products, pumping and re-pumping of water, labor required for supervision, facility in making repairs and replacements.

Excavations required for a terraced site are not only larger in volume than for a level or gently sloping site, but are also more expensive per cubic yard, owing to the difficulty of employing horse or mechanical traction in the constricted working spaces. For methods and cost of excavation, see *Peele, Merriman, Gillette.* See also Table 43.

Retaining walls are an essential feature only in a terraced mill, although occasionally required elsewhere. On a steep hillside in loose material, retaining walls must have exceptional solidity to withstand the combined settling effect of drainage and the jarring of heavy machinery. When benches are in rock, retaining walls become more or less ornamental only, and are sometimes omitted. Retaining walls generally serve also as foundations for building and equipment. See Sec. 27, Art. 14.

Foundations for the mill building (aside from retaining walls) need have only moderate bearing strength for mills of low average height; in such mills, both terraced and level, the massive equipment rests on the ground, leaving little but the walls, roof, cranes and elevators to be supported by the vertical members of the structure. In tall mills, while it is possible likewise to place the heaviest crushers on the ground, provision must usually be made for carrying heavy and vibrating loads on fairly long vertical columns, and the foundations for these must be substantial. Safe bearing pressures for earth and rock are given in Table 17.

Table 17. Safe bearing pressures, tons per square foot. (*After Baker*)

	Minimum	Maximum
Rock equal to the best ashlar masonry...	25	30
Rock equal to the best brick masonry...	15	20
Rock equal to poor brick masonry......	5	10
Clay in thick beds, always dry..........	6	8
Clay in thick beds, moderately dry......	4	6
Clay in soft beds....................	1	2
Gravel and coarse sand, well cemented...	8	10
Sand, dry, compact, well cemented......	4	6
Sand, clean, dry......................	2	4
Quicksand, alluvial soils...............	0.5	1

Design and erection. In a terraced mill considerable diversity will occur in the dimensions of the several panels and their individual members, calling for a large amount of detailed designing. Erection is retarded by the necessary distribution of structural elements over a large area and at numerous levels. A tall mill also requires skillful and detailed designing; its erection is usually more rapid than that of a terraced mill because the materials can be assembled at a few convenient points, and hoisted into place by one or two derricks. A low, flat building has the advantage of simplicity in design; standardized, stock types of trusses can be selected, and the height of vertical members can be reduced to a few dimensions by bringing foundation walls or piers up to a common level at small expense. Erection of such a building can be done by men working mainly from the ground, with the assistance of a few gin poles. Cost data relating to the erection of typical mills are given in Art. 11.

Enlargements are made most easily at a terraced mill, since the direction of flow is usually directly down the slope, with only subordinate amounts of lateral transfer of prod-

ucts, and additional and similar sections at either end can be readily supplied with or by an extension of the receiving bins, or by a distributing conveyor. A flat mill can usually be extended in the same manner, provided it has been designed with a flow mainly i one direction. A tall building offers the most difficulty, since its ore must be received a a central point and the flow is mainly vertical. BUNKER HILL & SULLIVAN doubled th original capacity of its No. 2 West mill by erecting a duplicate 5-story addition on th opposite side of its receiving bin.

Gravity flow of feed and products, with the accompanying large volume of water, an as nearly complete elimination of elevators and pumps as is possible, are the main object sought by the terraced and tall types of mill. In districts such as south-west Colorad and the coasts of Alaska and British Columbia, choice is practically limited to the terrace site, and in other localities, where ore or water or both can come by gravity to a mill havin the necessary space for tailing disposal, also by gravity, the advantages of a terraced sit probably outweigh its drawbacks. In other situations, requiring initial elevation of ore c water or mechanical elevation of tailing, the choice of a site and the decision as to type c mill demand careful investigation.

Type of mill. As between a tall or terraced and a low mill structure the decision is based on comparison of the costs of the following items: (a Initial elevation of ore. (b) Initial elevation of water. (c) Final elevation c tailing. (d) Final elevation of concentrate. (e) Intermediate elevation of or and products. (f) Re-elevation of water. (g) Interest and amortization o excess cost of erecting and installing a terraced or tall mill. (h) Increase labor charges, due to inconvenience of supervising operations on numerou floors; efficiency of extraction may be adversely affected for the same reason

Initial elevation of ore to the top of the mill by means of the mine-shaf hoist can be performed at little or no expense above that required to delive the ore at ground level; this is general practice in the Tri-State district and often done elsewhere, as at Mascot, Butte & Superior, Engelmine, an Bonne Terre. Other common methods of initial elevation are by chain-buck elevator, as at Utah Apex; inclined pan conveyor, as at United Comstock an at Federal Lead Co., No. 4 mill; inclined belt conveyor as at Bunker Hill Sullivan, Chino, Copper Queen, Santa Barbara, and many others; and incline trams, as at those mills of the Joplin district that receive ore from other source than adjacent shafts.

At BUNKER HILL & SULLIVAN (*S. A. Easton, PC*) the entire feed for No. 2 West m (50 tons per hr. of −1.25-in. material weighing 150 lb. per cu. ft.) is elevated by a be conveyor 227 ft. long, inclined 22°, and rising 52 ft.; 5-ply belt is 20 in. wide, speed 187 f per min. Head pulley 42 in., tail pulley 30 in., 5-pulley troughing idlers. Operati power, including five feeders, one weigher, one pump, one distributer, and one sampler 18 hp. Operating cost, per ton: equipment (troughing and idler pulleys, etc.), 0.029 belting, total length, 465 ft., 0.068¢; power, 0.009¢; labor (cleaning, oiling, etc.), 0.217 total, 0.323¢ per ton.

At UTAH APEX (*J. H. Manwaring, PC*) a chain-bucket elevator 76 ft. long, incline 71° and moving at 63 ft. per min., is used to lift the entire mill feed of 100 tons per h The drive is a 25-hp. motor which draws 11.2 kw. at full load, 7.9 kw. empty. Run-of-mi ore is fed from a track hopper by a steel-apron feeder driven from the tail pulley of t elevator. Keystone rivetless manganese 9-in. chain lasted 5 years; 9-in. Simplex rivetle manganese chain, was still in use at the end of five years. Buckets, 108 spaced 18 in., a 24 × 14 × 17½-in., No. 8 steel; cost $10.61 each. The original cost of the elevator 1913, f.o.b. plant was $3093. The total cost of repairs during 10 years, including o entire replacement of chains and sprockets, was 0.715¢ per ton; power (@ 1¢ per kw.-hr. 0.112¢ per ton.

Initial elevation of water. See Art. 2. In those cases where wat must be pumped, the cost of elevating water to the storage reservoir may more costly than elevation of ore. In general, pumps are more efficien mechanically, than ore elevators, but the fact that they may be required lift 4 to 40 tons of water for every ton of ore, and also to a higher level, makes

essential to keep down mill height, unless abundant water under natural head is available.

Final elevation of tailing is ordinarily unavoidable at any mill on level ground. If treating an ore from which it is possible to extract clean tailing at a fairly coarse stage, a tall or a terraced mill may have the advantage of being able to dispose of this portion of its tailing without further elevation; but at Bunker Hill & Sullivan, a tall mill on level ground at which some coarse-sand tailing is discharged, it is necessary to use a large tailing elevator with a lift of 25 ft. (*120 P 525*). Modern practice discourages coarse tailing; hence the disposal problem has less bearing upon the type of mill than upon the selection of a site. (See Art. 3.)

Elevation of concentrate. The importance of this feature is often exaggerated. Concentrate rarely exceeds 20 per cent. the weight of original ore, and at most of the largest mills it ranges from 3 per cent. to 7 per cent.; hence, any design that provides an additional story or terrace solely to permit gravity disposal of concentrate will be unnecessarily expensive to construct, and is likely to be uneconomical in operation, if it throws additional work upon pumps or elevators at earlier stages of the process.

Intermediate elevation of ore in process can rarely be wholly avoided, even by the most steeply terraced mill.

Britannia, a flotation mill with seven terraces and a drop of 250 ft. in a horizontal length of 209 ft., requires only one elevator. Alaska-Gastineau, a table mill on a steeply-terraced hillside, requires two sets of automatic skips (with 100-ft. lifts) and two bucket elevators. Silver Dyke mill (tables and flotation) with 11 terraces and a total drop of 150 ft. in a horizontal length of 277 ft., requires one elevator of 27-ft. lift and an inclined conveyor with 19-ft. rise, in addition to a number of sand pumps.

In general, the necessity for intermediate elevation is most pronounced in those mills treating an ore in which the valuable minerals occur as particles of graduated size, recoverable by a stage process of reduction and giving rise to important quantities of middling products which must be returned for re-crushing; in such mills, terracing shows the least advantage over the flat system because no practicable amount of terracing (except in rare instances) can provide an exclusively gravity flow for all unfinished product. On the other hand, ores containing only finely-disseminated minerals can often be reduced at once to the final size by consecutive crushing operations, most of the unavoidable re-elevation being performed by scraper classifiers, and separation is made on tables or flotation machines requiring but little mill height. For a milling operation of this character, a gravity flow through the whole concentrating division of the plant can be obtained by a moderate amount of terracing; the re-elevation saved thereby, as compared with a flat mill, while of relatively small lift is large in total volume, the pulp usually containing 75 per cent. or more of water. Methods of re-elevating ore, dry or in pulp, are described in Art. 6 and Sec. 20.

Re-elevation of water. Assuming water reclamation necessary, the advantage is with a low mill. A tall or terraced mill can sometimes utilize the tailing water from jigs treating sized or washed ore as wash water on tables at a lower elevation, but in general clarified water in large amounts is not obtainable until near the end of the concentrating scheme, and most frequently is not recovered until after it has left the mill at the lowest point. If ore is re-elevated by pumps, it must be accompanied by at least an equal weight of water, and may require three times that amount, or more, depending upon its coarseness.

Interest and amortization. The excess cost of a terraced or tall mill as

compared with a low mill of corresponding capacity should be taken into account in comparison of operating costs. The amortization charge per ton will obviously be small for a mill of long life. An elaborate and expensive mill would be injudicious for a mine of dubious life. This explains the character of mill structures commonly erected in the Wisconsin and Joplin zinc districts.

Supervision of machines is greatly impeded when the millmen are compelled to walk up and down stairs; hence in a large mill, justifying the employment of specialized millmen, it is advisable to place as many as possible of the machines of one kind on the same level; in a small mill, as much as possible of the whole equipment should be on one floor, to insure equality of supervision. Facility of supervision not only fixes the number of millmen to be employed at a small mill, but may influence the tonnage and recovery attained. A mill using several dissimilar crushers, or operating a process requiring a variety of concentrating apparatus or involving extended use of hydraulic classifiers, will need more supervision than a mill of the same capacity using only ball mills and flotation. Any mill, however small, needs a certain minimum of supervision, while in another mill of the same type a much larger tonnage may often be treated with the same labor force. A large mill is justified in the installation of mechanical equipment for performing certain operations, such as collection of concentrate, which can more profitably be done in a small mill by hand labor.

Repairs and renewals are much simplified in a level-site mill, where workshops and the operating floor can be joined by a level traveling way or overhead crane.

Lack of working space on the ball-mill terrace was one defect of the ALASKA-JUNEAU mill; the ALASKA-GASTINEAU provides a shop on every terrace; at the UNITED COMSTOCK commodious shops serve every part of the ball-mill floor by track and crane (*114 J 846*; *117 J 516*).

5. Materials for mill construction

The durability of a mill building should bear an approximate relation to its expected life; any expense incurred for making the structure outlast the mine is wasted. The useful life of a mill cannot always be predicted, but during the development of any mine or group of mines up to the stage at which erection of a mill becomes justified, enough information should have been obtained to permit a reasonable estimate of the minimum tonnage likely to be available. The largest and most expensive mills are not undertaken until the factor of ultimate tonnage has been most carefully investigated.

Foundations. Concrete is almost universally employed, except at certain small mills on ground not likely to be heaved by frost, where wooden blocking is sometimes sufficient. Materials for aggregate, already crushed, are usually readily available around any mine, particularly if a mill has previously been operated on the premises.

At ALASKA-GASTINEAU all of the concrete was made with rock and sand provided by excavation of an underground storage pocket adjacent to the mill.

The customary batter of the outside face of terrace retaining walls is 1 to 1¼ in. per ft. but at ANACONDA and SANTA BARBARA retaining walls are vertical. Concrete foundations for vibrating equipment, notably stamp batteries, require special solidity, and the upper surfaces should be protected by a semi-elastic mat. See Sec. 3, Art. 17.

At ALASKA-JUNEAU, oak blocks were necessary under the ends of the vertical columns carrying jaw crushers, to avoid disintegration of the concrete foundations.

Framework. Timber, steel, and reinforced concrete are the customary materials. Wood is the only material found in older mills and is still occasionally employed for framing large mills and nearly always for small ones. Wood has the advantages of: (*a*) lower cost per unit of weight, and also, in most places, per unit of strength; (*b*) reduced amount of detailed designing; (*c*) quicker delivery; (*d*) cheaper erection, by less highly skilled and more easily obtained labor; (*e*) elasticity, as compared with reinforced concrete. Its principal drawbacks are inflammability and liability to decay, especially in floors and mud-sills, which are unavoidably damp.

Structural steel is the prevailing material for large permanent mills, such as Britannia (1426 tons of steel in a terraced mill covering a horizontal area of 56,400 sq. ft. or 51 lb. per sq. ft.), Copper Queen, Chino, Kimberley, Panda, Silver King, Homestake (South), Utah Copper, and the cyanide division of the United Comstock mill (441 tons of steel in a building of 75 ft. maximum height covering 2¼ acres, or 9.2 lb. per sq. ft. of area). In addition to being fireproof and durable (if painted), steel has the advantage of permitting longer trusses and wider spacing, thus reducing the necessary number of columns which occupy or obstruct useful floor space (66-ft. spacing both ways at United Comstock); the columns themselves can also be longer without requiring such extensive cross bracing as would be needed for a wooden structure of same height. Many of the heavy loads (up to 60 tons) commonly carried by cranes serving the crushing departments of modern mills could not be supported safely on any practicable timber structure. While steel structures call for more detailed designing than wooden frames, much of this work can be delegated to the steel-work contractors; many steel fabricators carry in stock or can quickly supply columns, trusses, or whole buildings to cover specified floor areas with a roof of given height. Bearings or hangers for line shafts can be easily attached to steel beams by clamps; they are readily shifted and do not weaken the members by bolt holes, as is the case with wooden beams.

Reinforced concrete has not yet been widely adopted for structural framework, although it was used in the coarse-crushing, fine-crushing, and concentrating departments of the United Comstock mill (*114 J 846, 117 J 516*); in this instance, owing to the easily available aggregate for concrete, and the relatively high cost of structural steel, reinforced concrete was estimated to be nearly 20 per cent. cheaper than steel. Estimates of wooden construction were 30 per cent. lower than for concrete, but the saving on insurance within three years was enough to offset this difference. The cost of the structural concrete work (excluding 15,000 cu. yd. of foundation and retaining walls) was: Concrete, 132 cu. yd., \$1980; reinforcing steel, 21,600 lb., \$1050; forms, 9500 sq. ft., \$1700; total, \$4730, or \$35.83 per cu. yd. For all-steel construction, the corresponding cost for 106,020 lb. of steel, at 8¢ erected, was estimated at \$8481. In a mill of reinforced concrete, special attention must be given to support of oscillating machinery, on account of the severity of the stresses caused by vibration continuously in one direction.

Walls. Corrugated iron, galvanized or asbestos coated, is the commonest material for walls. A wooden frame is usually sheathed with boards, to which corrugated iron is nailed over a layer of paper. On a steel frame the corrugated sheet is attached by bolts, clamps, or wire, with no wood sheathing. Where this construction would not afford the necessary protection against cold, the interior can be coated with gunite, applied against woven-wire or expanded-metal reinforcement, with as much insulating material as desired.

The walls of the United Comstock cyanide section are composed of an outer layer of No. 24 corrugated and an inner layer of No. 28 plain galvanized steel, separated by two thicknesses of tar paper (see below). At the N. Y. Zinc Co. 5-story mill at Edwards, N. Y., the walls are hollow tile, and the equipment is entirely supported by a steel framework having no connection with the walls (*116 J 95*). The tall, steel-framed Richard mill has

hollow-tile walls for the lower half of its height, and asbestos-coated corrugated iron for the upper half (*115 J 973*).

Tile walls are much improved in appearance by an outer coating of mortar or GUNITE; when this finish is intended, the tile should be placed rough side out. The best mixture for applying with a cement gun is four parts clean sharp sand to one part cement; in a dry climate, the sand may be increased to six parts. The outer face of the tile must be thoroughly moistened before applying the mortar, but no reinforcement should be necessary, as would be required with a wooden wall. When applied with a cement gun (*Bul. 114, Cement Gun Co.*) one bag of cement and three cu. ft. of sand will cover 22 sq. ft. with a layer 1 in. thick. A force of eight men at $41 per day (including the operator of a portable compressor, which may not be necessary at an established mine plant) can average 1300 sq. ft. of gunite per day. The cost of a cement gun, not including a portable compressor, was (1923) from $1325 to $1565 corresponding to free-air capacities of 100 and 225 cu. ft. per min. respectively.

A comparison of estimates of costs and heat-insulating characteristics of different types of walls for the UNITED COMSTOCK cyanide building is shown in Table 18.

Table 18. Comparison of estimates of costs and heat-insulating characteristics of different types of wall

	Cost per square foot, cents	Boiler horse-power to heat plant
Plain galvanized corrugated sheet	14.0	220
Gunite, 1 ½ in. on metal lath	19.6	116
Hollow clay tile, 4-in.	35.0	93
Galvanized corrugated steel outside, plain galvanized inside, 2 layers of tar paper between	19.5	125
Wood sheathing, tar paper, galvanized corrugated steel	24.5	93

Roofs. Corrugated galvanized iron is the commonest roofing material. In a cool climate, a board sheathing is almost indispensable to prevent condensation and dripping of moisture; the corrugated sheet is fastened down to this by lead-washered nails.

BRITANNIA mill required 96 tons of corrugated sheet for a total roof area of 58,100 sq. ft. SMUGGLER UNION mill in Colorado (cold winters with heavy snow) has a roof of No. 22 corrugated iron laid on one layer of 1⁄16-in. asbestos sheet and two layers of tar paper; the inside is gunite on woven-wire reinforcement. The roof over the cyanide department of UNITED COMSTOCK (96,400 sq. ft.) is made of 1 ¾-in. Oregon pine, tongued and grooved, covered with No. 20 corrugated sheet. The roof of the KIMBERLEY steel-framed mill (77,000 sq. ft.) is composed of 2 × 4-in. timber on edge laid face to face and covered with felt, tar and gravel (*115 J 244, 116 J 453*). The "Malthoid" roof originally put on the ALASKA-JUNEAU mill proved unsatisfactory, and was replaced by corrugated iron.

Asbestos materials are durable without painting and resist fire. They are also good heat insulators.

In ONTARIO, where winters are long and severe and forest fires have been frequent, the usual roof construction is board sheathing, an intermediate layer of quilted hair felt with paper covers, and an outer layer of Flexstone asbestos-asphalt sheeting, or Transite asbestos-cement boards. Keystone hair felt (*J. W. Morrison, PC; Johns-Mansville, Inc.*) is sold in folded strips 3 ft. wide containing 500 sq. ft.; the edges are beveled and bound to give smooth lapping. Flexstone 3-ply roofing comes in rolls of 100 sq. ft., 32-in. wide; the 4-ply comes only in flat sheets 32 × 80 in. Transite boards, corrugated or plain, are made in thicknesses of ¼ and ½ in. and cut into sheets 42 in. wide by 4, 5, 6, 7 and 8 ft. long; they are largely used for walls as well as for roofs having a pitch of 2 in. or more per ft. The ¼-in. boards can be laid directly on purlins spaced up to 45 in.; the ½-in. boards on supports spaced up to 60 in.

Snow, in addition to its dead weight of 12 lb. per cu. ft. (*Trautwine*), interferes with roof lighting and may cause damage by sliding in heavy masses. This may be prevented by: (*a*) snow guards; (*b*) giving the roof sufficient slope (30° or more) to cause the snow to slide soon after it falls (ALASKA-JUNEAU installed salt water sprays to flush the snow off the

roofs as fast as it fell); (c) making roof so nearly level that snow cannot slide (as at HOMESTAKE SOUTH mill). According to *Kidder*, metal roofs in the Rocky Mountain and northwestern states should be designed for the following snow loads per sq. ft. of roof surface: ½-pitch, none; ⅓-pitch, 10 to 12 lb.; ¼-pitch, 20 to 25 lb.; ⅕-pitch, 27 to 37 lb.; ⅙-pitch or less, 35 to 45 lb. UNITED COMSTOCK roof, with an unbroken slope of 20° (⅓-pitch) was designed for a snow load of 40 lb. and a wind load of 20 lb. per sq. ft.

Windows and skylights. Daylight is of the utmost importance in practically every department of a concentrating mill. It is easily provided in a tall structure, the walls of which can be composed of glass to a large extent, as in anthracite breakers. A terraced mill can be amply lighted from its sides, and also by vertical windows in the breaks of the roof.

The steeply-terraced BRITANNIA mill has 22,300 sq. ft. of windows for lighting a horizontal area of 56,400 sq. ft. (*29 MM 204*).

A low, flat mill can be lighted by skylights in the roof, subject to interference by snow and probability of leakage unless constructed with special care; a turreted or saw-tooth roof with windows in all available vertical spaces is frequently used for industrial plants and might be equally useful for ore dressing plants.

Fenestra steel sashes have been installed in large numbers at UNITED COMSTOCK, HOMESTAKE, and numerous other mills with both steel and wood construction. At COPPER QUEEN the windows are glazed with ribbed glass, for diffusion of sunlight, and the skylights are of RUBBER GLASS. This material is used for skylights in many other mills in the southwest, where snow is unknown, rain not abundant, and the sunlight so intense as to make the yellow tint imparted agreeable.

Floors. Wood and concrete are used indiscriminately in mills of either wood or steel construction. A wooden floor in the wet-concentrating section of a mill should be tight, to prevent loss of concentrate, and should preferably be laid with green timber, to avoid warping. Concrete floors are usually spread in place.

UNITED COMSTOCK used pre-cast concrete slabs supported by steel frames. At the steeply-terraced mills of the SILVER DYKE, NATIONAL COPPERMINES, and UTAH CONSOLIDATED mills, reinforcement was obtained by discarded hoisting rope in lengths running unbroken from the highest to the lowest floor, passing horizontally through every floor and downward through the intervening retaining walls, thus tying the latter securely together.

The SLOPE of floors in the wet parts of a mill should be sufficient to permit rapid drainage; dry floors are usually cleaned by sweeping and the floors require no slope. Slopes of ¼ and ½ in. per ft. are most common, the latter preferred. Slopes up to 2 in. per ft. are sometimes adopted to permit launders to be laid on the floor, but this is unnecessary and makes walking unsafe. The discomfort of walking on a concrete floor, especially if wet, should be ameliorated by providing walk-ways of wooden slats.

Painting. Black corrugated iron should be protected by at least two coats of paint, renewed at frequent intervals. Galvanized iron does not usually require paint protection, although it is subject to rapid deterioration anywhere in the vicinity of a smelter. A durable paint for new galvanized iron has not yet been found, but after the metal has been exposed for two or three years any good paint will adhere firmly. The inside of a mill should be painted white or a light tint. An air brush is a useful tool for applying oil paint. Whitewash does not adhere strongly enough to resist loosening under continuous vibration.

6. Arrangement of mill equipment

The grouping of mill equipment should aim to satisfy the following requirements: (*a*) Mechanical transfer of feed and products by the shortest and most direct routes, utilizing gravity flow so far as economically practicable (see Art. 4). (*b*) Convenience of superintendence (see Art. 4). (*c*) Economical connection with driving power (see Art. 7). (*d*) Facility of repairs (see Art. 9). If possible, provision should be made for by-passing any piece of machinery undergoing repair, to avoid complete suspension of operations; in a small mill, without duplicate equipment, this may not be possible. (*e*) Facility of enlargement or remodeling (see Art. 4). (*f*) Isolation of dust-making operations, with or without arrangements for collecting the dust (see Art. 8).

Grouping in plan. Dimension sheets giving over-all dimensions of the individual pieces of ore-dressing equipment are usually obtainable from the makers. The additional necessary allowance of floor space between and around the machines composing a single group should provide for: (*a*) Walkways for inspection and adjustment of machinery; also, in some cases, for manual disposal of concentrate by wheelbarrow or tram car. (*b*) Working space for making repairs with minimum amount of carriage. (*c*) Launders, chutes, or conveyors for the several products of the operation. (*d*) Motors, in case of individual drives, with speed reducers when required. (*e*) Elevators or pumps, possibly serving other groups of mill equipment.

Jigs, tables, pneumatic flotation cells, and other equipment to which a sufficient amount of attention can be given from one side, are often consolidated into pairs, or blocks of four, mainly to facilitate feeding and to combine discharges, but also to economize floor area. Ball, pebble, or rod mills are usually set as close as possible to a sand-slime separator. Screens and hydraulic classifiers seldom require special allowance of floor space, since they can usually be supported overhead. Spacing of coarse crushers is frequently determined by the dimensions of the bins from which they receive their feed or to which they deliver, rather than by the amount of floor space they actually require. Table 19 gives total floor area of representative mills.

Grouping in vertical relation. The difference in elevation between the points at which a given piece of apparatus receives its feed and discharges its products is most important from the standpoint of mill design, since it is this dimension that fixes the position of the machine with respect to the "stream line" of the mill. Over-all vertical dimensions are needed for placing foundations and making allowance for head room; the latter should make due provision for hoisting out parts of machines requiring replacement.

Chutes and launders. (See Sec. 20, Art. 9, 10.) In general, a chute for nominally dry material should have a slope of not less than 45°, to avoid choking in case of accidental or temporary wetting. A launder that proves to have insufficient grade can be corrected, if it is impossible to increase its slope or if inadvisable to increase the proportion of water, by diminishing its width or by introducing liners of smooth material with low coefficient of friction. Rubber, both of crude crepe and vulcanized varieties, is receiving wide attention as lining material for launders subjected to hard service; in spite of its higher cost per pound, it is usually cheaper than steel or chilled iron per sq. ft. of surface, and compares favorably with those materials in withstanding wear. Locally made concrete slabs are usually much cheaper per sq. ft. than iron. In places where sufficient gravity flow is not easily obtainable, as in collection of concentrate or tailing from a long line of jigs or tables, a shaking launder on a grade as low as 3/8 in. per ft., suspended by flexible wood strips and oscillated

by an ordinary table head-motion at one end, has been found useful at New Jersey Zinc Co. and Santa Barbara (*112 J 1050*). Another method applicable to jig tailing is to dewater on a screen and deliver to a horizontal belt conveyor.

Launder slopes. The slopes given in Table 20 are suggested as working limits for rectangular wooden launders conveying average ores of pyrite, zinc, and copper, with concentrating ratios between 4 and 20 to 1, and dilutions of not less than 2 water to 1 ore. See also Sec. 20, Art. 10.

Table 20. Average slopes for launders

Jig and table mills	Inches per foot	Fine-grinding and flotation mills	Inches per foot
Trommel product:		Sands, 20 per cent. moisture, classifier to tube-mill:	
+20-mm	5–6	30-mesh	4–6
−20+10-mm	4–5	80-mesh	3–4
−10+5-mm	3–4	Tube-mill discharge to classifier:	
−5+2½-mm	2–3	30-mesh	2–2½
−2½-mm	1½–2	80-mesh	1½–2
Table feed, 20-mesh	1¼–1½	Classifier overflow to flotation:	
Table tailing, 20-mesh	1½	48-mesh	½–¾
Table middling, 20-mesh	1½	80-mesh	¼–½
Table concentrate, 20-mesh	2½	Flotation concentrate	2–3
Tail race, mixed sizes	⅜–¾	Flotation tailing	¼–½
		Tail race	3⁄16–¼

For zinc-lead and iron-oxide ores of low concentrating ratio, the launder slopes would need to be probably 25 per cent. steeper than those stated above.

Cost of launders. From the figures in Table 21, relating to reconstruction of the Phelps-Dodge Morenci mill in 1924, it is seen that the labor cost to install $1 worth of material ranges from $1 to $1.25. In this mill, only 14.4 per cent. of the whole launder system was over 16 in. wide.

Elevation of ore in transit through a mill is practically unavoidable, even on steeply terraced sites; on flat sites, elevators or sand pumps constitute a large and expensive part of the mill equipment, beside requiring close attention to maintenance. Structural details of inclined belt or pan conveyors, belt-bucket or chain-bucket elevators, sand pumps, centrifugal pumps, and suction pumps for ore pulps are given in Sec. 20.

Inclined belt conveyors (see Sec. 20, Art. 1) for initial delivery of ore to the mill are discussed in Art. 1, and those for disposal of tailing in Art. 3. Inside a mill, they are largely employed in the coarse-crushing department, being especially useful in delivery of ore into a long bin or receipt of ore from a row of chutes. Data on a few noteworthy installations are given in Table 22. Distribution of ore from a belt conveyor can be accomplished by (*a*) movable tripper, shifted by hand from place to place; (*b*) automatic traveling tripper, actuated by the belt itself; (*c*) shuttle conveyor mounted on a truck running on longitudinal rails and discharging only from its end; this system is particularly useful for materials which have to be handled only at long or irregular intervals.

Inclined pan conveyors (see Sec. 20, Art. 2) are most used for elevating crude ore in lumps of such size (say 4-in. and over) that they would be injurious to rubber belts; incidentally, they may serve as feed regulators for coarse crushers.

At United Comstock (*114 J 846, 117 J 516*) a 48-in. Stephens-Adamson pan conveyor 91 ft. long and rising 30 ft. (20°), driven at 9 to 15 ft. per min. by a 20-hp. variable-

speed, slip-ring motor, carries 125 tons of mine-run ore per hour. At the COPPER QUEEN concentrator are two 54-in. pan conveyors in parallel, each capable of carrying 1800 tons −8-in. ore per hour (250 tons normal rate); length, 61 ft.; rise, 21 ft.; slope, 20° 10′.

Belt-bucket elevators (see also Sec. 20, Art. 6) are by far the most common appliance for elevating ore, whether wet or dry. For wet work they have the advantage over chain-bucket elevators of requiring no difficult and expensive lubrication and of having fewer wearing and friction-producing surfaces. The capacity of a given belt, however, is limited by its adhesion to the head pulley; this can be augmented by a wrapping of less slippery material around the pulley. As compared with inclined conveyors, they occupy much less floor space, and can also elevate thin pulps. It is important to provide means for emptying the boot of an elevator when repairs are needed; so placed that the discharged material can be sluiced or easily transferred by other means to an adjoining elevator.

Chain-bucket elevators (Sec. 20, Art. 7), in spite of their multiplicity of wearing and breaking elements, can be used satisfactorily for dry work but must then be lubricated with heavy grease to minimize the effect of grit; their capacity is limited only by the size of buckets that can be supported. Certain types have a pronounced advantage in being able to receive or discharge at a number of points in their travel, thus combining the functions of elevator and conveyor.

Table 22. Examples of inclined belt conveyors in mills

	310	48	15	450	7	700	100

a In tandem.

In one 250-ton mill, a single Peck conveyor-elevator was devised to perform all the following operations: (*a*) receive crushed ore via belt conveyor from a sampler; (*b*) elevate and deliver this ore, at will, into smelter bin, mill bin, storage bin for any class of ore (with the aid of a distributing belt conveyor), or bins for doubtful ore (pending assay); (*c*) withdraw doubtful ore from bins and deliver to smelter, storage, or mill bins; (*d*) withdraw ore from any storage bin (with the aid of a belt conveyor) and deliver to a smelter bin or mill bin.

Sand pumps. (See Sec. 20, Arts. 11, 12, 13.) Centrifugal pumps for elevating gritty pulp must be specially lined, and even this affords little protection to the shaft, which is a source of weakness in all but the latest form of Wilfley pump. For pulp carrying solids coarser than ⅛-in., a bucket elevator will usually require less repair than any centrifugal pump; for fine pulps (−30-mesh), centrifugal pumps are generally better than bucket elevators.

At the Clifton mill of Arizona Copper Co. an Aldridge plunger pump, specially designed as to valves and plunger clearances, was used to dispose of table and vanner tailing. At Magma Copper Co. all mill concentrate (5 per cent. +20-, 63 per cent. −200-mesh), derived about equally from tables and flotation, is pumped in the form of a thickened pulp (70 per cent. solids) to filters at the smelter, which discharge cake directly into the smelter bins, thereby dispensing with at least one handling (*J. W. Thompson, PC*). The pipe line is 4 in. diameter, 2760 ft. long, and rises to height of 92 ft. near its middle point with slopes of 7°. No trouble has been experienced from sedimentation so long as the pulp consistency is held at 70 per cent. solids. A 4-in. Wilfley pump, driven at 1600 r.p.m. by a 75-hp. motor, delivers 165 gal. of this pulp per min., equivalent to 60 tons solids per hour. The operating costs per ton of concentrate (dry) in 1925 were: repair parts, etc., 3.00¢; labor, operating and repairs, 1.94¢; power, 0.60¢; total, 5.54¢.

Air-lifts (see Sec. 20, Art. 15) for elevating ore pulps in process are satisfactorily employed in the Nevada Consolidated, Chino, Ray, New Cornelia, and Copper Queen mills, and in the older types of cyanide plants.

Skips are used for elevating roll products to screens at two points in the intermediate-crushing department of the Alaska-Gastineau mill (*63 A 488*). The product from the

primary rolls, set at 1-in., is hoisted in four skips of 5-ton capacity; that from the secondary rolls, at 10-mesh, in ten skips of the same size. The lift is 100 ft. in both cases. The skips are operated automatically and in counterbalance by a 75- to 135-hp. hoist motor for each pair; plow-steel rope is flat, $\frac{3}{8} \times$ 5-in. The loading gate is operated by a compressed-air cylinder controlled through a 3-way valve actuated by the descending skip; high-pressure water can also be used for operating the gate. Loading time is governed by an oil dash-pot which also throws the motor switch. Loading takes 11 sec., and the complete cycle for two skip loads is 1 min. 50 sec. The cost of operation compares favorably with that of dry elevators; maintenance is 0.9¢ per ton milled.

7. Driving power for mills

Individual power requirements for commonly employed machines, operating under stated conditions, are given in connection with the descriptions of the various machines. Table 23 gives the total motive power (installed or used) at a few mills of representative types.

Line-shaft drives are used at small mills operated from a central power unit, whether water, steam, oil, or electric; large and small mills operated by steam power; and large motor-driven mills operating long blocks of similar machines having relatively small power requirements. At mills of the first two types line shafts are unavoidable; in the third type they reduce the number of motors necessary and the large motors cost less per unit of power and require no more frequent attention than small ones. Some large, modern mills, however, as Copper Queen, have introduced individual 1-hp. motors for driving concentrating tables. The use of line shafts for heavy-duty equipment has the disadvantage of requiring numerous friction clutches (frequently a source of trouble) while, if electrically driven, the stopping of an individual machine produces a bad effect on the power factor of the motor, the capacity of which is fixed by the total connected load; this irregularity can be more efficiently compensated by steam or oil-driven engines.

Installation of line-shaft drives. For the elements of design, refer to mechanical-engineering handbooks (Kent, Marks, etc.; see also *107 J 1132*). The following general suggestions refer particularly to ore-dressing works. (*a*) Shafts should have a wide margin of strength above that required for transmission alone; this is to provide against abnormal loads on pulleys due to shrinkage of damp belts, excessive shortening of belts to take up slack, etc. (*b*) Pulleys, couplings, and clutches should be closely adjacent to bearings; the end of an oiled bearing, however, should lie 1 to 2 in. outside the nearer edge of an adjoining pulley, so that oil drippings will not fall on belt or pulley. (*c*) Hangers with ball-socket journal boxes are as satisfactory as pillow blocks for shafts of moderate sizes, up to $2\frac{7}{16}$-in. Larger shafts should be carried in pillow blocks, and for extra heavy service, a shaft should be mounted near the ground, on concrete piers if possible. (*d*) Ball-socket, or other self-aligning pillow blocks and journal boxes should always be installed for long shafts, and preferably also for short ones. (*e*) Ring-oiling journal boxes are satisfactory for general service; in dusty places, heavy-grease lubrication affords better protection. (*f*) Leather belts are admissible only in permanently dry places. Canvas belts deteriorate with moisture, and lack pliability in large sizes. Rubber-covered belts give the best service in all parts of a wet mill; the most satisfactory weights are: 4-ply for 4- and 6-in.; 6-ply for 8- to 12-in.; 8-ply for 18-in. (*g*) Vertical belts should be avoided. Quarter-turn belts are admissible in sizes up to 8-in., and are unavoidable for driving a group of vanners placed side by side and operated from a single line shaft. The minimum length between centers for belts without tightening idlers should be five times the diameter of the larger pulley. (*h*) Tightening idlers give good service, when needed, but require

Table 23. Total motive power for representative mills

Mill	Daily tonnage	Nature of operation	Total power, horse-power	Horse-power per ton-day
Alaska-Gastineau.	7,000	Crushing mine-run to 57 per cent. +48-mesh	1909*a*	0.2727*a*
		Concentrating (tables only), elevating, etc.	1532	.2188
		Pumping, lighting, etc.	448	.0641
			3889*a*	0.5556*a*
Armstead.	150	Blake, rolls, Hardinge, Callow flotation, tables	318*b*	2.1*b*
Consolidated Coppermines.	1,000	Blake, Hardinge, flotation, tables. (Steam)	520*b*	0.52*b*
Honduras Rosario.	428	Coarse crushing, 2 gyratories	15*a*	0.0342*a*
		Stamps, 20 @ 1850-lb.	117	.2722
		Tube mills, 3 @ 5×22-ft.	233	.5443
		Pumps, 10 triplex, various sizes	142	.3326
		Agitation tanks and compressors	140	.3282
			647*a*	1.5115*a*
Inspiration (1922).	11,437	Coarse crushing	340*a*	0.0297*a*
		Fine crushing and tables, 94 per cent. −48-mesh, 52 per cent. −200-mesh	6686	.5846
		Flotation blowers	1498	.1310
		Filtering and reclaiming water	487	.0426
		Lighting	77	.0067
			9088*a*	0.7946*a*
Mountain Copper.	600	Crushing to 2.5-in., 2 gyratories in series, 8 hr.	100*b*	0.167*b*
		Fine crushing and M. S. flotation	592	.970
			692*b*	1.137*b*
Ottawa, Slocan, B. C.	50	Jaw, tube mill, M. S. flotation. Water power	110*b*	2.2*b*
Panda.	4,000	Crushing: 10 gyratories, 6 rolls, to 1-in., 8 hr.	1500*b*	0.375*b*
		Conveying and distributing, 8 hr.	285	.071
		Jigs, tables, re-crushing to 1-mm.	1800	.450
			3585*b*	0.896*b*
Richard.	1,500	Gyratory, rolls, magnetic separation beginning at 2-in.; finest crushing, ⅛-in.	200*b*	0.13 *b*
St. Joseph Lead Co., Bonne Terre (1917).	2,700	Jigs, tables, flotation. Concentration begins at 9-mm.	925*a*	0.343 *a*
St. Joseph Lead Co., Rivermines (1917).	4,000	Jigs, tables, flotation. Concentration begins at 9-mm.	1840*a*	0.460 *a*

a Power consumed. *b* Power installed.

Table 23. Total motive power for representative mills—*Continued*

Mill	Daily tonnage	Nature of operation	Total power, horse-power	Horse-power per ton-day
Santa Barbara.	500	Crushing all to 2-mm., gyratory, disk, rod mill	300*b*	0.600 *b*
		40 Deister tables	33	.066
		Conveyors, elevators, screens, classifiers	207	.414
		Pumps, tram, settlers	51	.102
			591*b*	1.182 *b*
Silver King.	300	Jigs, tables, flotation; crushing to 16-mesh.	425*b*	1.420*b*
S. E. Missouri, average practice.	2,000 to 4,000	Crushing: gyratory, disk, rolls, ball and rod-mills		0.157 *a*
		Concentration: Hancock jigs, tables		.095
		Flotation: Federal, Janney, K. & K., Callow		.062
		Water service		.081
		(General tailing averages 55 per cent. on 8-mesh and 75 per cent. on 20-mesh.)		0.395 *a*
Sunnyside	550	Crushing to 70 per cent. —200-mesh, flotation and tables	900*b*	1.64 *b*
Tul Mi Chung, Korea.	470	3 Jaw crushers (to 1-in.), trommel, conveyors	47 *a*	0.1009 *a*
		6 Hardinge (ball and pebble), 6 Dorr classifiers	393	.8369
		M. S. flotation (8 @ 29½-in.; 8 @ 16-in. square)	74	.1570
		5 Deister tables	6	.0130
		Re-grinding table tailing: 5 × 5-ft. ball granulator	64	.1357
		Tailing disposal (3600 tons 1 : 7 pulp), centrifugal pump	27	.0569
		Water supply (1700 tons pumped 1½ miles)	53	.1129
			664*a*	1.4133*a*
United Comstock.	2,000	Gyratory, rolls, ball-mills, agitation, cyaniding	2800*b*	1.400 *b*
United Eastern.	300	Gyratory, ball and tube-mills, cyanidation (85 per cent. —200-mesh)	330*a*	1.100*a*
United Verde crushing plant.	6,000 (24 hr.)	4 jaw crushers (36 × 24) to 3-in., 4000 tons per 8 hr.	500*b*	0.0833*b*
		3 vertical disks (48-in.) to ¾-in., 4000 tons per 16 hr.	225	.0375
		3 rolls (56 × 24) to ¼-in., 4000 tons per 16 hr.	450	.0750
		2 exhaust fans (45,000 cu. ft. per minute each)	250	.0417
		Conveyors, feeders, elevators	1200	.2000
			2625*b*	0.4375*b*

a Power consumed. *b* Power installed.

endless belts, since no form of lacing or coupling has proved satisfactory in this service; endless belts of leather can be spliced by glueing on the premises (*107 J 1132*) but endless rubber belt can be made only at the factory. (*i*) Chain drives are useful for transmissions too short-centered for belts or where the desired speed ratio would require too small a pulley at one end; also for transmitting small power at low speed in dusty places. Their efficiency is high, and as they require no tension on the slack side, the journal friction at both ends is less than that caused by a short, tight belt. They are particularly applicable to the driving of tubular mills, blowers, etc.; for a good example, see *119 P 7*.

Stopping and starting from line shafts. Tight-and-loose pulleys with a belt shifter are suitable for machines of relatively small power requirements, up to 25 or 30 hp., with belts up to 8 in. wide; for larger powers, belt shifting not only throws excessive stresses on all moving parts, but the price of a loose pulley of large size and the extra cost for a large double-width flat-faced pulley will usually be greater than the cost of a suitable clutch. Dental or jaw clutches for throwing the load on a moving shaft can be used safely for speeds under 30 r.p.m. Clutch pulleys are unsatisfactory where their power is likely to be unutilized for considerable periods, owing to rapid wear of the bushings, which cannot be constructed or lubricated like a standard journal box; this is particularly objectionable in case of a stationary pulley riding on a moving shaft, since the wear will then be eccentric and likely to cause breakage of the clutch pulley. Friction-clutch couplings, of band, jaw, or disk types, connected with a short jack-shaft, or with a quill, and supported by adequate journal boxes, are much better than clutch pulleys. The quill system is well adapted to driving a row of machines from a long main shaft: It requires two large journal boxes for each quill, in addition to the smaller boxes for the line shaft, and the whole installation must be rigidly supported, preferably on concrete piers, to avoid internal friction from distorted alignment.

Slack belt, with a swinging tension idler, was formerly the standard method of driving individual stamp batteries operated by a single line shaft; this practice is now almost obsolete, modern stamp mills using an individual motor for every five or ten stamps.

Individual motor drives are almost universally installed at modern mills, for all classes of equipment. For tables and other small-power apparatus which can be closely grouped into rows or blocks and easily driven from line shafts, the economy of individual drives, whether as to cost of installation or expense for maintenance, has not yet been fully established; manufacturers expect soon to market a 1-hp. motor and speed reducer for $100, which is no greater than the cost per table for installing equivalent line-shaft drive. For tables, the present advantage of individual drives is mainly their ease of installation; they make accurate alignment unnecessary, avoid overhead supports for line-shafts, and are easy to maintain. For driving heavy equipment, individual motors offer the same advantages, with the added economies introduced by operating at higher efficiencies and power factors.

Motor characteristics. Large ore-dressing plants in North America operate, almost without exception, with 3-phase alternating current, usually at 60 cycles but occasionally at 25 (50 cycles is standard practice in Europe). The advantages over direct current lie in the simplicity of apparatus, and, usually, lower cost of equipment. Standard rugged designs are cheapest both in first cost and maintenance expense. Motors having the same speed and size of shaft extension should be installed so far as is consistent with good efficiency, to reduce the number of spares carried.

Standard voltages are given in Table 24. Large a-c. motors (more than 50-hp.) are commonly 2200- or 2300-volt; 440-volt current is used for large

Table 24. Standard voltages

Direct current		Alternating current		
Generator	Motor	Generator	Transformer	Motor
125	115	120	115	110
250	230	240	230	220
575	550	480	460	440
....	....	600	575	550
....	....	2,300	2,300	2,200[a]
....	....	6,600	6,600	6,600
....	....	11,000	11,000	11,000
....	....	13,200	13,200	13,200

a With synchronous motors it is customary to design the motor to operate at 2300 volts.

motors in exposed conditions and for motors from 5- to 50-hp.; 220- or 110-volt for 5-hp. and smaller.

At Honduras Rosario mill (*115 J 1147*) all but two of the motors of 15-hp. and larger are on 2200 volts, whereas at the United Comstock (*114 J 846*, *117 J 516*) all of the hundred motors (some of 150- and 200-hp.), aggregating 2800 hp., are on 440-volt current.

Low-voltage operation causes higher operating losses and higher cost of conductor, but the equipment cost is less than in high-voltage work. In general, the economic voltage depends upon the load factor, the power consumed, and the distance from the generator to the point of consumption. (See Table 25.) Distribution and interruption of current in a large mill are difficult at low voltage, and expansion is expensive, nevertheless the usual tendency is to adopt too low rather than too high voltage.

Motor speed. High-speed motors are lighter, cheaper and usually more efficient than low-speed, provided they are equipped with efficient speed-reducing drives. Speeds recommended (*109 J 849*) for 60-cycle synchronous motors in general mill service are shown in Table 27. E. Bachman (*PC*) recommends the speeds given in Table 28 for motors for general service.

Outboard bearings should be specified for geared motors of 75 hp. and larger.
